Foreword

Heat-treating technology has long been an area of deep interest and concern to ASM members. In fact, the origin of the Society can be traced back to 1913 when the Steel Treaters Club was launched in Detroit. This group joined with the American Steel Treaters Society to form the American Society for Steel Treating in 1920. It was the latter organization that issued the first bound Handbook in 1928, a volume that would serve as the prototype for future generations of the *ASM Handbook.*

During the ensuing six decades, many changes have taken place--both in terms of the positioning of the Society and the technology base it serves. In 1933 a name change to the American Society for Metals completed the transition from an organization concerned primarily with heat treating to one that served the interests of the entire metals industry. Finally in 1987, the technical scope of the Society was further broadened to include the processing, properties, and applications of all engineering/structural materials, and thus ASM International was born.

Despite these momentous changes, one fact has remained unchanged--ASM's recognition of heat treating as one of the foundations of the metals sciences and its unflagging commitment to this ever-changing technology. The publication of Volume 4 of the *ASM Handbook* is the most recent and significant example of the sustained leadership of the Society in addressing the needs of the heat treat community.

The present volume reflects the continuing research and effort that have led to a deeper understanding of the response of ferrous and nonferrous alloys to thermal treatments. For in the 10 years since publication of its 9th Edition predecessor, significant developments have taken place in quenching and hardenability studies, computer modelling of heat-treating operations, plasma-assisted case hardening methods, and improved quality control through advanced instrumentation and/or the application of statistical process control. These are but a few of the important topics that will undoubtedly contribute toward making the Heat Treating Handbook a timeless contribution to the literature.

Successful completion of such a formidable project, however, is dependent on the collective effort of a vast pool of knowledgeable and dedicated professionals. For their significant roles in this project, we are truly indebted to the ASM Heat Treating Technical Division and its subcommittees, to the Handbook Committee, to the hundreds of individual authors and reviewers, and the Handbook Editorial Staff. For their valuable contributions, we extend our thanks and gratitude.

- Stephen M. Copley
President
ASM International
- Edward L. Langer
Managing Director
ASM International

Preface

In compiling this new volume on heat treating, the challenge was to produce a book that contained subject matter strongly oriented toward industrial practice but that did not omit discussions of the underlying metallurgical fundamentals. With previously published ASM Handbooks devoted to heat treating, the omission of material on fundamentals was justified by either space limitations and/or the availability of other ASM books that described the physical metallurgy associated with thermal treatments. For example, when the 8th Edition was published in 1964, only 306 pages were related to heat treating (this Volume was divided between heat-treating technology and surface cleaning and finishing). As such, readers were referred to the classic book *Principles of Heat Treatment* by M.A. Grossmann and E.C. Bain, which was also published in 1964 by ASM. A similar situation arose in 1981 when the expanded 9th Edition Heat Treating Handbook was published. In the year prior to this publication, a completely revised version of the Grossmann/Bain book was prepared by G. Krauss and subsequently published by ASM.

The 1980s proved to be a dynamic period for heat-treating technology--a decade that witnessed the introduction of new alloys and processes as well as new "tools" for understanding the response of heat-treated materials. For example, new alloys under active development or brought to market during the 1980s that were not described in previous heat-treating Handbooks included duplex stainless steels, microalloyed (HSLA) steels, low-cobalt maraging steels, austempered ductile iron, directionally solidified and single-crystal superalloys, and aluminum-lithium alloys.

Changes in processing include improvements in continuous annealing, induction heating, and surface hardening operations using lasers or electron beams, the commercial viability of plasma-assisted case-hardening processes, and advances in thermomechanical processing.

But by far the most dramatic changes in heat-treat technology that have marked the past decade have been those involving newly developed tools for improving process characterization and process control. These include improved instrumentation for controlling furnace temperature, furnace atmosphere, and surface carbon content, the practical

application of statistical process control (SPC), and the use of computer modelling for both the prediction of hardness profiles after quenching and the quantitative modelling of properties after tempering or case hardening. It is this latter category of computer modelling that necessitates the inclusion of material on the basic principles or fundamentals of heat treating. For example, there are several articles in this Volume that deal with computer-assisted prediction of steel hardening and hardenability as a function of heat treatment parameters. In this regard, the primary measures of steel hardening are the end-quench hardenability curves (Jominy curves), isothermal transformation (IT) curves, and continuous cooling transformation (CCT) curves. In order to understand how computer programs can be used to calculate such diagrams, some brief background information is provided in several key articles to emphasize how these diagrams make possible the selection of steel and the design of proper heat treatments.

Principal Sections

Volume 4 has been organized into eight major sections:

- Heat Treating of Steel
- Surface Hardening of Steel
- Heat-Treating Equipment
- Process and Quality Control Considerations
- Heat Treating of Cast Irons
- Heat Treating of Tool Steels
- Heat Treating of Stainless Steels and Heat-Resistant Alloys
- Heat Treating of Nonferrous Alloys

A total of 71 articles are contained in these sections. Of these, 16 are new, 17 were completely rewritten, with the remaining articles revised and/or expanded. In addition, several important appendices supplement the Volume. These include a glossary of terms, a temper color chart for steels, and tabulated austenitizing temperatures for steels. A review of the content of the major sections is given below; highlighted are differences between the present volume and its 9th Edition predecessor. Table 1 summarizes the content of the principal sections.

Table 1 Summary of contents of Volume 4, Heat Treating, of the ASM Handbook

Section title	Number of articles	Pages	Figures[(a)]	Tables[(b)]	References
Heat Treating of Steel	16	253	355	123	430
Surface Hardening of Steel	18	203	305	69	324
Heat-Treating Equipment	6	62	83	17	43
Process and Quality Control Considerations	9	135	130	43	190
Heat Treating of Cast Irons	5	42	67	19	27
Heat Treating of Tool Steels	4	56	48	34	20
Heat Treating of Stainless Steels and Heat-Resistant Alloys	3	51	41	53	23
Heat Treating of Nonferrous Alloys	10	124	147	77	72

Total	**71**	**926**	**1176**	**435**	**1129**

(a) Total number of figure captions; most figures include more than one illustration.

(b) Does not include in-text tables or tables that are part of figures

Heat Treating of Steel. This section begins with two entirely new articles that introduce the reader to the physical metallurgy of heat-treated steels and newly developed methodologies for quantitatively predicting transformation hardening in steels. These companion papers set the stage for a series of articles that describe specific types of heat treatments. Of particular note is the definitive treatise on "Quenching of Steel" by Bates, Totten, and Brennan. Featuring some 95 figures and 23 tables, this 55 page article has been substantially revised and expanded from previous Editions. Other highlights include new articles on continuous annealing, cryogenic treatment of steel, and thermomechanical processing of microalloyed steel. The section concludes with completely rewritten articles on heat-treat procedures for ultrahigh strength steels, maraging steels, and powder metallurgy ferrous alloys.

Surface Hardening of Steel. As explained in the introductory article to this section, emphasis has been placed on *thermally driven, diffusion processes* that induce solid-state transformation hardening. These processes include flame hardening, high-energy processes that utilize laser beams or electron beams, and conventional surface treatments such as carburizing, nitriding, and carbonitriding.

It is important to note the significant processing characteristics between the aforementioned processes and surface modification techniques 'such as ion implantation, PVD/CVD coatings, and surface melting/surface alloying processes that will be described in future volumes of this Handbook series. For example ion nitriding, which is described in this section, and nitrogen ion implantation are two distinctly different techniques for producing a case hardened surface layer. The implementation of each process, the characteristics of the case layers produced, the metallurgical strengthening mechanisms generated, and the economics and end use of each, are quite different.

Ion nitriding is a thermally driven, equilibrium, diffusion process that produces a relatively deep (100 to 400 μm), hardened, case layer. Nitrogen ion implantation is a non-thermal, non-equilibrium, physically driven, ballistic alloying process, which produces a relatively shallow (1 μm), extremely hard case layer. Ion nitriding is implemented at high temperatures in a glow discharge atmosphere, while nitrogen ion implantation is carried out at room temperature, at high vacuum, in a dedicated atomic particle accelerator. Case layer strengthening in ion nitrided surfaces is due primarily to formation of transition metal nitride precipitates, while strengthening in nitrogen ion implanted surfaces is due primarily to dislocation pinning. A summary of processing comparisons is given in Table 2.

Table 2 Process characteristics comparison

Process	Type	Process time, h	Process temperature		Process pressure, torr	Case depth[a], μm	Hardness[a], HRC
			°C	°F			
Ion nitriding	Thermal diffusion	10-30	500-1100	900-2000	0.2-5.0	400	62-67
Nitrogen ion	Physical	1-6	<150	<300	10^{-6}	1	80-90

(a) Value for steel

Key additions to this section include articles that describe increasingly used processes such as plasma-assisted case hardening methods, boriding, and the Toyota diffusion process. Of critical importance to this section is the article "Microstructures and Properties of Carburized Steels" by G. Krauss which examines the correlation between processing, structure, and resulting fatigue, fracture, and wear properties of case-hardened steels.

Heat-Treating Equipment. Types of heat-treating furnaces, the materials used to construct furnaces, and the advantages and limitations associated with each are described next. More emphasis has been placed on furnace energy efficiency and proper design than in previous Editions.

Process and quality control considerations are more important than ever to heat treaters. Reliable sensors, computerized control equipment, and process control of heating and cooling and furnace atmospheres are described in detail in this section. Supplementing this material are new articles on the recognition and prevention of defects in heat-treated parts and the use of computer programs for designing heat-treat operations and predicting the properties of heat-treated steels.

Because the heat-treating industry is being challenged to introduce statistical concepts in order to minimize variability and ensure consistent quality of heat-treated parts, an important article on "Statistical Process Control of Heat-Treating Operations" is also included. Emphasis is on the practical application of SPC concepts in order to demonstrate to heat treaters how to identify critical process parameters that influence product quality and how to establish methods to monitor and evaluate such parameters.

Heat treating of cast irons is described in five articles. The "Introduction to Heat Treating of Cast Irons" was completely rewritten for this Volume. The remaining four articles contain new information on austempering of ductile iron and procedures for heat treating highly alloyed abrasion-resistant, corrosion-resistant, and heat-resistant cast irons.

Heat Treating of Tool Steels. Because tool steels must be processed to develop specific combinations of wear resistance, resistance to deformation or fracture under high loads, and resistance to softening under elevated temperatures, proper heat treating is critical. This section describes the procedures and equipment necessary to meet these criteria.

Heat Treating of Stainless Steels and Heat-Resistant Alloys. Procedures and process control for heat treating the principal types of stainless steels and superalloys are discussed in this section. The article on "Heat Treating of Superalloys" was completely rewritten for this Volume and includes information on both wrought and cast alloys, many of which are used in the aerospace industry. The article on refractory metals and alloys is completely new to the Handbook series.

Heat Treating of Nonferrous Alloys. The principles which govern heat treatment of nonferrous alloys are first described in this final section of the Handbook. Differences between ferrous and nonferrous processing are highlighted. Nine articles follow on heat treating of specific classes of nonferrous alloys.

Acknowledgments

This Handbook would not have been possible without the generous contributions of the nearly 350 leading heat-treating experts who donated their expertise as authors and reviewers. They represent many of the leading industries and educational institutions in this country and abroad. The articles in this Handbook represent tremendous individual as well as committee efforts. We are also grateful to the ASM Heat Treating Technical Division and the ASM Handbook Committee. Their guidance during the critical planning stages of this project proved invaluable. This has truly been a collective effort of the technical community. We thank those who willingly have shared their knowledge with us.

Staff

ASM International staff who contributed to the development of the Volume included Robert C. Uhl, Director of Reference Publications; Joseph R. Davis, Manager of Handbook Development; Grace M. Davidson, Production Project Manager; Steven R. Lampman, Technical Editor; Theodore B. Zorc, Technical Editor; Janice L. Daquila, Assistant Editor; Alice W. Ronke, Assistant Editor; Kari L. Henninger, Editorial/Production Assistant. Editorial assistance was provided by Robert T. Kiepura, Heather F. Lampman, Penelope Thomas, and Nikki D. Wheaton.

Conversion to Electronic Files

ASM Handbook, Volume 4, *Heat Treating* was converted to electronic files in 1998. The conversion was based on the Third Printing (1995). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Scott Henry, Robert Braddock, and Kathleen Dragolich. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Principles of Heat Treating of Steels

Torsten Ericsson, Linköping Institute of Technology, Sweden

Introduction

A STEEL is usually defined as an alloy of iron and carbon with the carbon content between a few hundreds of a percent up to about 2 wt%. Other alloying elements can amount in total to about 5 wt% in low-alloy steels and higher in more highly alloyed steels such as tool steels and stainless steels. Steels can exhibit a wide variety of properties depending on composition as well as the phases and microconstituents present, which in turn depend on the heat treatment. In subsequent articles in this Section, various types of heat treatment are described in detail. In this article, an outline of the physical metallurgy associated with heat treating of steels will be given and some important "tools" will be introduced. Deliberately no microstructures are shown as a well-illustrated article exists in "Microstructures, Processing, and Properties of Steels," by G. Krauss in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook.* A companion article that emphasizes information systems for predicting microstructures and hardnesses of quenched steels follows (see the article"Quantitative Prediction of Transformation Hardening in Steels" in this Volume).

The Fe-C Phase Diagram

The basis for the understanding of the heat treatment of steels is the Fe-C phase diagram (Fig. 1). Because it is well explained in earlier volumes of *ASM Handbook*, formerly *Metals Handbook* (Ref 1, 2, 3), and in many elementary textbooks, it will be treated very briefly here. Figure 1 actually shows two diagrams; the stable iron-graphite diagram (dashed lines) and the metastable Fe-Fe_3C diagram. The stable condition usually takes a very long time to develop, especially in the low-temperature and low-carbon range, and therefore the metastable diagram is of more interest. The Fe-C diagram shows which phases are to be expected at equilibrium (or metastable equilibrium) for different combinations of carbon concentration and temperature. Table 1 provides a summary of important metallurgical phases and microconstituents. We distinguish at the low-carbon end ferrite (α-iron), which can at most dissolve 0.028 wt% C at 727 °C (1341 °F) and austenite (γ-iron), which can dissolve 2.11 wt% C at 1148 °C (2098 °F). At the carbon-rich side we find cementite (Fe_3C). Of less interest, except for highly alloyed steels, is the δ-ferrite existing at the highest temperatures. Between the single-phase fields are found regions with mixtures of two phases, such as ferrite + cementite, austenite + cementite, and ferrite + austenite. At the highest temperatures, the liquid phase field can be found and below this are the two phase fields liquid + austenite, liquid + cementite, and liquid + δ-ferrite. In heat treating of steels, the liquid phase is

always avoided. Some important boundaries at single-phase fields have been given special names that facilitate the discussion. These include:

- A_1, the so-called eutectoid temperature, which is the minimum temperature for austenite
- A_3, the lower-temperature boundary of the austenite region at low carbon contents, that is, the $\gamma/\gamma + \alpha$ boundary
- A_{cm}, the counterpart boundary for high carbon contents, that is, the $\gamma/\gamma + Fe_3C$ boundary

Sometimes the letters c, e, or r are included. Relevant definitions of terms associated with phase transformations of steels can be found in Table 2 as well as the Glossary of Terms in this Volume and Ref 3. The carbon content at which the minimum austenite temperature is attained is called the eutectoid carbon content (0.77 wt% C). The ferrite-cementite phase mixture of this composition formed during cooling has a characteristic appearance and is called pearlite and can be treated as a microstructural entity or microconstituent. It is an aggregate of alternating ferrite and cementite lamellae that degenerates ("spheroidizes" or "coarsens") into cementite particles dispersed with a ferrite matrix after extended holding close to A_1.

Table 1 Important metallurgical phases and microconstituents

Phase (microconstituent)	**Crystal structure of phases**	**Characteristics**
Ferrite (α-iron)	bcc	Relatively soft low-temperature phase; stable equilibrium phase
δ-ferrite (δ-iron)	bcc	Isomorphous with α-iron; high-temperature phase; stable equilibrium phase
Austenite (γ-iron)	fcc	Relatively soft medium-temperature phase; stable equilibrium phase
Cementite (Fe_3C)	Complex orthorhombic	Hard metastable phase
Graphite	Hexagonal	Stable equilibrium phase
Pearlite		Metastable microconstituent; lamellar mixture of ferrite and cementite
Martensite	bct (supersaturated solution of carbon in ferrite)	Hard metastable phase; lath morphology when <0.6 wt% C; plate morphology when >1.0 wt% C and mixture of those in between
Bainite	. . .	Hard metastable microconstituent; nonlamellar mixture of ferrite and cementite on an extremely fine scale; upper bainite formed at higher temperatures has a feathery appearance; lower bainite formed at lower temperatures has an acicular appearance. The hardness of bainite increases with decreasing temperature of formation.

Table 2 Definitions of transformation temperatures in iron and steels

See the Glossary of Terms in this Volume for additional terminology.

Transformation temperature. The temperature at which a change in phase occurs. The term is sometimes used to denote the limiting temperature of a transformation range. The following symbols are used for iron and steels.

Ac_{cm}. In hypereutectoid steel, the temperature at which the solution of cementite in austenite is completed during heating.
Ac_1. The temperature at which austenite begins to form during heating, with the c being derived from the French *chauffant.*
Ac_3. The temperature at which transformation of ferrite to austenite is completed during heating.
Ae_{cm}, Ae_1, Ae_3. The temperatures of phase changes at equilibrium.
Ar_{cm}. In hypereutectoid steel, the temperature at which precipitation of cementite starts during cooling, with the r being derived from the French *refroidissant.*
Ar_1. The temperature at which transformation of austenite to ferrite or to ferrite plus cementite is completed during cooling.
Ar_3. The temperature at which austenite begins to transform to ferrite during cooling.
Ar_4. The temperature at which delta ferrite transforms to austenite during cooling.
M_s (or Ar''). The temperature at which transformation of austenite to martensite starts during cooling.
M_f. The temperature at which martensite formation finishes during cooling.

Note: All of these changes, except the formation of martensite, occur at lower temperatures during cooling than during heating and depend on the rate of change of temperature.

Source: Ref 2

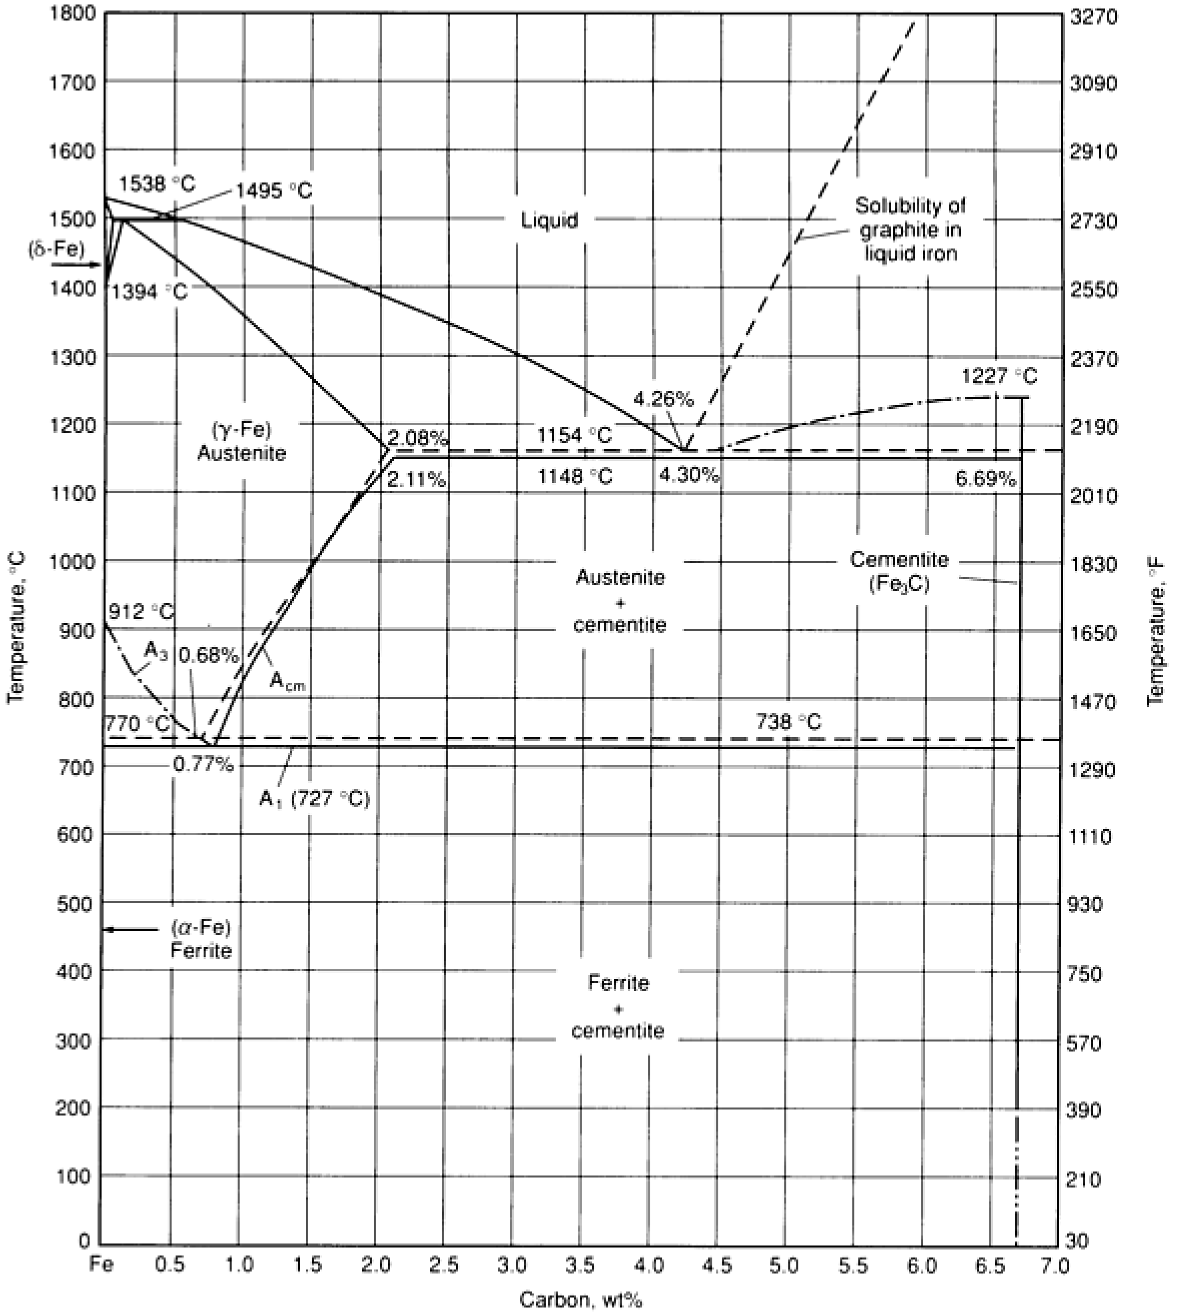

Fig. 1 The Fe-C equilibrium diagram up to 6.67 wt% C. Solid lines indicate $Fe-Fe_3C$ diagram; dashed lines indicate iron-graphite diagram. Source: Ref 1

The Fe-C diagram in Fig. 1 is of experimental origin. The knowledge of the thermodynamic principles and modern thermodynamic data now permits very accurate calculations of this diagram (Ref 4). This is particularly useful when phase boundaries must be extrapolated and at low temperatures where the experimental equilibria are extremely slow to develop.

If alloying elements are added to the iron-carbon alloy (steel), the position of the A_1, A_3, and A_{cm} boundaries and the eutectoid composition are changed. Classical diagrams introduced by Bain (Ref 5) show the variation of A_1 and the eutectoid carbon content with increasing amount of a selected number of alloying elements (Fig. 2). It suffices here to mention that (1) all important alloying elements decrease the eutectoid carbon content, (2) the austenite-stabilizing elements manganese and nickel decrease A_1, and (3) the ferrite-stabilizing elements chromium, silicon, molybdenum, and tungsten increase A_1. These classifications relate directly to the synergisms in quench hardening as described in the articles "Quantitative Prediction of Transformation Hardening in Steels" and "Quenching of Steel"in this Volume.

Modern thermodynamic calculations allow accurate determinations of these shifts that affect the driving force for phase transformation (see below). These methods also permit calculation of complete ternary and higher-order phase diagrams including alloy carbides (Ref 6). Reference should be made to the Calphad computer system (Ref 7).

Transformation Diagrams

The kinetic aspects of phase transformations are as important as the equilibrium diagrams for the heat treatment of steels. The metastable phase martensite and the morphologically metastable microconstituent bainite, which are of extreme importance to the properties of steels, can generally form with comparatively rapid cooling to ambient temperature, that is, when the diffusion of carbon and alloying elements is suppressed or limited to a very short range. Bainite is a eutectoid decomposition that is a mixture of ferrite and cementite. Martensite, the hardest constituent, forms during severe quenches from supersaturated austenite by a shear transformation. Its hardness increases monotonically with carbon content up to about 0.7 wt%. If these unstable metastable products are subsequently heated to a moderately elevated temperature, they decompose to more stable distributions of ferrite and carbide. The reheating process is sometimes known as tempering or annealing.

The transformation of an ambient temperature structure like ferrite-pearlite or tempered martensite to the elevated-temperature structure of austenite or austenite + carbide is also of importance in the heat treatment of steel.

One can conveniently describe what is happening during transformation with transformation diagrams. Four different types of such diagrams can be distinguished. These include:

- Isothermal transformation diagrams describing the *formation* of austenite, which will be referred to as ITh diagrams
- Isothermal transformation (IT) diagrams, also referred to as time-temperature-transformation (TTT) diagrams, describing the *decomposition* of austenite
- Continuous heating transformation (CHT) diagrams
- Continuous cooling transformation (CCT) diagrams

Isothermal Transformation Diagrams

This type of diagram shows what happens when a steel is held at a constant temperature for a prolonged period. The development of the microstructure with time can be followed by holding small specimens in a lead or salt bath and quenching them one at a time after increasing holding times and measuring the amount of phases formed in the microstructure with the aid of a microscope. An alternative method involves using a single specimen and a dilatometer which records the elongation of the specimen as a function of time. The basis for the dilatometer method is that the microconstituents undergo different volumetric changes (Table 3). A thorough description of the dilatometric method can be found in Ref 8.

Table 3 Volume changes due to different transformations

Transformation	**Volume change, %[(a)]**
Spheroidized pearlite-austenite	4.64-2.21 × (%C)
Austenite-martensite	4.64-0.53 × (%C)
Austenite-lower bainite	4.64-1.43 × (%C)
Austenite-upper bainite	4.64-2.21 × (%C)

Source: Ref 19

(a) Linear changes are approximately one-third the volume changes.

ITh Diagrams (Formation of Austenite). During the formation of austenite from an original microstructure of ferrite and pearlite or tempered martensite, the volume (and hence the length) decreases with the formation of the dense austenite phase (see Fig. 3). From the elongation curves, the start and finish times for austenite formation, usually defined as 1% and 99% transformation, respectively, can be derived. These times are then conveniently plotted on a temperature-log time diagram (Fig. 4). Also plotted in this diagram are the Ac_1 and Ac_3 temperatures. Below Ac_1 no austenite can form, and between Ac_1 and Ac_3 the end product is a mixture of ferrite and austenite. Notice that a considerable overheating is required to complete the transformation in a short time. The original microstructure also plays a great role. A finely distributed structure like tempered martensite is more rapidly transformed to austenite than, for instance, a ferritic-pearlitic structure. This is particularly true for alloyed steels with carbide-forming alloying elements such as chromium and molybdenum. It is important that the heating rate to the hold temperature be very high if a true isothermal diagram is to be obtained.

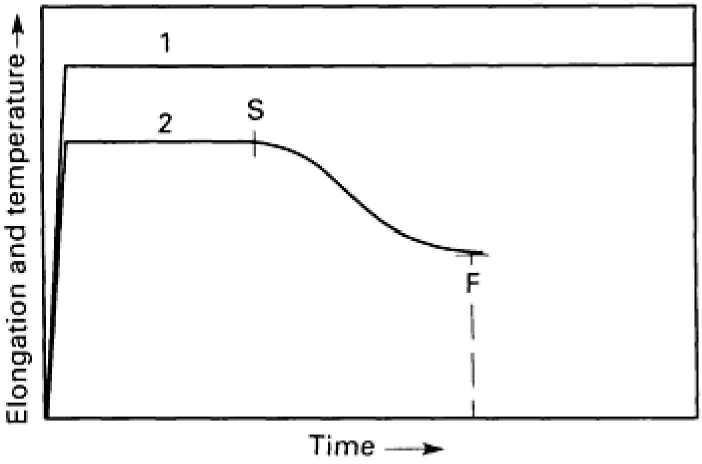

Fig. 3 The procedure for determining isothermal heating (ITh) diagrams. Line 1: Temperature versus time. Line 2: Elongation versus time. S represents the start and F the finish of the transformation of the original microstructure to austenite transformation, respectively.

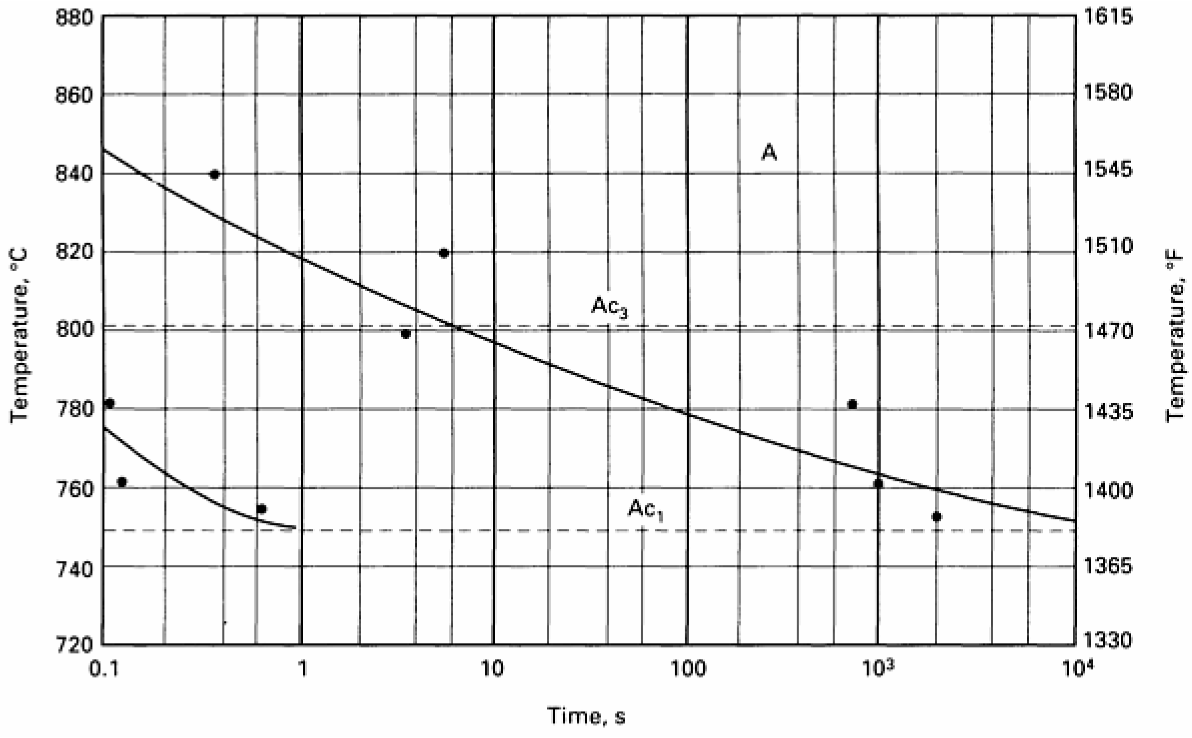

Fig. 4 Isothermal heating diagram for AISI 4140 steel. Heating rate to reach holding temperature is 1020 °C/s (1835 °F/s). Between Ac_3 and Ac_1, the final structure is a mixture of austenite and ferrite. A, austenite. Source: Ref 9

The ITh diagram is not as common as the isothermal cooling diagrams described next. Heating diagrams are useful in short time heat treatments like induction and laser hardening. An extensive collection of ITh diagrams can be found in Ref 10.

IT Diagrams (Decomposition of Austenite). The procedure starts at a high temperature, normally in the austenitic range after holding there long enough to obtain homogeneous austenite without undissolved carbides, followed by rapid cooling to the desired hold temperature (Fig. 5). An example of an IT diagram is given in Fig. 6. The cooling was started from 850 °C (1560 °F). The A_1 and A_3 temperatures are indicated as well as the hardness. Above A_3 no transformation can occur. Between A_1 and A_3 only ferrite can form from austenite. In Fig. 6, a series of isovolume fraction curves are shown; normally only the 1% and 99% curves are reproduced. Notice that the curves are C-shaped. This is typical for transformation curves. A higher-temperature set of C-shaped curves shows the transformation to pearlite and a lower-temperature set indicates the transformation to bainite. In between is found a so-called austenite bay, common for certain low-alloy steels containing appreciable amounts of carbide-forming alloying elements such as chromium or molybdenum.

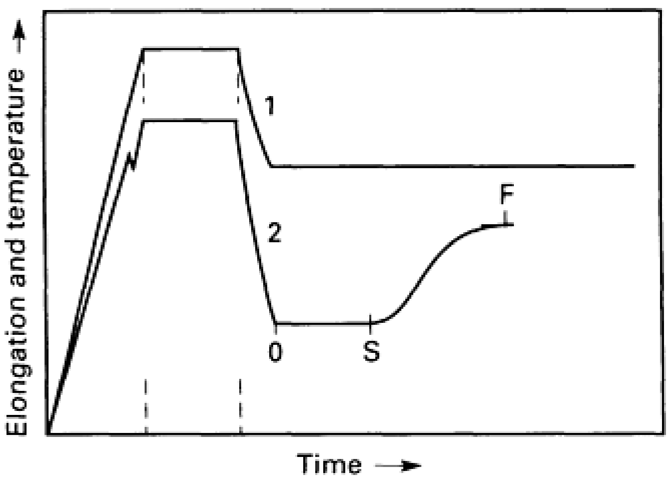

Fig. 5 The procedure for determining isothermal cooling (IT) diagrams. Line 1: Temperature versus time. Line 2: Elongation versus time. S represents the start and F the finish of austenite decomposition, respectively.

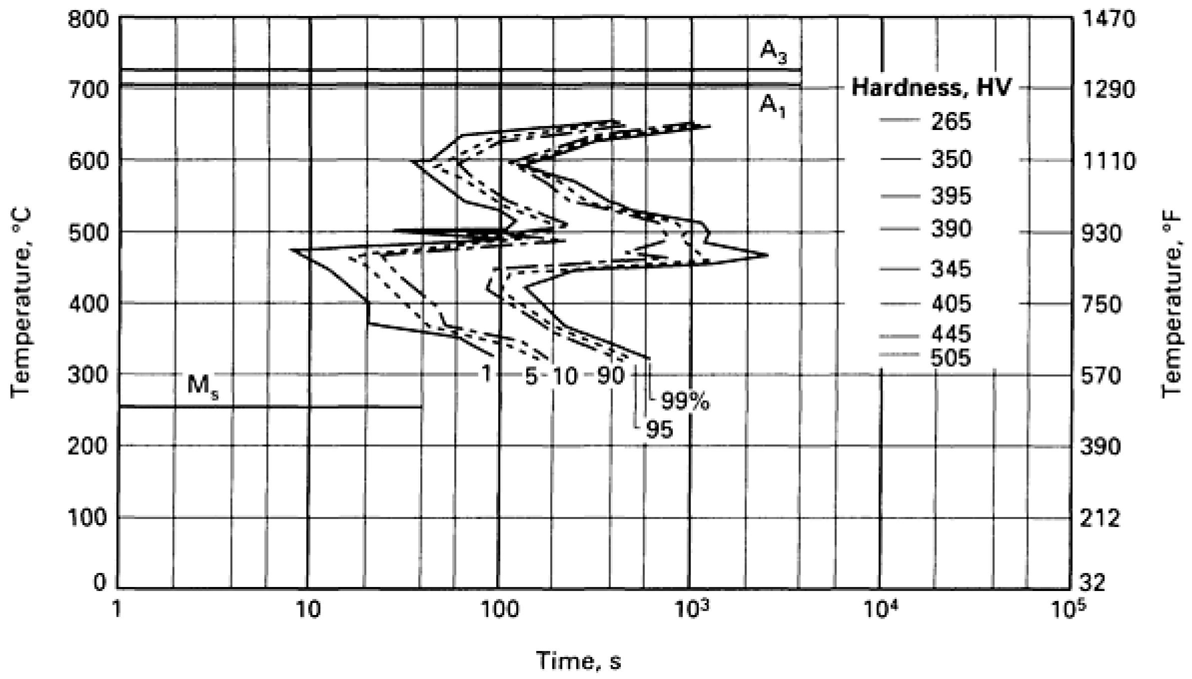

Fig. 6 Isothermal transformation diagram for a steel with 0.39% C, 0.86% Mn, 0.72% Cr, and 0.97% Ni. The upper C-shaped curves describe transformation to pearlite; the lower C-shaped curves to bainite. Ferrite is not visible. The column on the right side of the figure indicates the hardness after completed transformation measured at room temperature. Source: Ref 11

The transformation start curve shows as an upper-limiting estimate of the time (in seconds) for nucleation, τ. The isovolume fraction curves τ_x can semiempirically be described by a relation of the type (Ref 12):

$$t_x = \frac{\exp(Q/RT)}{2^{N/8}.\Delta T^3} f.I(X) \qquad \textbf{(Eq 1)}$$

where x is the volume fraction of the transformed phase, Q is an activation energy related to the boundary diffusion activation energies for the alloying elements, N is the ASTM grain size number for austenite, T is the temperature (in degrees Kelvin), ΔT is the undercooling (A_3 - T) for ferrite, (A_1 - T) for pearlite and an empirical value for bainite, f is a

linear function of the volume fractions of carbon and alloying elements and *I* is the volume fraction integral giving the dependence of the transformed phase on the volume fraction.

The combined effect of the $I/\Delta T^3$ factor, which increases with decreasing undercooling (that is, increasing temperature) and the exp (Q/RT) factor, which increases with decreasing temperature, results in long nucleation times, τ_x, for high and low temperatures and short nucleation times for intermediate temperatures. The C-shape can thus be obtained and understood. The factor $2^{N/8}$ is included to take into consideration the fact that the transformation rate is larger for smaller austenite grain sizes.

Figure 6 also indicates the martensite start temperature, M_s, which is time independent. A number of numerical expressions for the composition dependence of M_s have been suggested (Ref 13). One commonly used expression is (Ref 14):

$$M_s(°C) = 512-453C-16.9Ni + 15Cr-9.5Mo + 217(C)^2-71.5(C)(Mn)-67.6(C)(Cr) \quad \textbf{(Eq 2)}$$

where the alloying elements are represented by their weight percents. If the hold time in the austenitic range is too short the C-shaped cooling curves may be shifted to shorter times. This is the case in Fig. 7 where an IT diagram obtained after 6 s at 950 °C (1740 °F) is compared with an IT diagram after 10 min at 860 °C (1580 °F). The shift may be due to incomplete carbide dissolution or a smaller grain size after short austenitizing time.

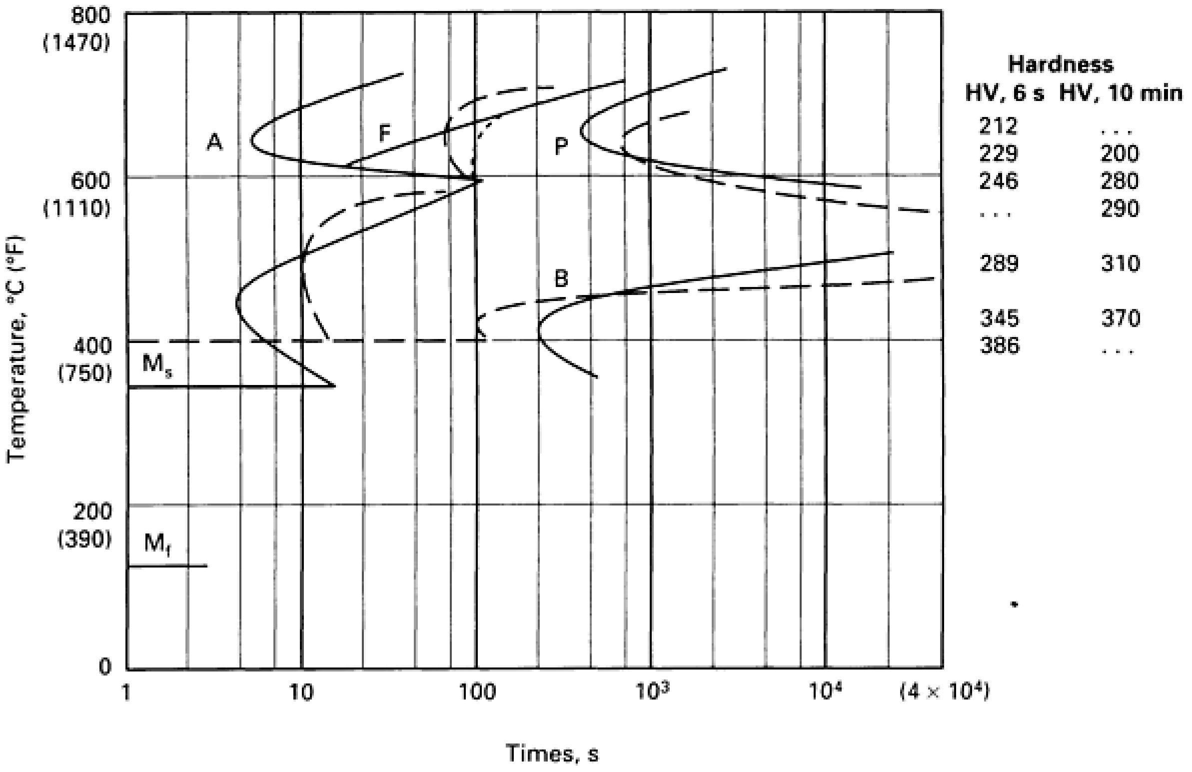

Fig. 7 Comparison of IT cooling diagrams for AISI 4140 steel after 6 s austenitizing time at 950 °C (1740 °F) (solid lines) and after 10 min austenitizing time at 860 °C (1580 °F) (dashed lines). Hardness values are also given for both heat-treated conditions. Source: Ref 9

Isothermal transformation curves can be found in standard graphs obtainable from the International Organization for Standardization (ISO), the Metallurgical Society of AIME, and ASM International (Ref 15). There is also a well-known German collection (Ref 10).

CHT Diagrams

In practical heat treatment situations, a constant temperature is not required, but rather a continuous changing temperature during either cooling or heating. Therefore, more directly applicable information is obtained if the diagram is constructed from dilatometric data using a continuously increasing or decreasing temperature. Figure 8 shows an example for continuous heating of the same steel as in Fig. 4. Indicated again are Ac_1 and Ac_3 and the same remarks as before are valid. The diagram was derived with constant heating rates and curves for 130 °C/s (265 °F/s), 10 °C/s (50 °F/s), and 0.2 °C/s (32 °F/s) are shown. Notice that the start and finish of the transformations are delayed relative to the isothermal diagram. This is generally true when one compares an isothermal and a continuous diagram, regardless of whether they are for heating or cooling.

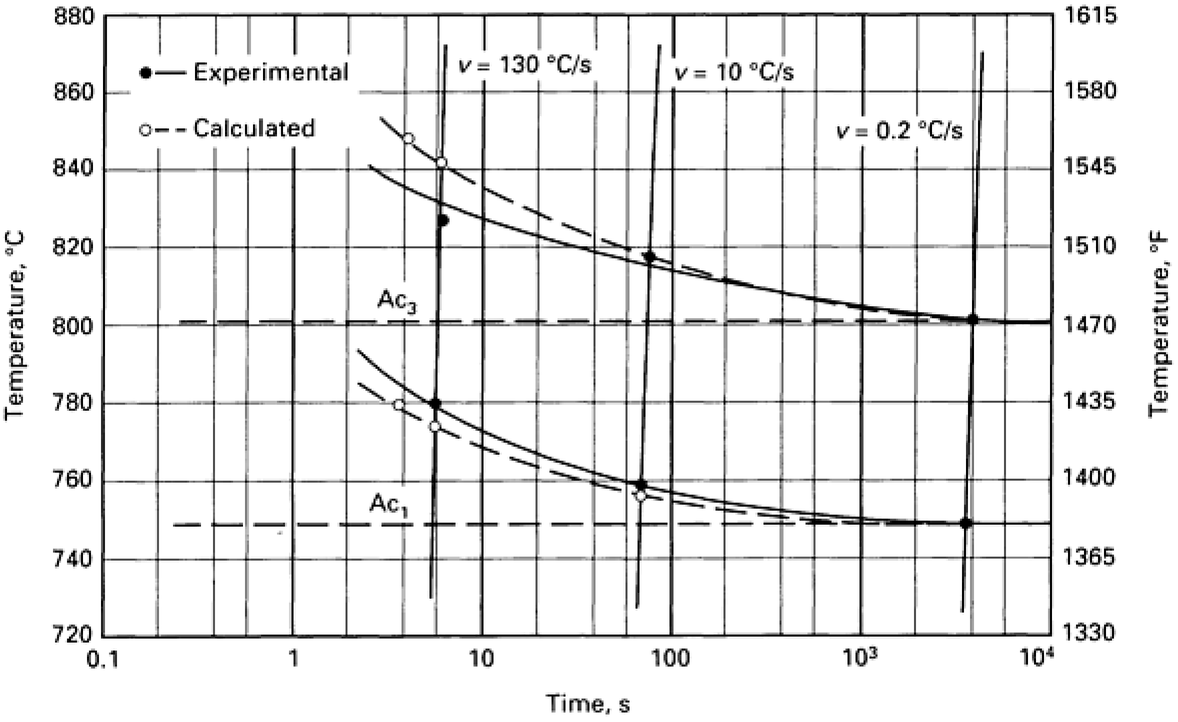

Fig. 8 Continuous heating transformation diagram for AISI 4140 steel. The phase being formed is austenite. Source: Ref 9

Like the ITh diagrams, the CHT diagrams are useful in predicting the effect of short-time austenitization that occurs in induction and laser hardening. One typical question is how high the maximum surface temperature should be in order to achieve complete austenitization for a given heating rate. Too high a temperature may cause unwanted austenite grain growth, which produces a more brittle martensitic microstructure. Reference 10 provides information on austenite grain growth as well as CHT diagrams.

CCT Diagrams

As for heating diagrams, it is important to clearly state what type of cooling curve the transformation diagram was derived from. Use of a constant cooling rate is very common in experimental practice. However, this regime rarely occurs in a practical situation. One can also find curves for so-called natural cooling rates according to Newton's law of cooling. These curves simulate the behavior in the interior of a large part such as the cooling rate of a Jominy bar at some distance from the quenched end. Close to the surface the characteristics of the cooling rate can be very complex as will be described below. In the lower part of Fig. 9 is shown a CCT diagram (fully drawn lines) for 4130 steel. Ferrite, pearlite, and bainite regions are indicated as well as the M_s temperature. Note that the M_s temperature is not constant when martensite formation is preceded by bainite formation, but typically decreases with longer times.

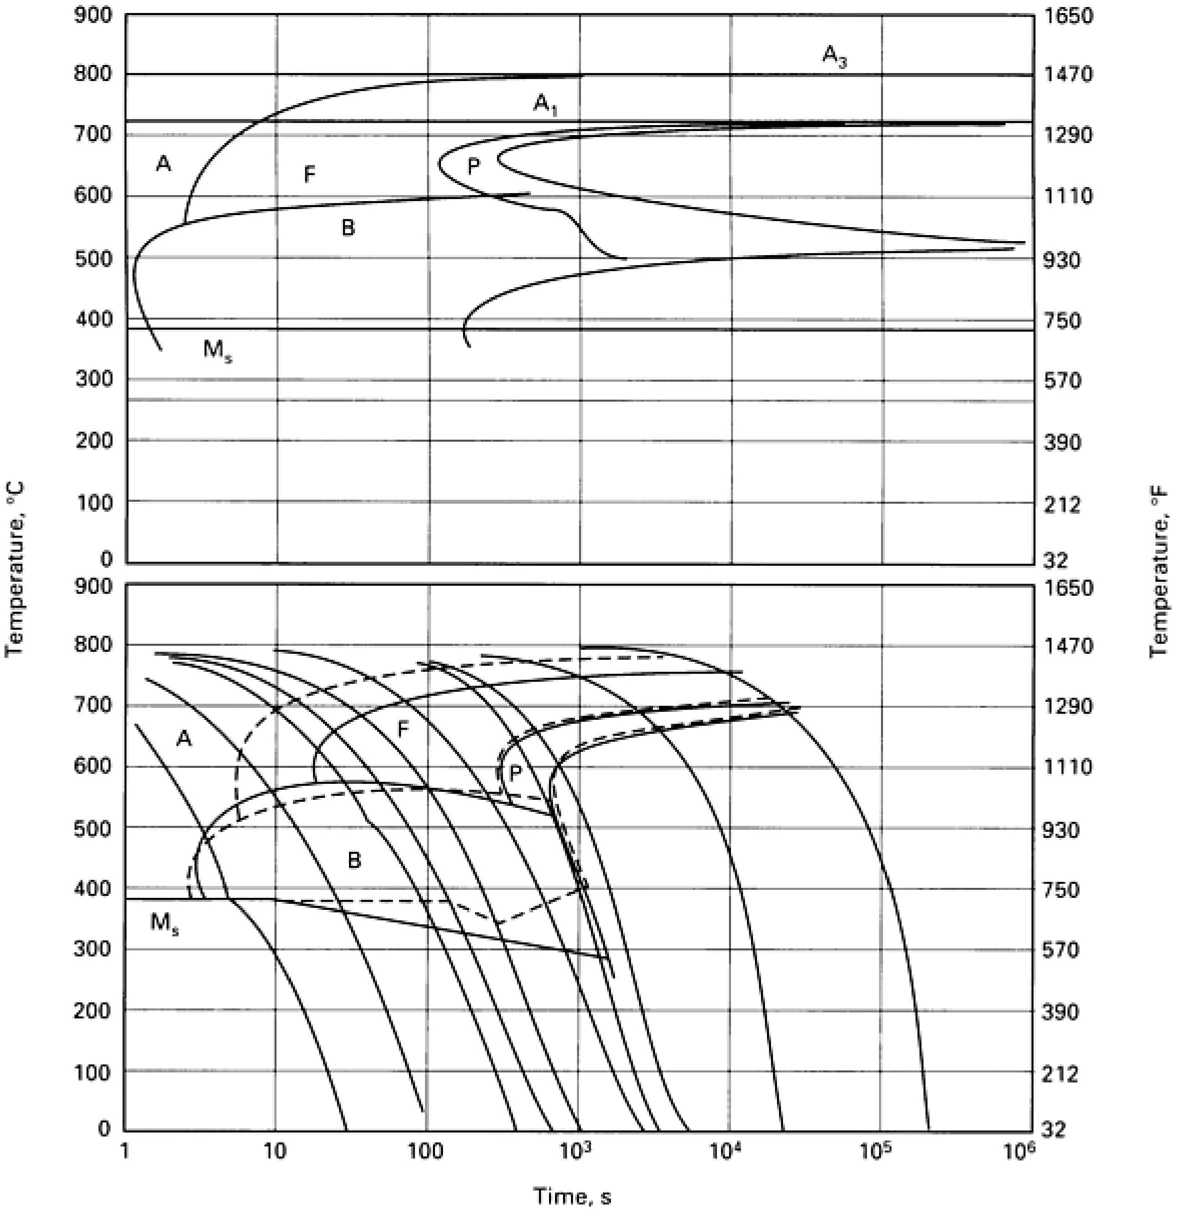

Fig. 9 Isothermal transformation (upper) and CCT (lower) diagrams for AISI 4130 steel containing 0.30% C, 0.64% Mn, 1.0% Cr, and 0.24% Mo. The IT diagram illustrates the input data representation for calculations described in the text. The CCT diagrams are computed (dashed lines) and experimentally determined (solid lines). Source: Ref 10, 11

The effect of different cooling curves is shown in Fig. 10. Each CCT diagram contains a family of curves representing the cooling rates at different depths of a cylinder with a 300 mm (12 in.) diameter. The slowest cooling rate represents the center of the cylinder. As shown in Fig. 10, the rate of cooling and the position of the CCT curves depend on the cooling medium (water produced the highest cooling rate followed by oil and air, respectively). The more severe the cooling medium, the longer the times to which the C-shaped curves are shifted. The M_s temperature is unaffected.

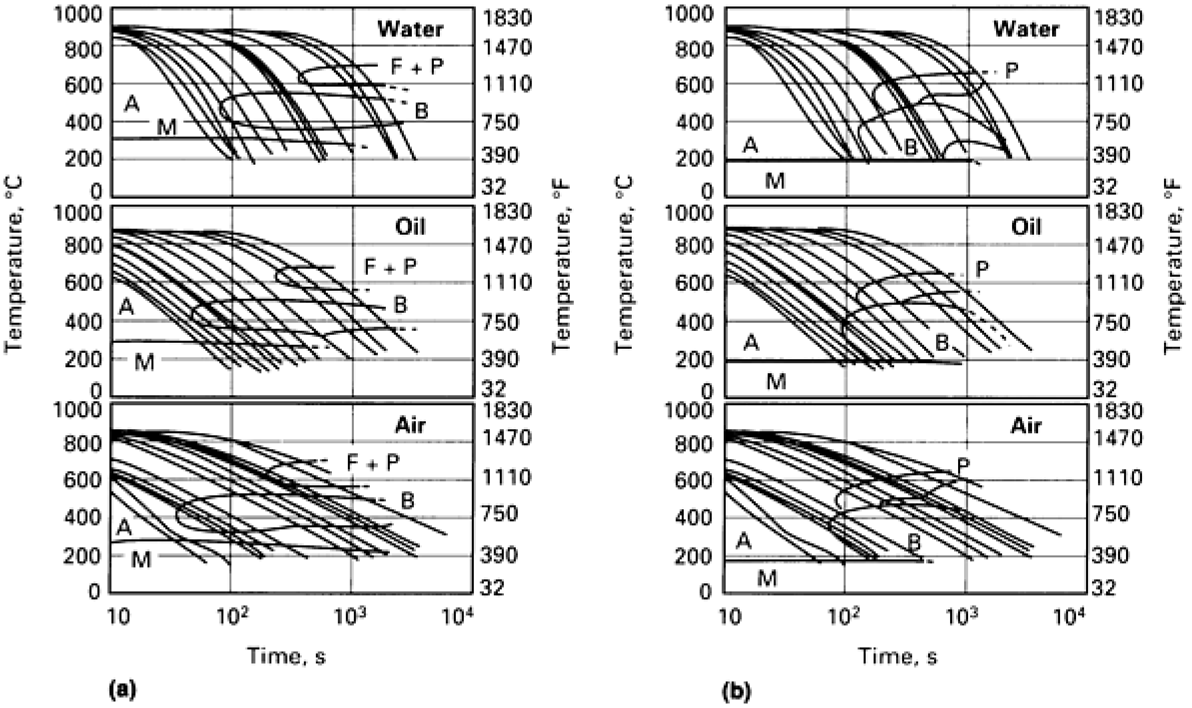

Fig. 10 Examples of CCT diagrams for low-alloy steels. (a) CCT diagrams of a chromium-molybdenum steel using simulated cooling curves for water, oil, and air. Source: Ref 16. (b) Computer-calculated CCT diagrams of a nickel-chromium steel containing 0.77 wt% C based on the cooling curves for water, oil, and air given in (a). Source: Ref 17

It should be noted, however, that transformation diagrams cannot be used to predict the response to thermal histories that are very much different from the ones used to construct the diagrams. For instance, first cooling rapidly to slightly above M_s and then reheating to a higher temperature will give more rapid transformation than shown in the IT diagram because nucleation is greatly accelerated during the introductory quench. It should also be remembered that the transformation diagrams are sensitive to the exact alloying content within the allowable composition range.

Various attempts have been made to facilitate the use of CCT diagrams by including the effect of the dimension of the workpiece and cooling medium on the microstructure and hardness obtained. Two such approaches have been described by Atkins (Ref 18) and Thelning (Ref 19). Experimental cooling curves were derived by Atkins for round bars of various diameters at fractional radii (*R*) 0.5 and 0.8 from the center during cooling in water, oil, and air. The cooling curves were used in dilatometer measurements to get the transformation temperatures and the resulting microstructures and hardnesses were also noted. A diagram of this type is shown in Fig. 11. From the diagram, one can correlate that a specimen, 2 mm (0.08 in.) in diameter being cooled in air, corresponds to a bar somewhat less than 40 mm (1.6 in.) in diameter cooled in oil, or to a bar 50 mm (2 in.) in diameter quenched in water. Shown in the upper part of the figure are the amount and type of microstructure; the lower part gives hardnesses after hardening and tempering at various temperatures.

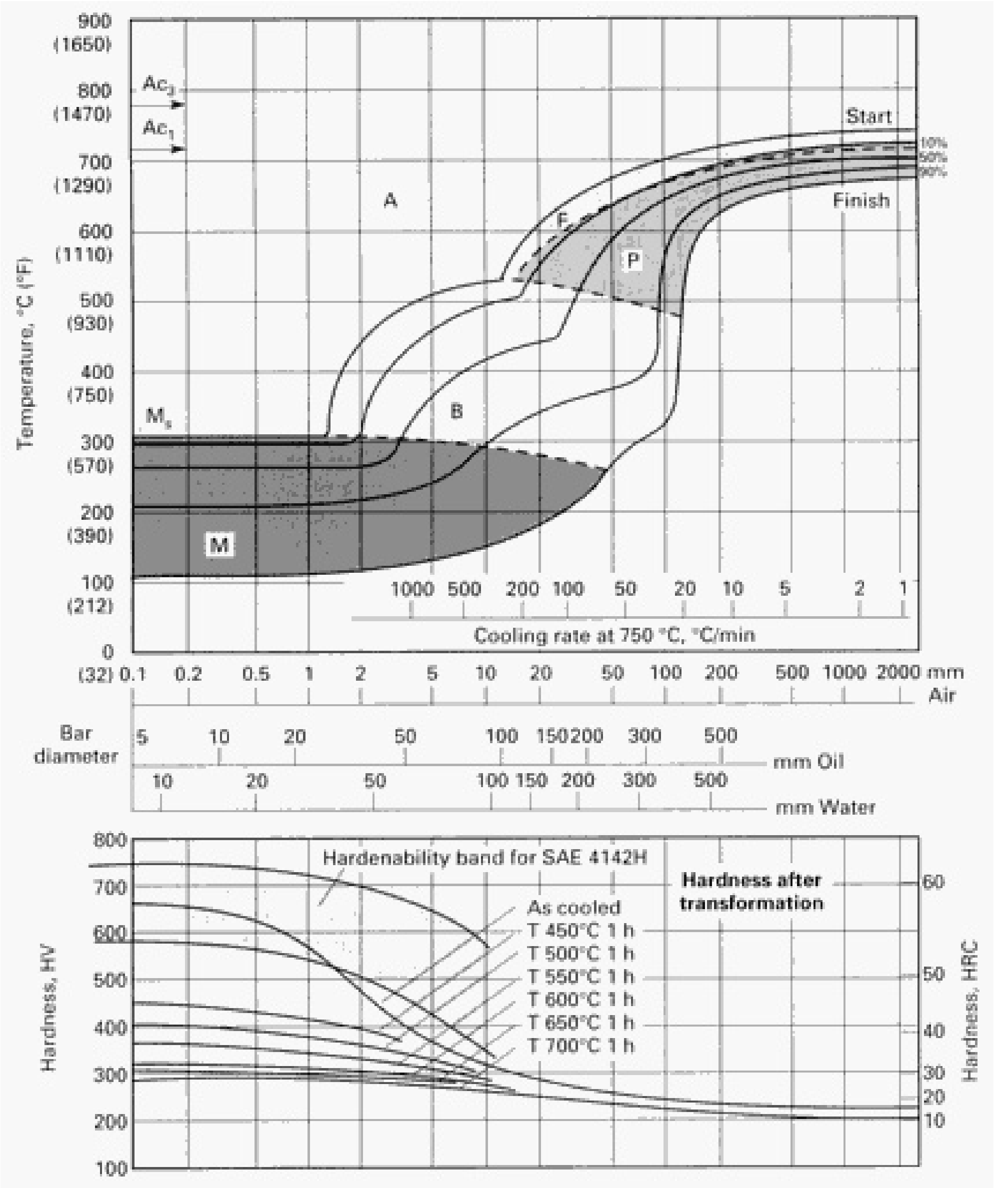

Fig. 11 A CCT diagram for 1.25Cr-0.20 Mo steel (SAE/AISI 4140-4142) that was austenitized at 860 °C (1580 °F). The vertical lines in the upper diagram give the cooling rate for the center of bars with different diameters when quenching in different media. The lower part of the figure shows the hardness after hardening and tempering (T) at various temperatures. Source: Ref 18

Thelning used the cooling curves just mentioned to derive dilatometer curves and presented the results in diagrams of the type shown in Fig. 12. From this diagram the structural constituents and hardness values that exist at 0.8 *R* and at the center of bars of various dimensions after cooling in water or oil can be determined.

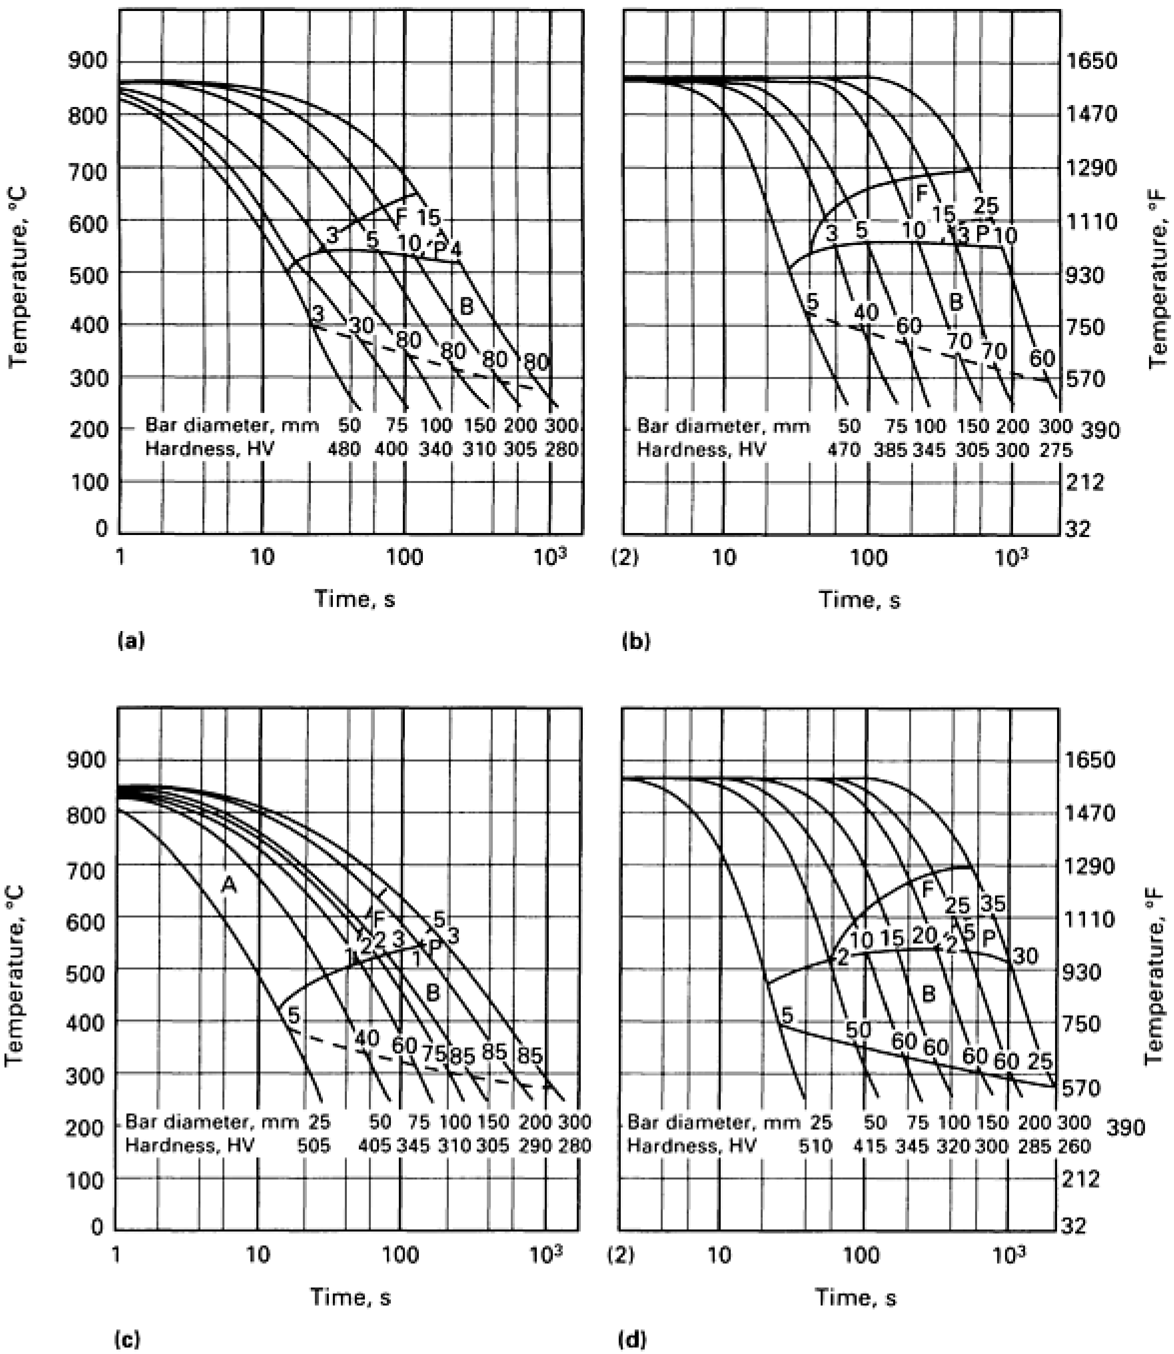

Fig. 12 CCT diagrams for AISI 4130 steel. (a) Water quench, 0.8 *R* specimen. (b) Water quench, center of specimen. (c) Oil quench, 0.8 *R* specimen. (d) Oil quench, center of specimen. Source: Ref 19

Computer Simulation of Transformation Diagrams

Because the experimental determination of transformation diagrams is costly and tedious, there is great interest in calculating these diagrams (Ref 20, 21). An effective computer model would allow the exact shape of the cooling curves discussed above to be determined.

The problems associated with developing such programs are twofold and involve the calculation of the TTT diagram and the calculation of the CCT diagram from the isothermal one. Because solving the first problem from first principles for a given steel composition is a formidable task, empirical correlations or semiempirical procedures are in current use (Ref 12). The second problem is much easier to handle, and several successful approaches have been tried. One of these will be presented below while alternative approaches are described in the following article in this Section (see"Quantitative Prediction of Transformation Hardening in Steels").

As a basis for the calculation, the Johnson-Mehl-Avrami expression that describes the diffusional transformation of austenite to either ferrite, pearlite, or bainite can be used:

$$v = 1 - \exp(-b \cdot t^{n}) \qquad \textbf{(Eq 3)}$$

where v is the transformed volume fraction, t is the time, and b and n are temperature-dependent constants; b and n are evaluated from the given TTT diagram except for ferrite for which it is assumed that n = 1. More generally, it can be stated that:

$$n = \frac{\log[\ln(1-v_s)/\ln(1-v_s)]}{\log[t_s(T)/t_f(T)]} \qquad \textbf{(Eq 4)}$$

$$b = \frac{-\ln(1-v_s)}{t_s(T)} \qquad \textbf{(Eq 5)}$$

where the subscripts s and f indicate start and finish, respectively. In a TTT diagram, v_s is usually chosen to be 1% and v_f 99%, but other percentages may also be chosen. The experimental C-shaped curves in the TTT diagrams are approximated by spline functions when stored in the computer. The cooling curve is approximated by a staircase, the step length being equal to the time step. The phase transformation is then calculated isothermally during each time step. This is equivalent to using the Scheil-Avrami additivity rule, which is described in the article "Quenching of Steel" in this Volume (see the discussion on quench factor analysis).

Note that in the general case several transformation products coexist and compete. For each phase being formed, a separate set of equations is written. For ferrite, the maximum volume fraction possible above A_1 is less than unity and is given by application of the lever rule to the multi-component phase diagram.

The martensitic transformation relation is based on the following expression (Ref 22):

$$v_M = (1 - v_F - v_P - v_B - v_C)\,(1 - \exp(-0.011 \cdot (M_s - T))) \qquad \textbf{(Eq 6)}$$

where F, P, B, and C represent ferrite, pearlite, bainite, and cementite, respectively.

A comparison between measured and calculated CCT diagrams derived by linear cooling is shown in Fig. 9. The agreement is quite satisfactory. Figure 10 shows that the effect of different cooling rates on the CCT diagram is well reproduced by the calculations.

The model described above has been refined by incorporating a nucleation stage before the diffusional-growth stage (Ref 21). Scheil's principle of additivity of incubation fractions has been used, that is, for each time step, denoted as Δt_i, the fraction $\Delta t_i/\tau_{iIT}$ is calculated where τ_{iIT} is the time to the start of the transformation of the temperature prevailing during the time step. The fractions are then summed:

$$\sum \frac{\Delta t_i}{t_{iIT}}$$

When this sum attains unity, the incubation period is over. The nonadditivity of pearlitic and bainitic nucleation is accounted for by a correction factor of the Scheil sum at the transition from pearlite to bainite.

The calculation of the CHT diagram from the ITh diagram on heating is quite analogous. Good agreement between calculated and measured CHT curves where linear heating was applied is shown in Fig. 8.

Hardenability Concepts

The goal of heat treatment of steel is very often to attain a satisfactory hardness. The important microstructural phase is then normally martensite, which is the hardest constituent in low-alloy steels. The hardness of martensite is primarily dependent on its carbon content as is shown in Fig. 13. If the microstructure is not fully martensitic, its hardness is lower. In practical heat treatment, it is important to achieve full hardness to a certain minimum depth after cooling, that is, to obtain a fully martensitic microstructure to a certain minimum depth, which also represents a critical cooling rate. If a given steel does not permit a martensitic structure to be formed to this depth, one has to choose another steel with a higher hardenability (the possibility of increasing the cooling rate at the minimum depth will be discussed later). There are various ways to characterize the hardenability of a steel. Certain aspects of this will be discussed in the following article in the Section and has also been described in detail in previous *ASM Handbooks*, formerly *Metals Handbooks* (Ref 23). The CCT diagram can serve this purpose if one knows the cooling rate at the minimum depth. The CCT diagrams constructed according to Atkins or Thelning presented above are particularly suitable.

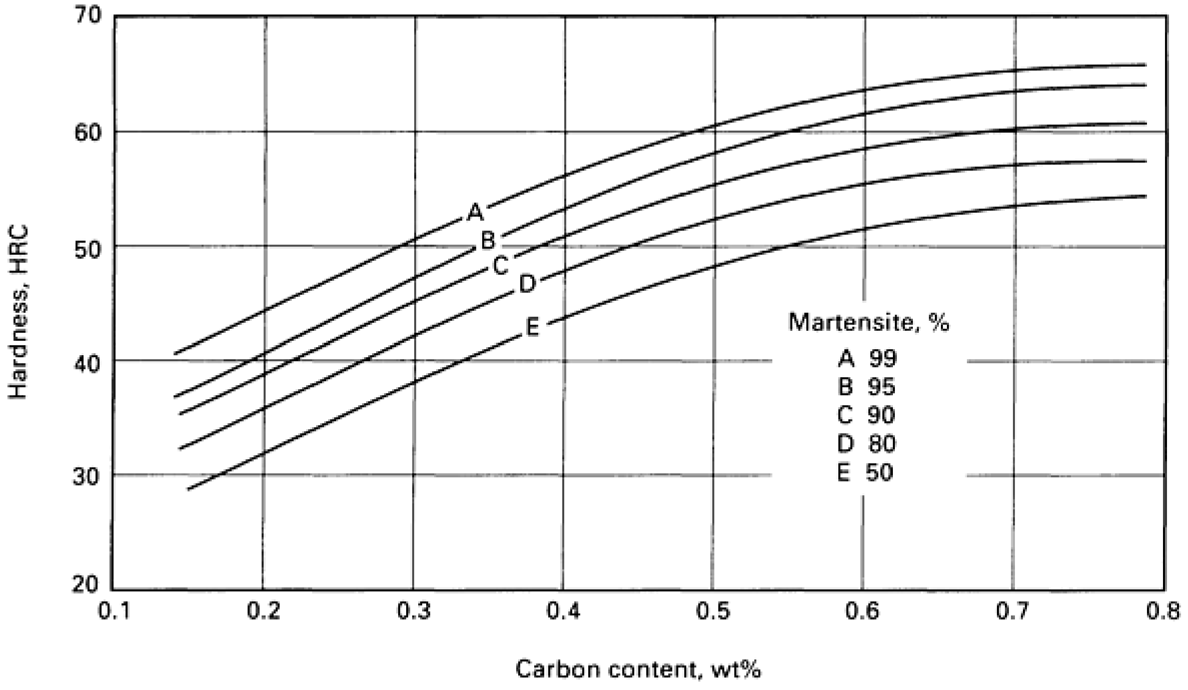

Fig. 13 Relationship between hardness, carbon content, and amount of martensite

Grossmann Hardenability Test. Another method using cylindrical test bars is the classical one of Grossmann (Ref 24). A number of cylindrical steel bars of different diameters are hardened in a given cooling medium. By means of metallographic examination, the bar that has 50% martensite at its center is singled out and the diameter of this bar is designated as the critical diameter (D_0). This D_0 value is valid for the particular cooling medium used as well as its cooling intensity. An ideal cooling situation is when the surface of the test bar is immediately cooled to ambient temperature, that is, an infinite cooling rate at the surface. Although such cooling cannot be carried out in practice, one can mathematically extrapolate this situation and derive the ideal Grossmann diameter, D_I, defined as the bar diameter that, when the surface is cooled at an infinite rate, will yield a structure containing 50% martensite at the center of the specimen. The value of D_I obtained is a measure of the hardenability of the steel and is independent of the cooling medium. Using this method, D_I values have been determined for low- and medium-carbon steels with different carbon contents and grain sizes. The additional effect of alloying elements has been determined for a number of alloying elements and is expressed as hardenability factors, f, which are multiplying factors corresponding to the percentage of alloying element present. The ideal diameter, D_I, for a certain steel can then be expressed as:

$$D_I = D_0 \cdot f_1 \cdot f_2 \cdot f_3 \ldots$$

where f_1, f_2, f_3 are the factors for alloying elements 1, 2, 3. . ., respectively, and D_0 applies to Fe-C alloys.

Diagrams have been developed that convert D_I to D_0 for the cooling medium of interest. The ISO has also developed diagrams to convert from rectangular to round sections.

The Grossmann method is frequently used but gives a very approximate measure of hardenability. However, it can be reliably employed to compare steels of different compositions. More detailed information on the Grossmann method and the calculation of D_I values from the chemical composition can be found in Ref 19 and in the article "Quenching of Steel" in this Volume.

Jominy End-Quench Test. The most commonly used experimental method for hardenability is the well-known Jominy test (Ref 23). For this test a round bar specimen that is 100 mm (4 in.) in length and 25 mm (1 in.) in diameter is used. The specimen is heated to the austenitizing temperature of the steel with a holding time of 20 min. One endface of the specimen is quenched by spraying it with a jet of water. This causes the rate of cooling to decrease progressively from the quenched end along the length of the bar. When it is cool, two diametrically opposite flats that are 0.4 mm (0.015 in.)

deep and parallel to the axis of the bar, are ground and the hardness is measured along the flats. The hardness values are plotted on a diagram at specified intervals from the quenched end. To get good reproducibility, the time and temperature of austenitizing, the grinding of the flats to avoid burning, and the placement of the specimen in the hardness tester should be carefully controlled. It is also important to protect the specimen against decarburization. Less critical are the water temperature, the diameter of the spraying nozzle, the height of the water jet, and the time to move the specimen from the furnace to the fixture. For steels with very high or very low hardenability, neither the Grossmann nor the Jominy methods are well suited and other methods are used. These methods are well covered in Volume 1 of *ASM Handbook*, formerly 10th Edition of *Metals Handbook* (Ref 23) and in Ref 24.

The rate of cooling at different distances from the quenched end is approximately independent of the steel used because the thermal conductivity and heat capacity of hardenable steels do not vary very much and the heat transfer at the cooled end is steel independent. Therefore, the Jominy bar presents a range of cooling curves that can be used to estimate a CCT diagram. The cooling rates are not linear but rather of the natural type according to Newton's law of cooling. The volume fractions of the various constituents of the microstructure are evaluated quantitatively at different Jominy distances as well as hardness measurements. Conversely, the Jominy curve can be calculated from the TTT diagram using the computer methods described above and expressions that give the hardness for the different phases (Ref 18). The total hardness is then the weighted average. Figure 14 shows the agreement between calculated and experimental Jominy curves that can be achieved.

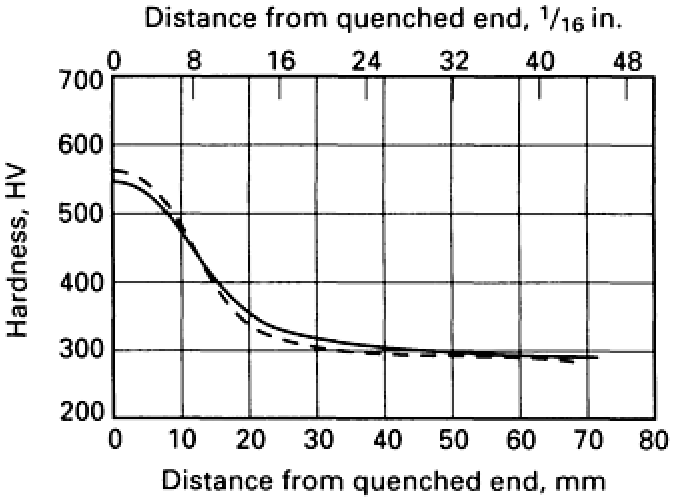

Fig. 14 Calculated hardness (dashed line) and reported hardness (solid line) from a Jominy test of AISI 4130 steel. Source: Ref 10, 11

There is an economic trend to reduce the amount of experimental Jominy testing and replace it by the calculation of Jominy curves from the chemical composition and the grain size. Several regression formulas have been developed for different grades of steel which are quite accurate for a limited composition range. A more general approach will be described in the article "Quantitative Prediction of Transformation Hardening in Steels" that immediately follows.

Principles of Tempering of Steels

As pointed out earlier in this article, martensite is a very hard phase in steel. It owes its high hardness to a strong supersaturation of carbon in the iron lattice and to a high density of crystal defects, especially dislocations, and high- and low-angle boundaries. However, except at low carbon contents, martensitic steels have insufficient toughness for many applications. Tempering of martensitic steels, by heating for a certain time at temperatures below the A_1, is therefore introduced to exchange some of the strength for greater ductility through reduction of the carbon supersaturation initially present and replacing it with more stable structures. Additionally, the retained austenite associated with martensite in steels containing more than about 0.7 wt% C can be decomposed during the tempering process. In carbon steels containing small percentages of the common alloying elements, one distinguishes the following stages during tempering (Ref 3):

- *Stage 1* (20 to 100 °C, or 70 to 212 °F). Short-range diffusion of carbon atoms to dislocations and martensite plate boundaries; formation of carbon clusters
- *Stage 2* (100 to 200 °C, or 212 to 390 °F). Precipitation of transition carbides, especially ϵcarbide ($Fe_{2.4}C$)
- *Stage 3* (200 to 350 °C, or 390 to 660 °F). Transformation of retained austenite to ferrite and cementite
- *Stage 4* (250 to 700 °C, or 480 to 1290 °F). Formation of ferrite and cementite. Spheroidized carbides in a matrix of equiaxed ferrite grains comprises well-tempered steels, that is, tempered for long times at temperatures approaching 700 °C (1290 °F)

In steels alloyed with chromium, molybdenum, vanadium, or tungsten, formation of alloy carbides occurs in the temperature range 500 to 700 °C (930 to 1290 °F).

During stage 1, the hardness increases slightly while during stage 2, 3, and 4 the hardness decreases. Figure 15 shows the hardness of some steels after tempering for 2 h at different temperatures.

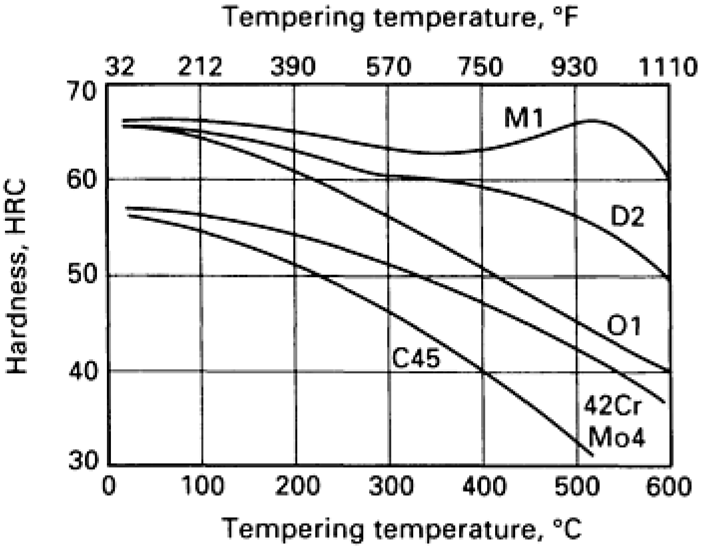

Fig. 15 Tempering curves for some current steels. The steel 42CrMo4 is equivalent to AISI 4142 and C45 to AISI 1045. Source: Ref 19

Hollomon and Jaffe (Ref 25) showed that the relation between hardness and time and temperature of tempering can be expressed graphically by plotting hardness as a function of a tempering parameter *P,* where:

$$P = T(k + \log t)$$

In this expression, T is the temperature (in degrees Kelvin), k is a constant with a value of about 20, and t is the time in hours. The physical background to this empirical expression is the fact that the various tempering reactions are thermally activated diffusional processes.

The toughness of a steel increases with decreasing hardness. However, when certain impurities such as arsenic, phosphorus, antimony, and tin are present, a toughness minimum termed "temper embrittlement" may occur in the temperature range 350 to 600 °C (660 to 1100 °F) due to segregation of impurities to grain boundaries. Temper embrittlement is a problem when parts are exposed to temperatures in the critical range for rather long times and is a concern for parts exposed to these temperatures while in service or when heat treating very massive parts which require long times to heat and cool. It is not a concern, even for susceptible alloys, if small parts are exposed to these temperatures for an hour or so during heat treatment, then used at ambient temperatures. Nuts and bolts, for example, made of various types of steels, are tempered in this temperature range with no problems as long as they are used at lower temperatures. The time for embrittlement to occur at differing tempering temperatures shows a C-shaped curve behavior in a temperature-log time diagram similar to what is found in transformation diagrams (Fig. 16). The long times in the upper temperature range are due to low thermodynamic driving force and in the lower temperature range to slow diffusion. Temper embrittlement can be removed by reheating the steel above 600 °C (1110 °F) followed by rapid cooling, for example, water quenching.

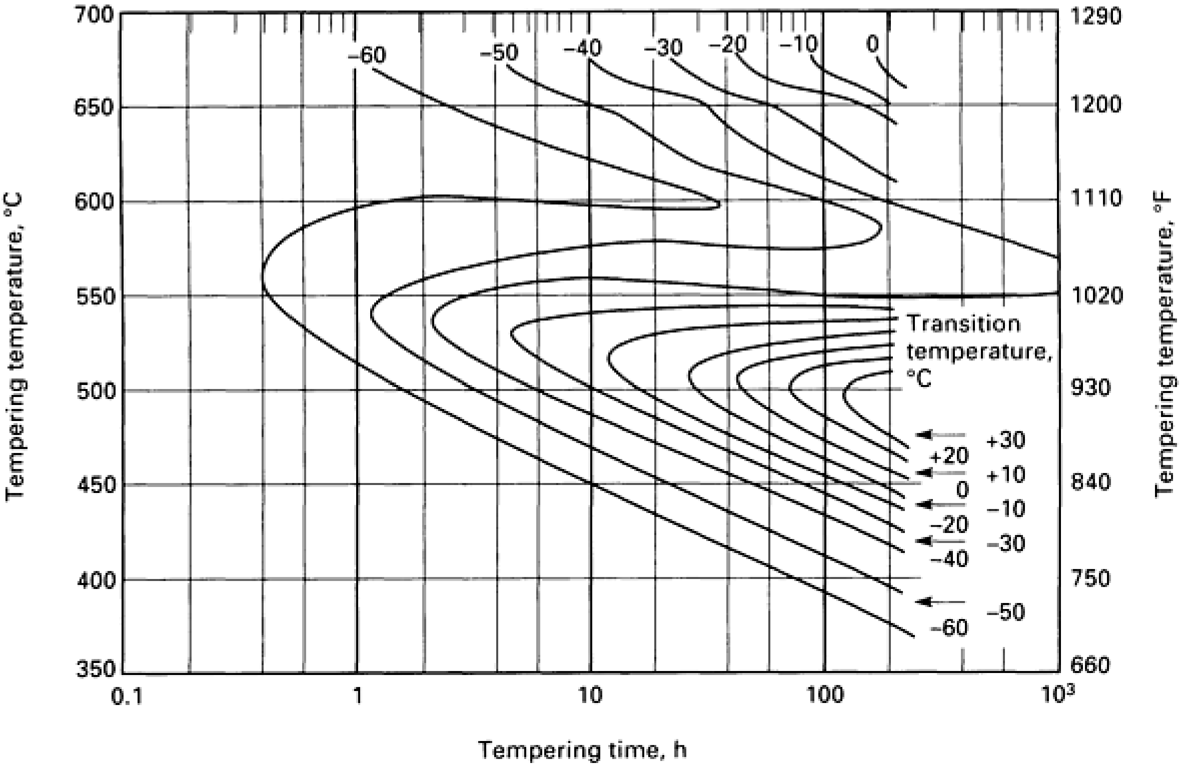

Fig. 16 Dependence of transition temperature on tempering temperature and time for SAE 3140 steel containing 0.40% C, 0.80% Mn, 0.60% Cr, and 1.25% Ni. Water quenched from 900 °C (1650 °F). Source: Ref 26

Another type of embrittlement that affects high-strength alloy steels is tempered martensite embrittlement (also known as 350 °C, or 500 °F, embrittlement), which occurs upon tempering in the range of 205 to 370 °C (400 to 700 °F). It differs from temper embrittlement in the strength of the material and the temperature exposure range. In temper embrittlement, the steel is usually tempered at a relatively high temperature, producing lower strength and hardness, and embrittlement occurs upon slow cooling after tempering and during service at temperatures within the embrittlement range. In tempered martensite embrittlement, the steel is tempered within the embrittlement range, and service exposure is usually at room temperature. Therefore, temper embrittlement is often called two-step temper embrittlement, while tempered martensite embrittlement is often called one-step temper embrittlement. Detailed information on both temper embrittlement and

tempered martensite embrittlement, including time-temperature diagrams for embrittled steels, can be found in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook* (see Ref 27).

Cooling Media and Quench Intensity

The depth of hardness at a given work-piece dimension is determined by the chemical composition of the steel, the austenite grain size as established during the austenitizing treatment, and the cooling rate. The steel is normally chosen on the basis of hardenability. The choice of cooling medium, on the other hand, is less exact and crude rules are normally applied (unalloyed steel is quenched in water, alloy steels in oil, and high-alloy steels in air). Molten salt is often used for bainitic hardening of medium-carbon steels and martempering of carburized parts (salt temperature above M_s for the case). Judicious selection of cooling medium is critical for obtaining optimum mechanical properties, avoiding quench cracks, minimizing distortion (to be discussed below), and improving reproducibility in hardening. Of most interest are the liquid quenching media, and they also show the most complicated cooling process. More detailed information on cooling (quench) media can be found in the article "Quenching of Steel" in this Volume.

Three Stages of Quenching. The most commonly used liquid quenching media are water and its solutions (brine and caustic solutions), oils, and polymer solutions. During the quenching of steel in liquid media, the process may be split up into the following three stages:

- The vapor blanket stage
- The boiling stage
- The convection stage

Figure 17 shows a typical cooling curve for an oil and at the same time shows what happens at the surface of a steel that is being quenched.

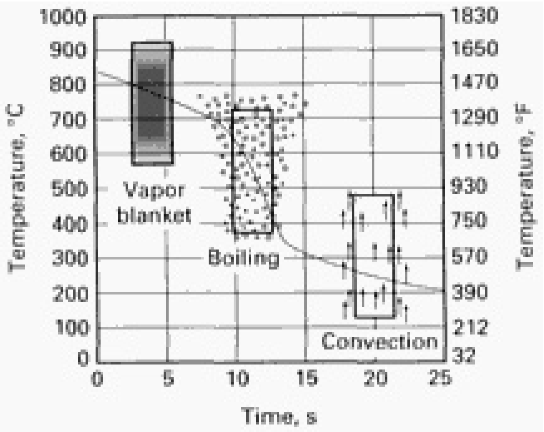

Fig. 17 The three stages of quenching. Source: Ref 19

In the vapor blanket stage the surface temperature is so high that the cooling medium is vaporized and a thin vapor is formed around the part. Heat transfer occurs by radiation through the vapor blanket, which thus acts as an insulating layer. The cooling rate is therefore low. The time duration of the vapor blanket stage can vary considerably among different cooling liquids and is also affected by the surface condition (for example, the presence of oxide scale) and how densely the work-pieces are loaded on the furnace tray.

The boiling stage starts when the surface temperature has decreased to the point where the heat of radiation does not sustain a stable vapor blanket. The liquid that is brought into contact with the hot surface boils immediately and vapor bubbles leave the metal surface and provide efficient heat transfer. This gives a high rate of heat extraction.

The convection stage starts when the surface temperature has decreased to the boiling point of the cooling medium. The heat transfer occurs by direct contact between surface and liquid. The cooling rate is low and is affected primarily by quench viscosity and convection rate.

Evaluating Quenching Media. There are a great number of different methods for evaluating quenching media. Frequently, a 12.5 mm diameter by 60 mm long (0.5 × 2.5 in.) cylinder (probe) made of a nickel-base alloy or stainless steel is used. A thermocouple is located at the center of the testing body and is connected to a recording instrument. Examples of such cooling curves are shown in Fig. 18. Of more interest in many situations is the cooling rate, also shown in Fig. 18, obtained by differentiation of the cooling curves. These types of curves are useful for comparison between quenching media and judging the condition of a certain medium. Earlier a silver ball, 20 mm (0.08 in.) in diameter, was employed as the probe. The cooling curves from such measurements are even more difficult to apply to hardness predictions because silver has very different thermal properties and the physical properties at the surface are not representative of steel.

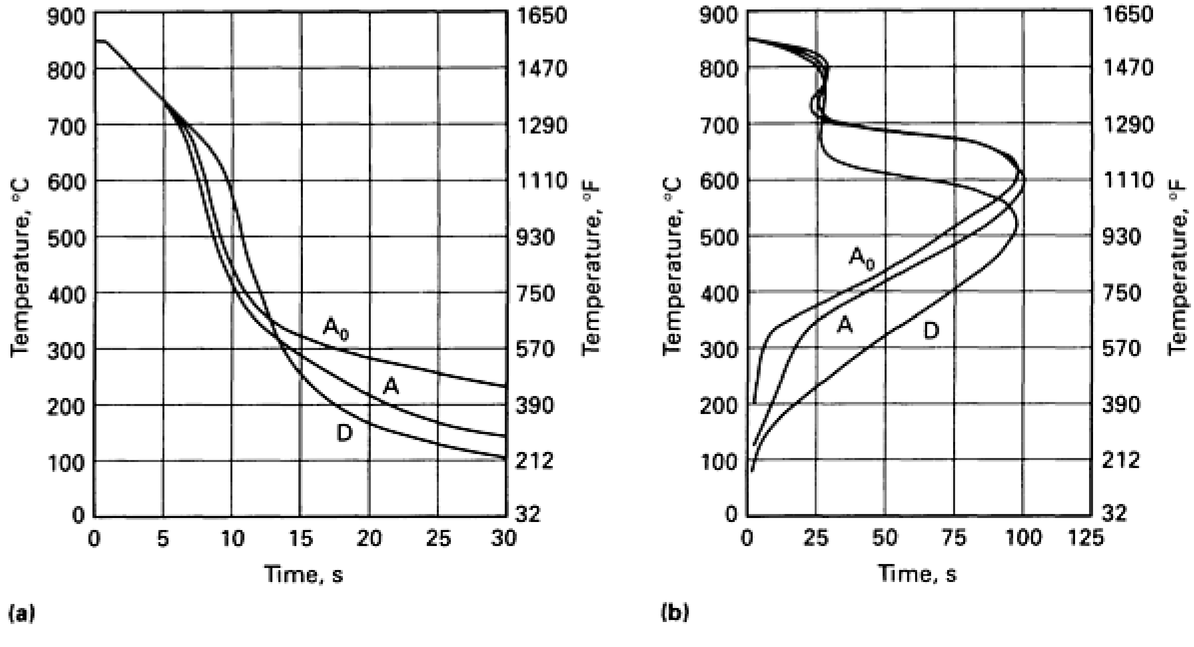

Fig. 18 Temperature-time curves (a) and temperature-cooling rate curves (b) obtained using an Alloy 600 probe. A and D are two oils with slight agitation, and A_0 is the oil A with no agitation. Source: Ref 28

Visual observations have shown that the breakdown of the vapor blanket starts at edges where the radius of curvature is small. The length of the test specimen can therefore affect the duration of the vapor blanket stage.

Figure 19 shows the temperature at different depths below the surface of an Inconel probe quenched in oil. This figure illustrates that the different quench stages are more pronounced closer to the specimen surface and that the resulting

temperature curves differ more from either linear or natural cooling curves. The conventional CCT curves must then be used with caution for hardening response predictions.

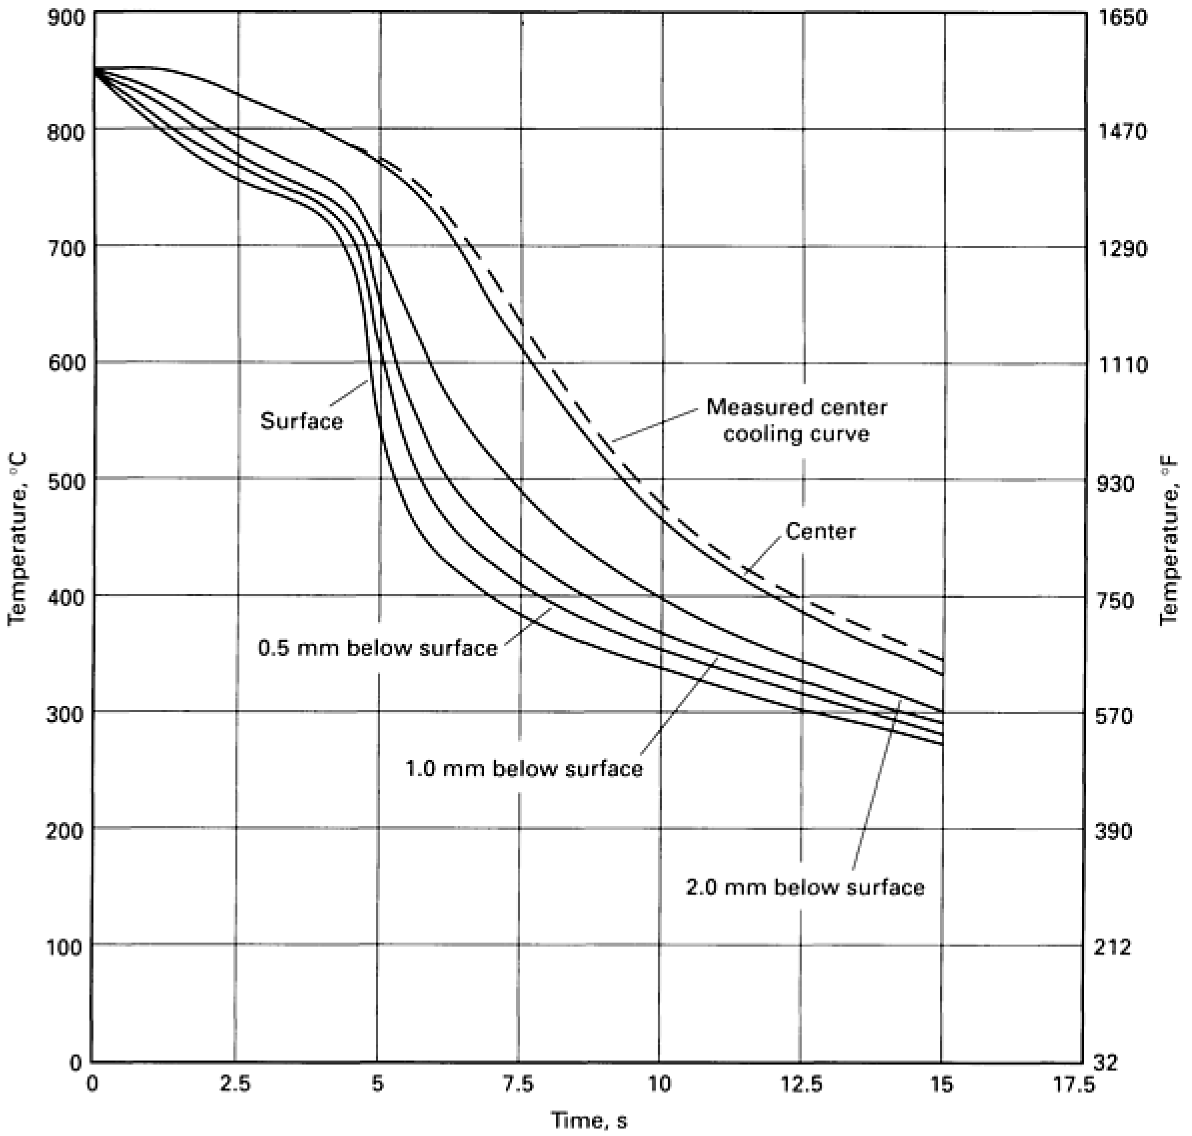

Fig. 19 Calculated cooling curves obtained using an Alloy 600 probe based on the heat flow curve in Fig. 20. Source: Ref 29

The curves in Fig. 19 are calculated using the temperature measured 2 mm (0.08 in.) below the surface. The calculation is based on the solution of the heat-flow equation. The experimental curve is assumed to be the boundary condition when determining the temperature-time history of the probe. The calculated temperature gradient through the surface is then employed to solve the heat transfer through the outer surface, which can then be expressed as a function of the surface temperature (Fig. 20). The heat-transfer function thus derived can be used to solve the heat-flow equation for the part of interest and to derive the temperature distribution in the part as a function of time, provided that the same state of quenching medium agitation prevails. A more accurate heat-transfer function is obtained if the experimental curve is measured closer to the surface. However, this is experimentally more difficult.

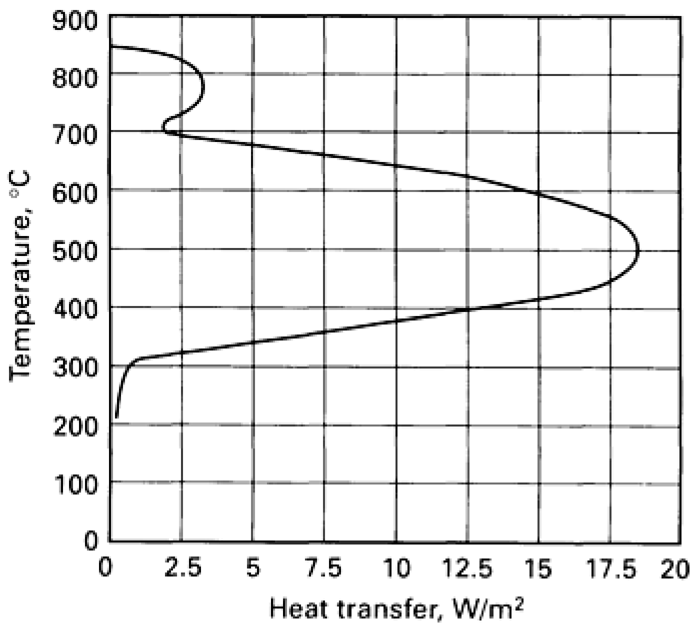

Fig. 20 Heat transfer as a function of surface temperature of the test probe used in Fig. 19. The curve is calculated from temperature measurements 2.0 mm (0.08 in.) below the probe surface. Source: Ref 29

In the classical literature, the quench severity concept, or the Grossmann number, is used. This is a single temperature independent value for each state of agitation of oil, water, and brines, respectively. It is a much cruder measure of the quench intensity than the heat-transfer function. The Grossmann number (*H*-value) is defined by $H = h/2k$, where h is the coefficient of heat transfer at the metal-quenchant interface and k is the thermal conductivity. See the article "Quenching of Steel" in this Volume for a more detailed discussion of the Grossmann number.

Very often it is stated that a short-lived vapor blanket stage will enhance the hardening result. This is not always correct as has been pointed out by Thelning (Ref 19). The most important consideration is the rate of cooling through the temperature ranges in which the diffusion-dependent transformations take place. Therefore, the characteristics of the steel must be considered at the same time as the quenching medium. It should also be noted that by adding certain organic substances to an oil or water quenchant, the cooling characteristics can be modified by extending the vapor blanket stage or delaying the transition from the boiling stage to the convection stage.

A more recently developed method is computer-controlled spray cooling (Ref 30). Using this technique, it is possible to program fast cooling past the pearlite nose on the CCT diagram, have a very slow cooling just above M_s, followed by a moderate cooling during the martensite transformation.

Thermal Stresses during and Residual Stresses after Heat Treatment

Heat treatment of steel, especially martensitic hardening, is usually accompanied by the evolution of large residual stresses, that is, stresses that exist without any external load on the part considered. Causes for such stresses include:

- Thermal expansion or contraction of a homogeneous material in a temperature gradient field
- Different thermal expansion coefficients of the various phases in a multiphase material
- Density changes due to phase transformations in the metal
- Growth stresses of reaction products formed on the surface or as precipitates, for example, external and internal oxidation

Residual stresses can be divided into three categories. A macroresidual stress is the average of the residual stress in many adjacent grains of the material. If a work-piece is cut or material is removed, the presence of macroresidual stress will cause a distortion. The introduction of macroresidual stresses into a workpiece by heat treatment or plastic deformation may also cause a distortion of the part. The pseudo-macroresidual stress is the average of the residual stress in many grains of one phase in a multiphase material minus the macroresidual stress. The microresidual stress in a part is the total residual stress minus the macroresidual and the pseudo-macroresidual stress. The residual stresses considered in this section are of the macrotype. Stresses that exist during the entire heat-treatment process will also be discussed in the following paragraphs.

The subject of residual stresses after heat treatment of steel has been studied extensively in the recent literature (Ref 31, 32, 33) and is also discussed in the article "Defects and Distortion in Heat-Treated Parts" in this Volume. The principle for the creation of thermal stresses on cooling is shown in Fig. 21 for a 100 mm (4 in.) diameter bar that was water quenched from the austenitizing temperature of 850 °C (1560 °F). The surface temperature (S) decreases more rapidly than the core temperature (C), and at time *w*, the temperature difference between the surface and core is at a maximum of about 550 °C (1020 °F). This means that the specific volume is greater in the core than in the surface. The volume contraction in the surface is prevented by the higher specific volume in the core. The thermal stress is approximately proportional to the temperature difference and is tensile in the surface and compressive in the core. Large thermal stresses are favored by low thermal conductivity, high heat capacity, and high thermal expansion coefficient. Other factors increasing the temperature difference and thermal stresses are large thickness dimensions and high-cooling intensity of the cooling medium. A large yield stress at elevated temperatures will decrease the degree of plastic flow and thus the residual stress, while the yield stress at the ambient temperature puts an upper limit on the residual stress.

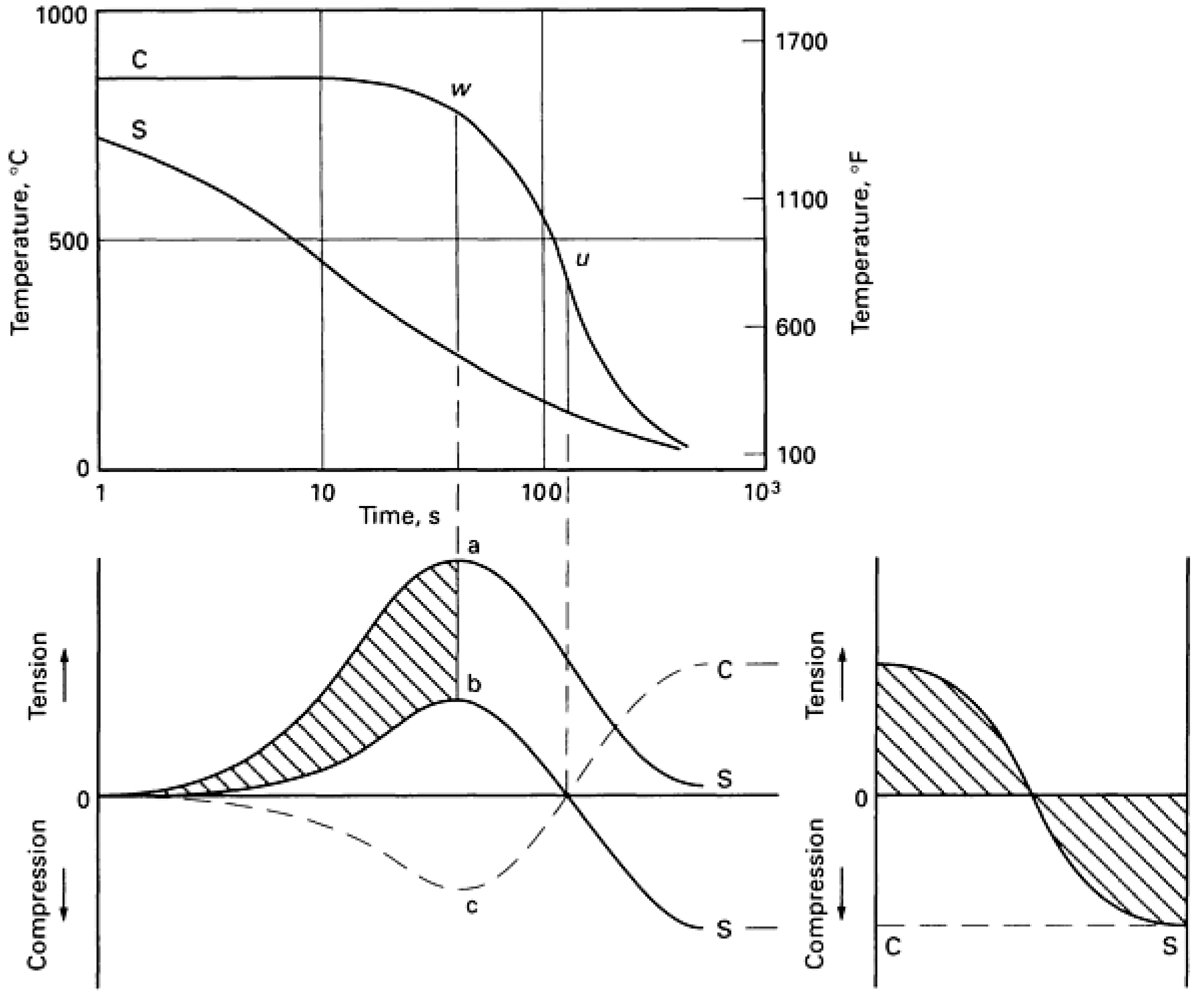

Fig. 21 Formation of thermal stresses on cooling in a 100 mm (4 in.) steel specimen. C designates the core, S the surface, *u* the stress reversal time instant, and *w* the time instant of maximum temperature difference. The top graph shows the temperature variation with time at the surface and in the core; the graph below shows the hypothetical thermal stress, a, which is proportional to the temperature difference between the surface and the core, the actual stress at the surface, b, which can never exceed the yield stress, and the actual stress in the core, c. To the right is shown the residual stress distribution after completed cooling as a function of the specimen radius. Source. Ref 33

The added effect of transformation of austenite to martensite in steel is demonstrated in Fig. 22. At time t_1, the surface temperature falls below the M_s temperature and the surface starts to transform. The surface expands and the thermal tensile stresses are counteracted. The stress reversal takes place earlier than when transformation stresses are not taken into consideration. At time t_2, the core transforms, causing another stress reversal. After cooling, transformation-induced tensile stresses at the surface dominate over the thermally induced compressive stresses.

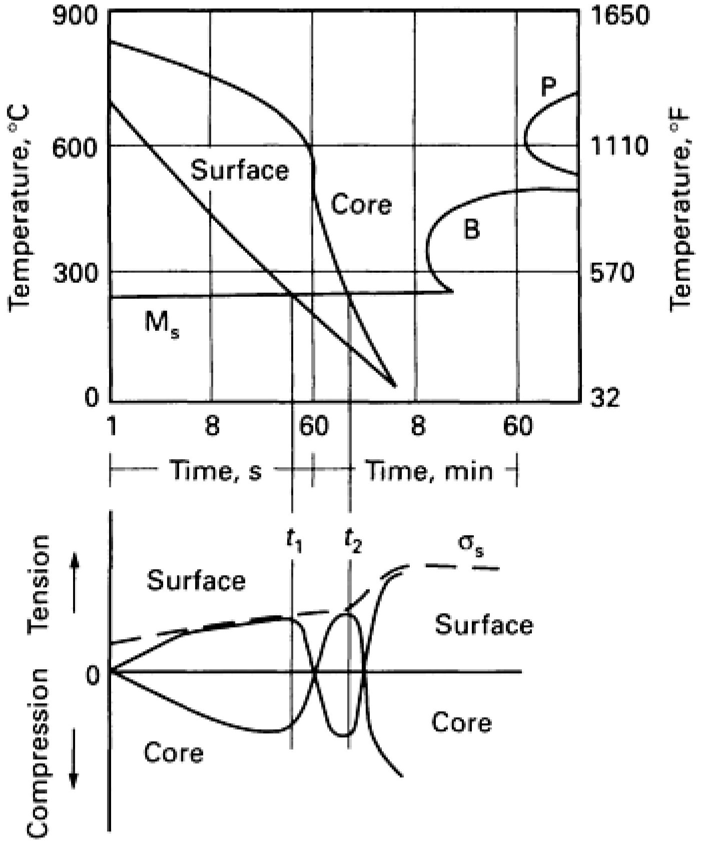

Fig. 22 Formation of residual stress on cooling considering thermal expansion and the austenite to martensite transformation. The dashed line is the yield stress, σ_s, at the surface. See text for details. Source: Ref 34

In order to predict hardening stresses quantitatively, it is necessary to consider interactions among various factors. As shown in Fig. 23, these include: (1) phase transformations, (2) latent heat, (3) thermal stress, (4) transformation stress and plasticity, (5) heat generation due to deformation, and (6) mechanically induced transformation. The most important of these are interactions 1, 3, and 5. Interaction 6, however, is also a very important factor. When discussing mechanically induced transformation, at least three different effects should be mentioned (Ref 36). The first is that the M_s temperature is decreased by hydrostatic pressure and raised by tensile stress (see Fig. 24, which shows an increase of ~15 °C (~27 °F) for a high-carbon steel). The second effect is the transformation plasticity, which is a permanent strain that occurs during an ongoing phase transformation under applied stress lower than the yield stress. It is displayed in Fig. 24 as an increase in the elongation from about 1% under an applied stress of 18 MPa (2.6 ksi) to 3% under 285 MPa (41 ksi) applied stress. The third effect is the incubation time of the nonmartensitic transformations, which is prolonged by hydrostatic pressure (Ref 37) and shortened by tensile stress (Ref 38). This is particularly important for large dimensions. It has also been shown that a separate steel sample that is inserted into a cylinder of the same hardenable steel (Carney-type test) has a higher hardness value than the material in the same position in a homogeneous steel cylinder. The inserted steel specimen has the same temperature history, but is not exposed to hardening stresses.

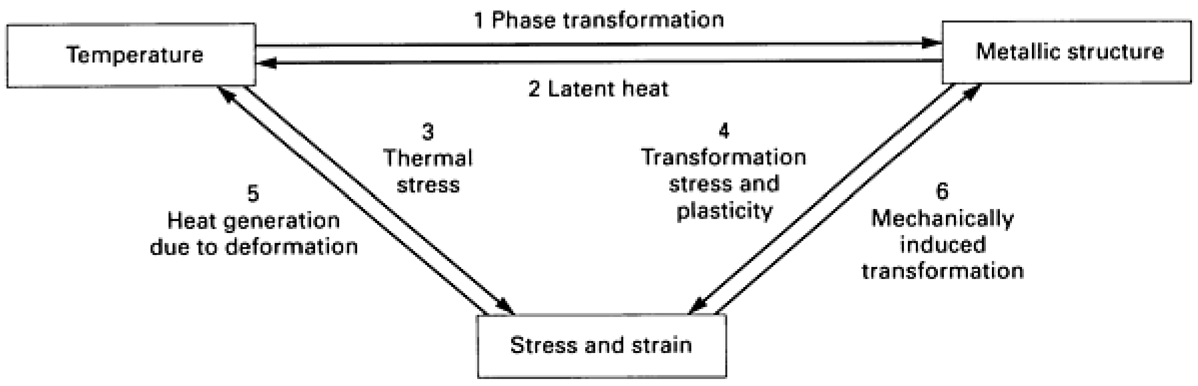

Fig. 23 The interactions between various factors of importance for residual stress generation. Source: Ref 35

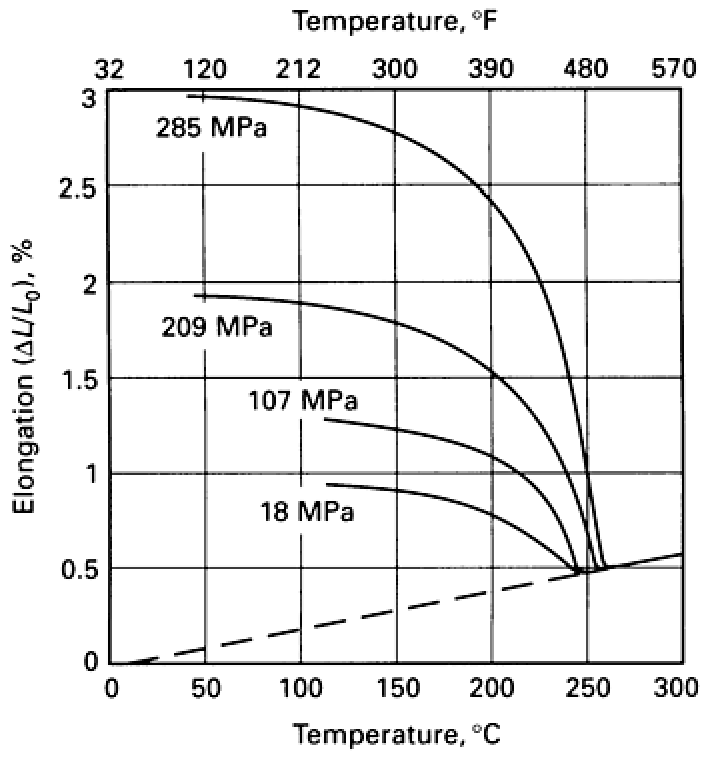

Fig. 24 Dilatometer curves for a steel with 0.6 wt% C for different applied tensile stresses. Source: Ref 36

Through Hardening. A series of computer calculations for a 50 mm (2 in.) diameter 0.6 wt% low-alloy steel cylinder illustrating the stress variation with time and the effect of the cooling medium (that is, the heat-transfer function) are shown in Fig. 25. In Fig. 25, which shows quenching in 20 °C (70 °F) oil, the transformation takes place well after the stress reversal in both surface and core. Some slight plastic deformation occurs in the surface in connection with the surface transformation, but otherwise the behavior is elastic. The effect of the transformation on the residual stress distribution is very slight. Quenching in 20 °C (70 °F) water is shown in Fig. 26. The transformation of the surface occurs before the stress reversal and transformation of the core occurs well after the stress reversal. The surface transformation helps to push the surface stress rapidly into compression, and compression yielding occurs. Before the core transformation, the core deforms plastically. With the onset of the core transformation, the tensile stress in the core is decreased, and the resulting deformation is elastic.

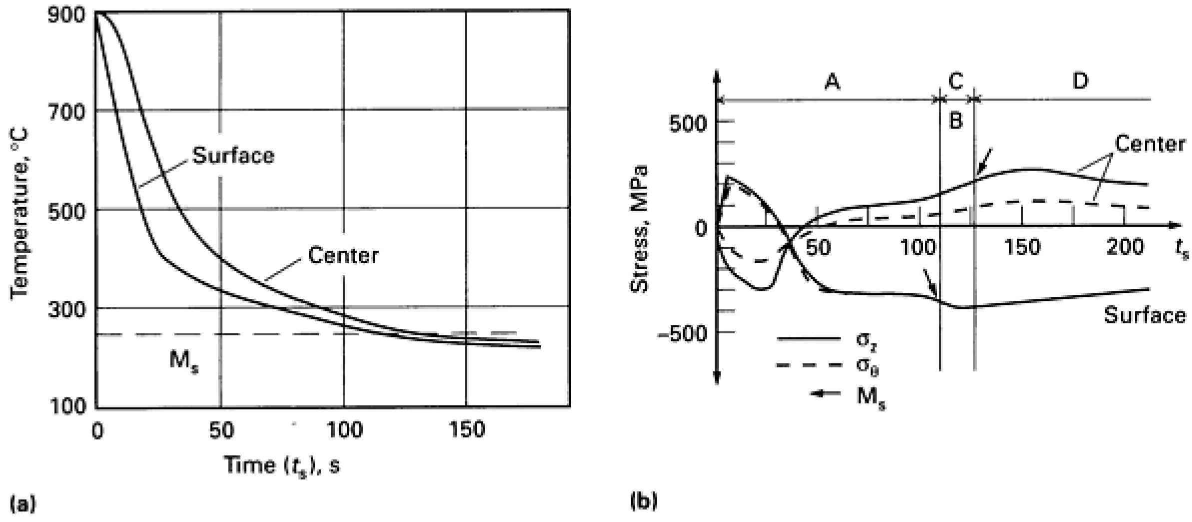

Fig. 25 Temperatures (a) and calculated stresses (b) in a long 0.6 wt% C low-alloy steel cylinder with 50 mm (2 in.) diameter quenched in 20 °C (70 °F) oil. In region A, the temperature is above M_s; in region D, it is below M_s. In region C, B, the temperature is above M_s at the center, but below M_s at the surface. σ_z, axial stress; $\sigma\theta$, tangential stress. Source: Ref 39

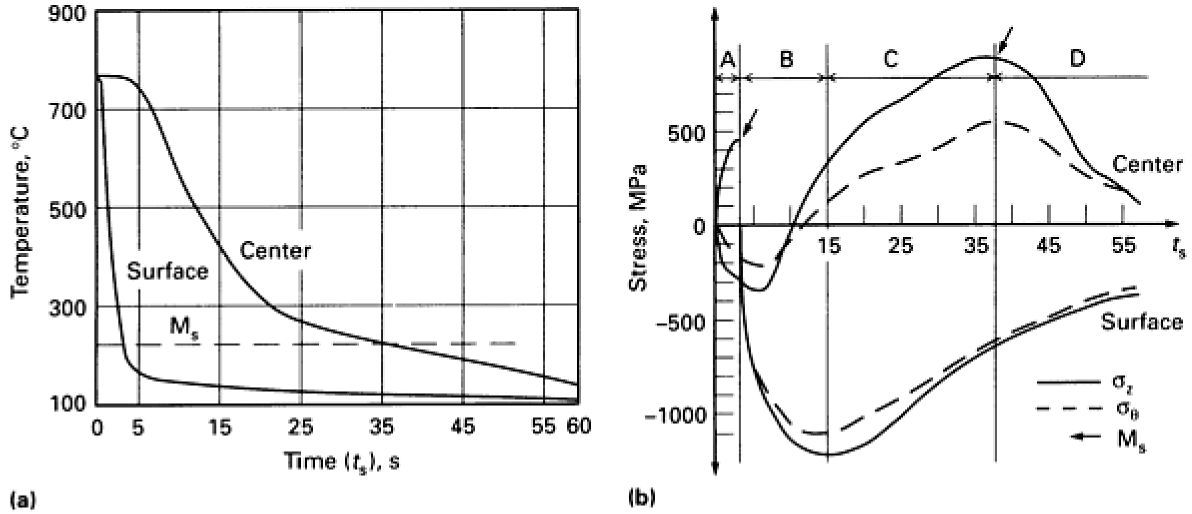

Fig. 26 Same type of diagram for the same steel and cylinder as in Fig. 25, but the specimen is quenched in 20 °C (70 °F) water. The final microstructure is completely martensitic. Source: Ref 39

In these calculations, the transformation plasticity was not considered. Figure 27 shows that it is important to include this effect in order to obtain the best agreement with measured residual stress values.

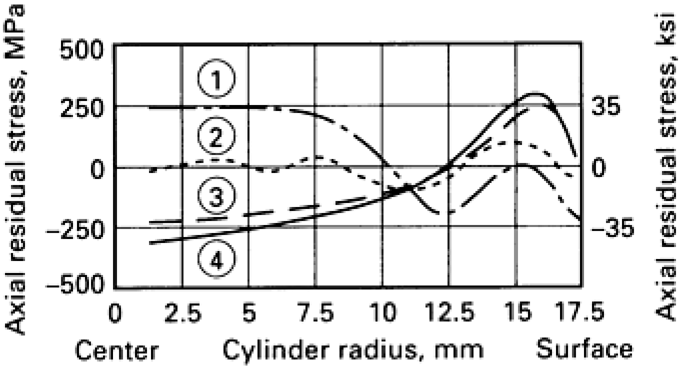

Fig. 27 Calculated residual axial stress profiles after martensitic quenching of a 0.6 wt% C low-alloy steel in 20 °C (70 °F) water. Curve 1: the effect of internal stresses on the kinetics of martensitic transformation. Curve 2: calculated without stress/transformation interactions. Curve 3: calculated with transformation plasticity alone. Curve 4: calculated with both stress and transformation effects considered. Source: Ref 36

Another series of calculations has been made to study the effect of cylinder diameter and cooling medium on residual stresses in 1045 steel. In the case of oil, ferrite-pearlite mixtures are formed; during water quenching, martensite and bainite are also formed. Figure 28 shows the stress development during water quenching. The 10 mm (0.4 in.) diameter cylinder starts to transform to martensite at the surface and the transformation front moves gradually inward resulting in a typical tensile stress at the surface. The large-diameter cylinders first transform to ferrite-pearlite at intermediate radii and then to martensite at the surface. This causes two stress minima seen in the dashed curves in Fig. 28(a), (b), and (c). The final residual stress is compressive at the surface and tensile in the core. Good agreement was obtained with x-ray stress measurements in several cases, as well as with older mechanically measured data. The dependence on specimen diameter and quenching medium is summarized in Fig. 29. The difference between oil and water quenching decreases with increasing diameter.

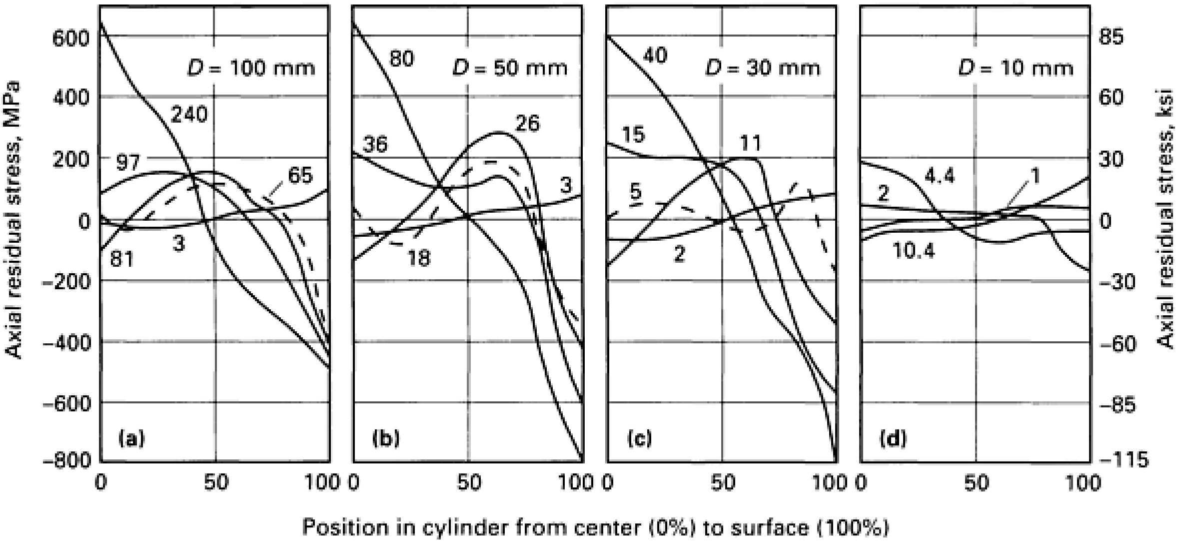

Fig. 28 Axial residual stress distributions for various AISI 1045 steel cylinder diameters, *D*, at selected times (in seconds) after the start of quenching from 850 °C (1560 °F) in 20 °C (70 °F) water. The final microstructure of the 10 mm (0.4 in.) diameter cylinder is completely martensitic, while the others have a ferritic-pearlitic core. Source: Ref 40

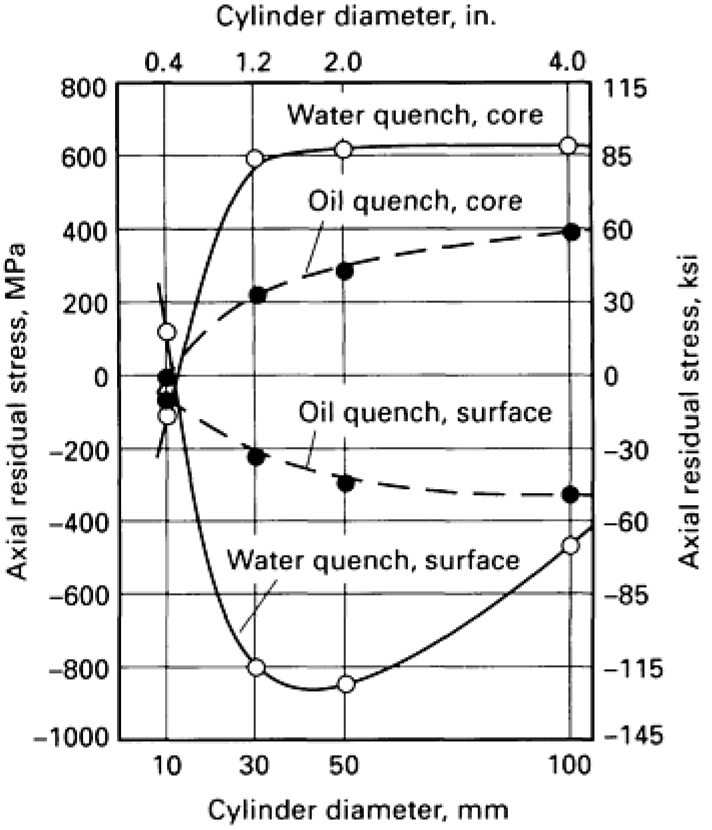

Fig. 29 The dependence of axial residual stresses on cylinder diameter. Same steel as in Fig. 28. The core is martensitic for 10 mm (0.4 in.) diameter, but ferritic-pearlitic for larger diameters. Source: Ref 40

Case hardening (that is, carburizing and quenching) is a rather complicated process. During the carburizing stage at about 900 °C (1650 °F), carbon diffuses into the steel from the surrounding environment, most often as a gas mixture. The carburizing takes several hours, and usually the temperature is lowered 50 to 100 °C (90 to 180 °F) for about one hour before quenching to reduce the risk of distortion. It is reasonable to assume that the material is stress-free when the quenching takes place.

Figure 30 shows the development of the residual stresses during the case hardening of a 17 mm (0.70 in.) diameter cylinder with a carburizing depth of 1 mm (0.04 in.). The onset of martensite formation can clearly be seen below the surface where, due to the combination of temperature and carbon content, the M_s is first attained. The transformation to martensite then moves toward the surface and the transformation to bainite moves toward the core. The transformation of austenite at the surface occurs very late and some retained austenite remains. The residual stress is first tensile at the surface due to thermal effects. The stress is shifted in the compressive direction where the martensite has formed, and simultaneously the tensile stresses are increased near the surface in the untransformed austenite as a compensating effect. Under these conditions, the hard and brittle martensite is never exposed to tensile stresses.

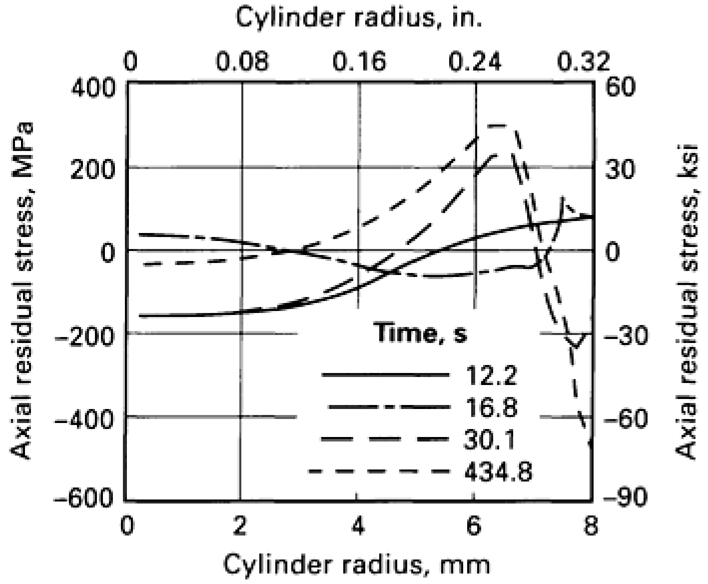

Fig. 30 Calculated axial residual stress for various times following the start of quenching after carburizing a 17 mm (0.70 in.) diameter cylinder made of AISI 3138 steel. Source: Ref 41

The final residual stress distribution has its minimum slightly below the surface. This is due to the presence of retained austenite near the surface. The position of the residual stress minimum occurs approximately at 50 to 60% of the total case depth corresponding to a carbon concentration at a position where the case carbon content is 0.5 wt% C. Below the hardened case, the residual stress may show a tensile peak.

This type of computer prediction can give good agreement with experimentally measured residual stress distributions (Fig. 31). The observed tensile stress at the surface is due to the presence of a soft pearlitic layer caused by the slight internal oxidation of the alloying elements chromium and molybdenum, which has reduced the hardenability of the surface layer. This reduction in hardness can be included in the calculations by adding a transformation diagram relevant to this surface layer (Ref 42).

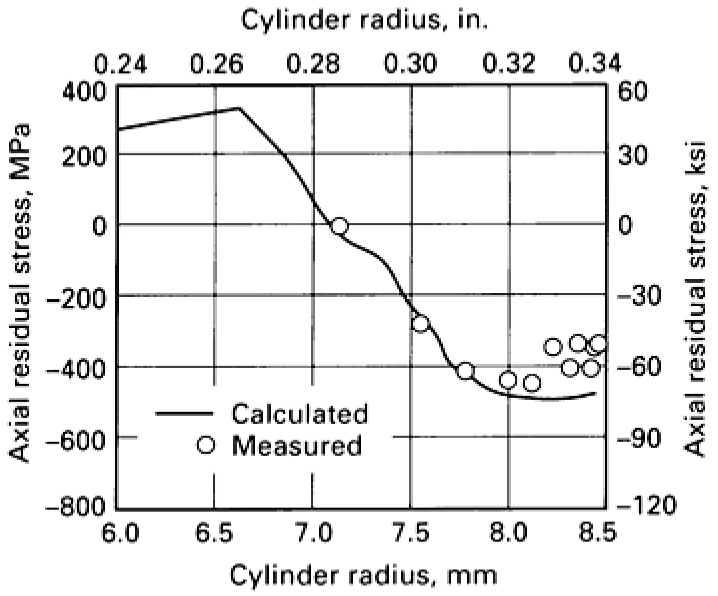

Fig. 31 Calculated and measured axial residual stress for a 17 mm (0.70 in.) diameter cylinder made of AISI 3138 steel. Source: Ref 41

With access to a good computer model, the effect of a number of variables, such as increased base carbon content, different cooling medium, and higher or lower base hardenability, can be studied. Increased base carbon content does not affect the magnitude of compressive stress significantly but the tensile peak below the case disappears. A more intense cooling medium like water instead of oil changes the compressive residual stress value to a higher value of 600 MPa (87 ksi) compared to 500 MPa (73 ksi), but does not increase the depth of the compressed layer.

Induction hardening is more complicated than carburizing. Both the heating stage as well as the cooling stage have been calculated (Ref 43). Static, or single-shot induction hardening, can be distinguished from progressive induction hardening. Using the single-shot method, a multiturn coil totally surrounds the area to be hardened; using the progressive technique, the workpiece and a single-turn coil are moved relative to each other. The single-shot method is more readily calculated and will be described here.

To calculate the heating during induction hardening, the magnetic field equation must be solved and the magnetic permeability, μis determined. A function fitted to experimental curves is:

$$m = \frac{a}{b + H} + c \qquad \textbf{(Eq 7)}$$

where a, b, and c are constants and *H* is the magnetic field strength. The electrical resistivity must also be determined as a function of temperature and phases present.

Quenching by a water spray requires experimental data for the corresponding heat-transfer function. For the description of the transformation to austenite from the starting structure, an isothermal diagram for heating (ITh diagram) is needed. To describe the transformation behavior during the subsequent cooling, an IT diagram representative of a short austenitizing time is necessary. The austenitizing time during induction hardening is normally less than one minute. This means that carbide dissolution has little time to take place, and therefore the type and distribution of carbides in the starting structure are important. It is well known that structures with fine carbides harden to greater depths than structures with coarse carbides.

Calculated values for single-shot induction hardening of a 4140 steel specimen are shown in Fig. 32. Experimentally measured residual stresses for the same steel are compared with the calculated values in Fig. 33. In Fig. 32(a), the evolution of the temperature with time at different depths is shown. It is clearly seen that the heating rate decreases at the Curie temperature and that the transformation to austenite absorbs heat (constant temperature at the surface between 10 and 20 s). A brief air cooling step is followed by water spraying. The final martensite distribution is shown in Fig. 32(b). The evolution of the stress versus depth at different times and stress versus time for different depths is shown in Fig. 32(c) and (d), respectively. At the outset, the stress becomes compressive in the heated zone, but is shifted in the tensile direction when the austenite formation sets in. Only the axial stress component is shown in Fig. 32 and 33.

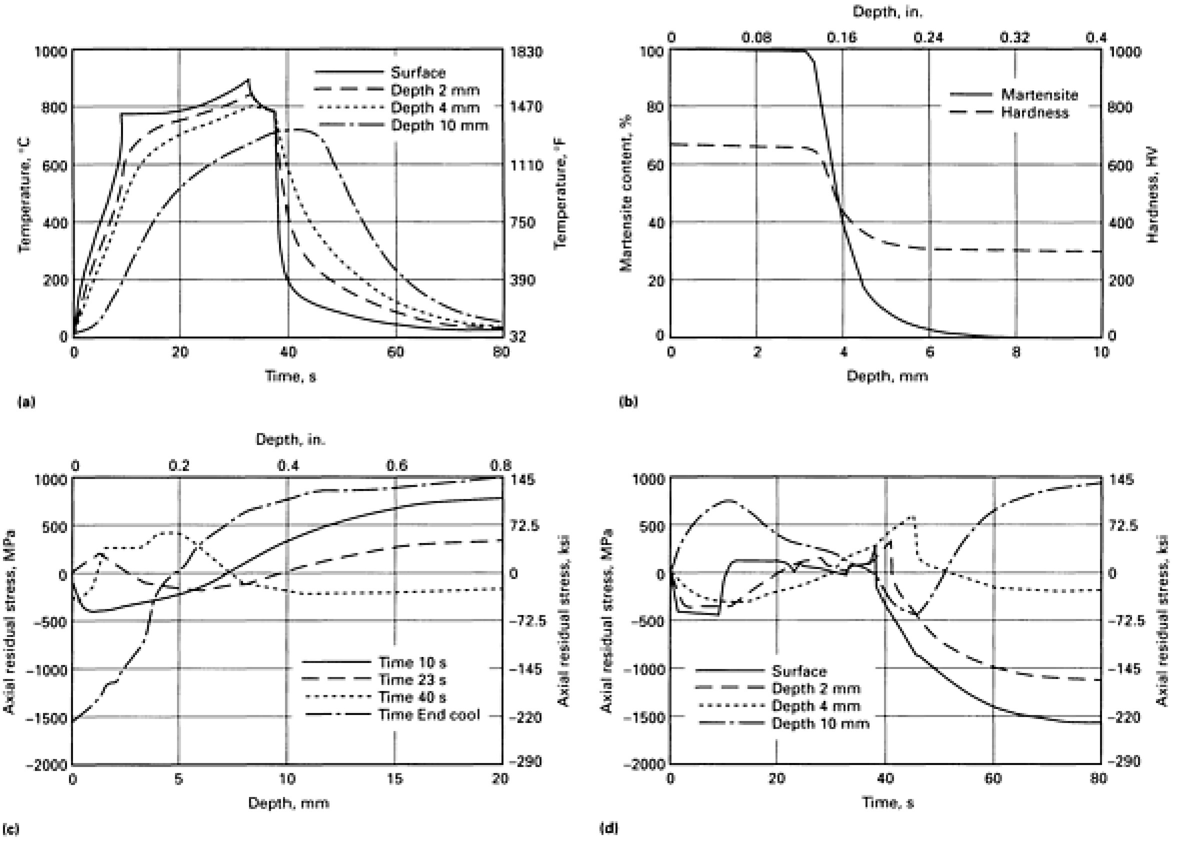

Fig. 32 Calculated values for single-shot induction hardening of a 40 mm (1.6 in.) diameter cylinder made of AISI 4140 steel. Induction frequency: 300 kHz. (a) Temperature versus time for different depths. (b) The final martensite and hardness distributions. (c) Axial residual stress versus depth at different times. (d) Axial residual stress versus time for different depths. Source: Ref 43

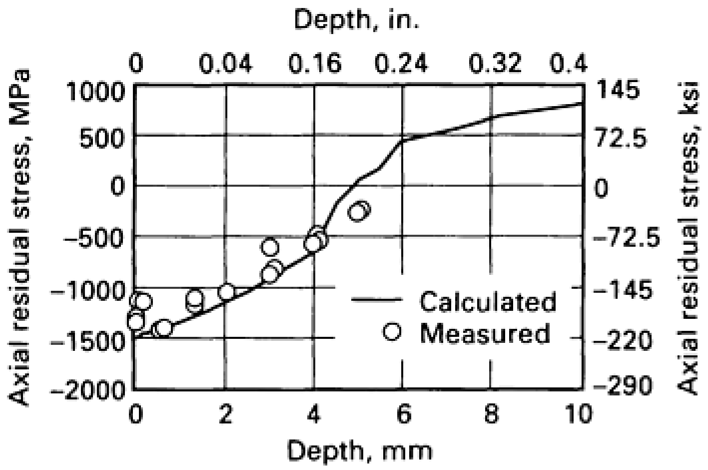

Fig. 33 Calculated and experimental axial residual stress after induction hardening versus depth for a 40 mm (1.6 in.) diameter steel specimen made of AISI 4140 steel. Source: Ref 43

The computer predictions are reasonably good as can be seen in Fig. 33. The experimental data show a smaller compressive stress at the surface than is predicted. The effect of variables such as the quenching medium and the ITh diagram has also been taken into consideration. Figure 34(a) shows how the hardening depth is increased when the transformation to austenite at elevated temperature occurs more easily. The different transformation rates can be due to different steel compositions or to different prior microstructures of the same steel. The cooling is rapid enough to transform all austenite that has formed to martensite and the residual stress distribution is only affected slightly as shown

in Fig. 34(b). If the water spray is replaced by oil quenching, the calculation shows that the magnitude of the compressive stress peak is reduced while the hardening depth is the same because the depth of austenitization is the same.

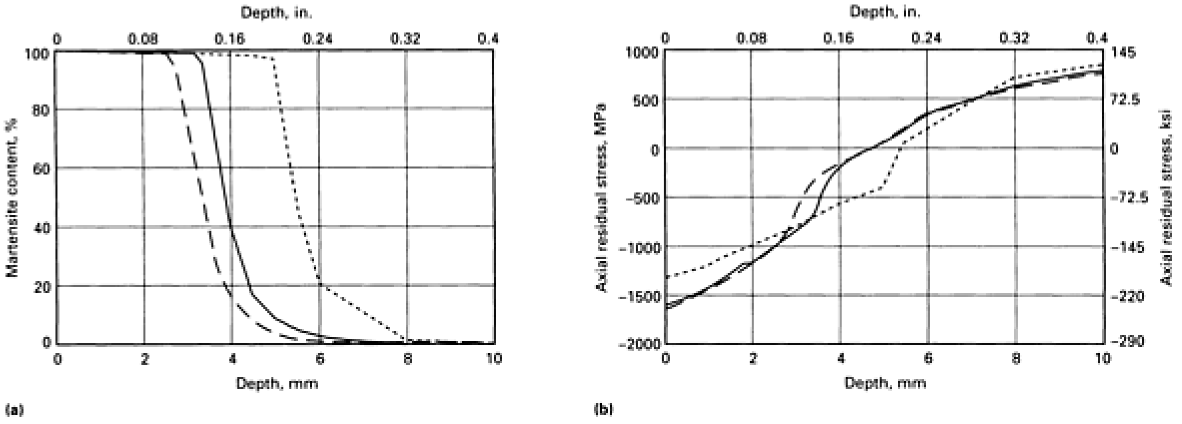

Fig. 34 Calculated values of martensite distribution and residual stress after induction hardening of a cylinder with a 40 mm (1.6 in.) diameter. The solid curve is calculated using the ITh diagram in Fig. 4, and the two others are hypothetical displacements of this diagram to shorter and longer times, respectively. This can illustrate the effect of different prior microstructures or different steel compositions. (a) Final martensite distribution. (b) Axial residual stress profiles for the three cases in (a). Source: Ref 43

Cracking and Distortion due to Hardening. There is a risk for cracking of a workpiece if large tensile stresses, transient or residual, are combined with the presence of a brittle microstructure (particularly martensite). Thermal stresses during cooling generally increase with the size of a workpiece. For phase transformation-induced stresses, geometric dimension, hardenability of the steel, and quench intensity interact in a complicated manner as has been described in earlier paragraphs. However, as a general rule it holds that the use of a more efficient cooling medium, for example, water as compared to oil, will lead to larger stresses as demonstrated in Fig. 25, 26, and 29. The presence of geometric stress raisers increases the risk of cracking.

Figure 22 indicates that tensile stresses are present at the surface when the surface transformation to martensite is complete and the core transformation is in progress. As such, there is the risk of surface cracking. However, it is shown in Fig. 25 and 26 that through hardening does not necessarily lead to tensile stresses at the surface. In case hardening, surface cracking is not to be expected (see Fig. 30, 31, and 33).

Large tensile stresses in the core at lower temperatures may lead to center cracks even if the microstructure is not martensitic. Figure 29 shows that such a situation exists for larger diameter cylinders with a martensitic surface and a ferritic-pearlitic core. Case hardening may also lead to core cracking.

Hardening is usually accompanied by distortion of a workpiece. The degree of distortion depends on the magnitude of the residual stresses. Hardening procedures that minimize transient and residual stresses are beneficial as well as the use of fixtures (press hardening). Distortion can also occur during tempering or annealing due to release of residual stresses or phase transformations during tempering as described previously in this article.

Introduction

HARDENABILITY STEELS, or H-steels, offer a wide range of mechanical properties that depend on the development of tempered martensite after quenching and tempering. Typical room-temperature properties of quenched and tempered steels can vary as follows:

- Hardness values of 130 to 700 HV (30 kgf load)
- Tensile strengths of 400 to 2000 MPa (58 to 290 ksi)
- Yield strengths of 300 to 1800 MPa (43 to 261 ksi)
- Elongation of 8 to 28% in 50 mm (2 in.)

This broad range of properties depends on the maximum (as-quenched) hardness and the degree of softening (tempering) after quenching.

The maximum (100% martensite) hardness of heat-treated steel depends primarily on the carbon content (Table 1), until carbon levels reach about 0.50 wt%. Above 0.50 wt%, carbon has little effect on hardness but does improve hardenability. Alloying elements have little effect on the maximum hardness that can be developed in steel, but they profoundly affect the depth to which this maximum hardness can be developed in a part of specific size and shape. Thus, for a specific application, one of the first decisions to be made is what carbon level is required to obtain the desired hardness. The next step is to determine what alloy content will give the proper hardening response in the section size involved. This is not to imply that tempered martensitic steels are alike in every respect, regardless of composition, because the alloy content is responsible for differences in the preservation of strength at elevated temperatures; in abrasion resistance; in resistance to corrosion; and even, to a certain extent, in toughness. However, the similarities are sufficiently marked to permit reasonably accurate predictions of mechanical properties from hardness rather than from composition, thereby justifying the emphasis on hardenability as the most important function of the alloying elements. The basic effects of alloying elements on hardening are described in the article "Principles of Heat Treating of Steels" in this Volume.

Table 1 Steel hardness for various carbon contents and percentages of martensite for some low-alloy steels

Carbon, %	Rockwell C hardness (HRC) with martensite contents of:

	50%	**80%**	**90%**	**95%**	**99.9%**
0.18	31	35	37.5	39	43
0.23	34	37.5	40.5	42	46

This article is primarily concerned with computer-assisted prediction of steel hardening and hardenability as a function of heat treatment parameters. In this regard, the two main measures of steel hardening are the Jominy end-quench hardenability curves and the continuous cooling transformation (CCT) curves. The intended focus is to outline the uses and limitations of computer modelling for the prediction of steel hardness profiles after quenching. Quantitative modelling of properties after tempering is also briefly discussed in this article and in the article "Computerized Properties Prediction and Technology Planning in Heat Treatment of Steels" in this Volume.

When considering any quantitative prediction of steel hardening, it is important to first recognize the inherent limitations of even well-established empirical data such as Jominy end-quench hardenability curves. For example, Fig. 1 and 2 show sets of Jominy curves selected from a large international set for 8620 carburizing steels and deep-hardening 4140 automotive steels of almost the same nominal composition and grain size (Ref 1). Such discrepancies could be attributed to incorrectly reported chemistry, careless test procedures, and/or unreported or uncontrolled process variables. Likewise, CCT curves also conceal comparable empirical errors because fractions transformed and cooling histories are incompletely determined or ambiguous, and these deficiencies can be expressed alternatively as an uncertainty in the time scale of the superposed cooling curves of factors reaching as high as four (Ref 2, 3). Notwithstanding the empirical difficulties, it is our aim to illustrate that sufficiently quantitative predictions can be attained so as to sustain reliable selection, improved quality control, cost optimization, on-line decision-making, and reduction of costly testing.

Relationship between IT, CCT, and Jominy Curves

Jominy curves and CCT curves are closely related as indicated in Fig. 3 for a eutectoid steel (Ref 4). Here the CCT curve has been derived from the isothermal transformation (IT) diagram by one of the methods to be described later. This construction gives more than a hint as to how one might proceed to develop a mechanical property predictor for arbitrary shapes and quench media from a fundamental theory of isothermal transformation (Ref 5, 6, 7). Figure 4 presents a schematic description of a recent semi-empirical, finite element computer program (Ref 8) which claims to predict the full course of a continuous cooling transformation, including the development of residual stresses and dilatation. This illustrates the complex interplay of thermal and deformation physics, multicomponent thermodynamics, and phase transformation kinetics which relates a room-temperature stress and hardness distribution to the geometry, thermal treatment, and chemistry of a part. Other programs for predicting residual stresses after quenching are discussed in the articles "Principles of Heat Treating of Steels" and "Computerized Properties Prediction and Technology Planning in Heat Treatment of Steels" in this Volume.

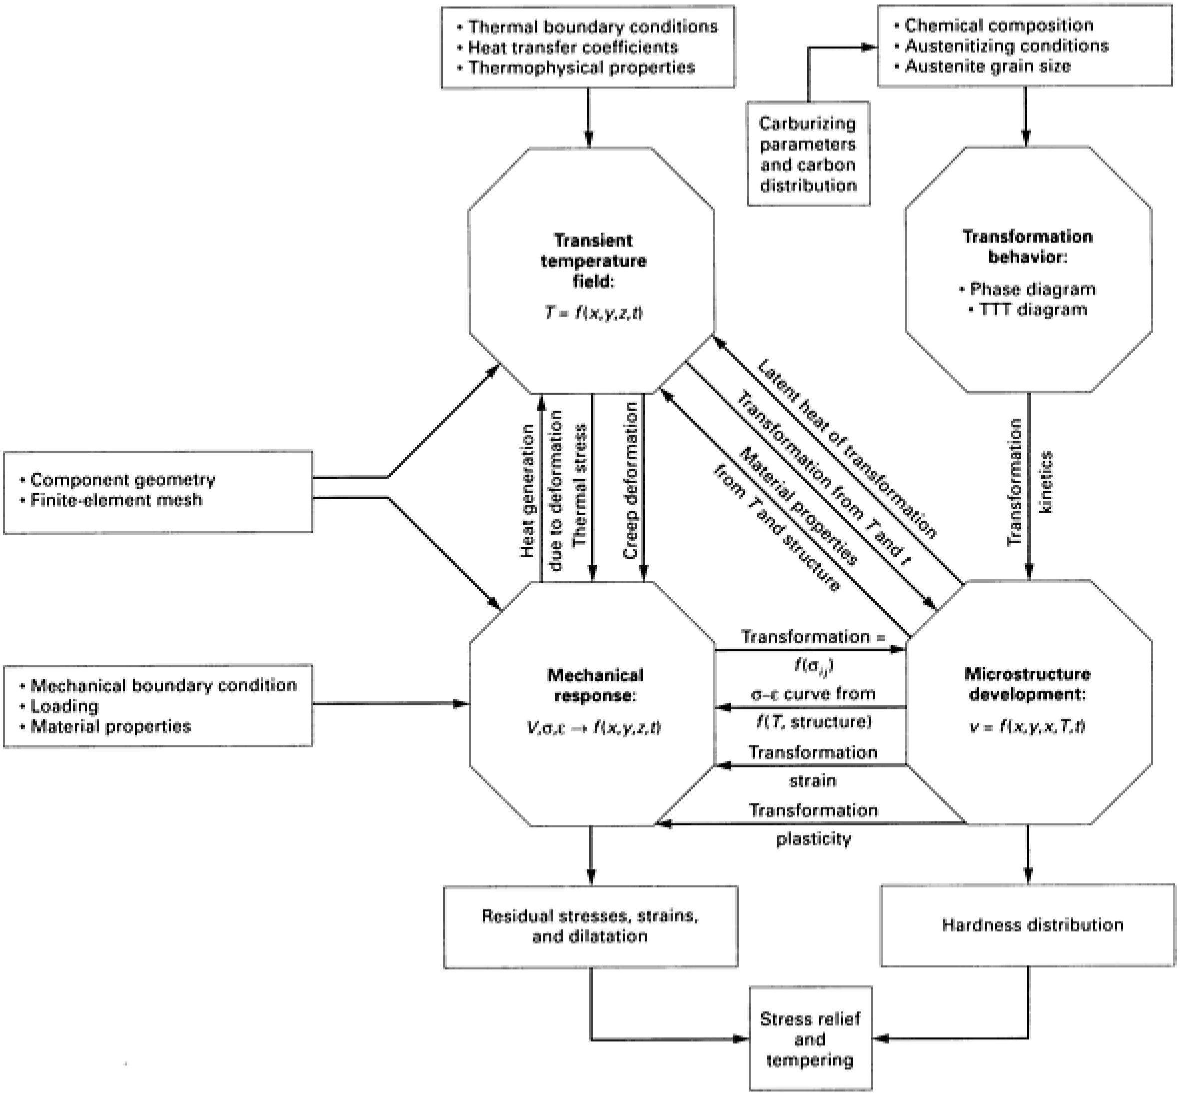

Fig. 4 General system overview of a program to predict the thermomechanical behavior of low-alloy steels. Source: Ref 8

The key assumption in this kind of development is that an IT prediction, empirically calibrated against a metallographic data set, defines an integrating factor over time and temperature through which the CCT curve can be directly calculated (Ref 9). Approximately equivalent information could be drawn from a large empirical set of CCT diagrams suitably interpolated and adjusted for varying geometry and cooling histories. The shape of CCT curves depends on the detailed shape of the cooling curves for the part being considered and therefore on the nature of the quenchant.

Unlike an IT diagram (Fig. 5), a CCT diagram is only unique to a particular composition and grain size if in the measurement the cooling rate at every depth in the test specimen was constant (Ref 9). It is at best a very crude approximation to apply a universal CCT diagram evaluated with constant cooling rates to a particular part by superposing natural or approximately exponential cooling curves upon the diagram. Newton's law of cooling, which applies to many fluid quenching or air-cooling situations, exhibits such decelerated or exponential cooling.

Quantitative Aspects of IT and CCT Curves

This section examines in detail the empirical and theoretical record for defining quantitative information on IT and CCT curves. This could be made part of an "expert" system, since probabilistic judgments based on ancillary subjective

information also play an essential part in quality control and design. Expansion of the system to deal with carburizing, tempering, and related processes is briefly discussed in subsequent sections of this article.

The international set of experimental CCT curves consists of some 1000 diagrams of highly varying quality. The smallest and most definitive set has been determined by precision metallography of sequentially quenched specimens according to natural cooling regimes (Ref 10). The largest set has been determined by dilatometry at mostly constant cooling rates (Ref 2, 3) with a necessary ambiguity in interpretation as to relative volume fraction of constituents (compare Fig. 5). Another less definitive set has been obtained by substituting hardness testing for metallography after sequential quenching (Ref 4). A rather complete compendium of sources is given in Ref 3, and in Ref 4, p 105 and 106. The simplest of information systems would be a complete compilation of the CCT curve subsets in computer memory, and upon specification of a new composition and grain size, each subset would be searched for close chemical correspondence; then three or more diagrams possessing cautionary statements would be presented graphically for inspection. In principle, interpolation formulas could also be developed for more explicit access. Atkins shows how outputs can be formatted with cooling rate data (Ref 11) to provide practical design and quality control information which is convenient (Fig. 6).

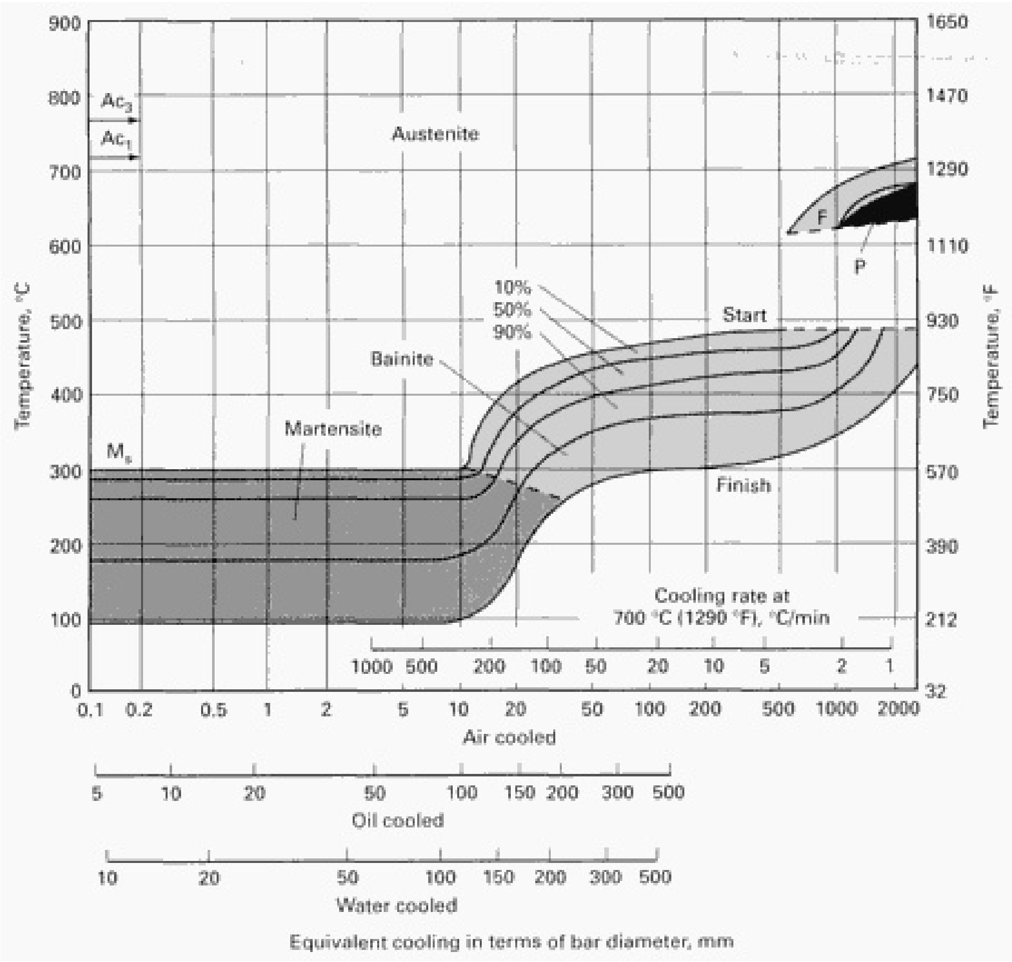

Fig. 6 CCT diagram for an alloy steel with 0.40% C, 1.50% Ni, 1.20% Cr, and 0.30% Mo, plotted as a function of bar diameter. Steel was austenitized at 850 °C (1560 °F); previous treatment: rolling, then softening at 650 °C (1200 °F). Source: Ref 4

An alternative to interpolation on a complete data set is to systematize a part or all of the data of a self-consistent subset according to linear regression formulas. A nonproprietary set of this kind has been developed by Creusot-Loire (Ref 3) in France based on approximately 200 dilatometrically determined, mainly constant cooling rate diagrams. Note that such a small data set can at best effectively span a matrix of 3 carbon levels, 3 manganese levels, 2 Si levels, 3 Ni levels, 2 Cr levels, 2 Mo levels, and one grain size ($3 \times 3 \times 2 \times 3 \times 2 \times 2 \times 1 = 216$) which falls far short of a precision analysis. As described in the following discussion on the Creusot-Loire system, the addition of two theoretical approximations ameliorates the situation somewhat. Here the interest is in room-temperature microstructure and hardness of low-alloy steels. It was found to be sufficient to systematize the data set by recording critical cooling rates at 700 °C (1300 °F) (or the average between 500 to 800 °C, or 930 to 1470 °F) for selected percentages of martensite, bainite, and pearlite-ferrite

(Fig. 7) and expressing these through linear regression analysis as a function of composition and austenitizing temperature. Relative volume fractions according to cooling rates are then found by interpolation and hardnesses through empirical formulas and a law of mixtures. Eleven numerical formulas are involved in the predictive algorithm. The numerical system recommended by the author is described below in "The Creusot-Loire Systematization of CCT Curves."

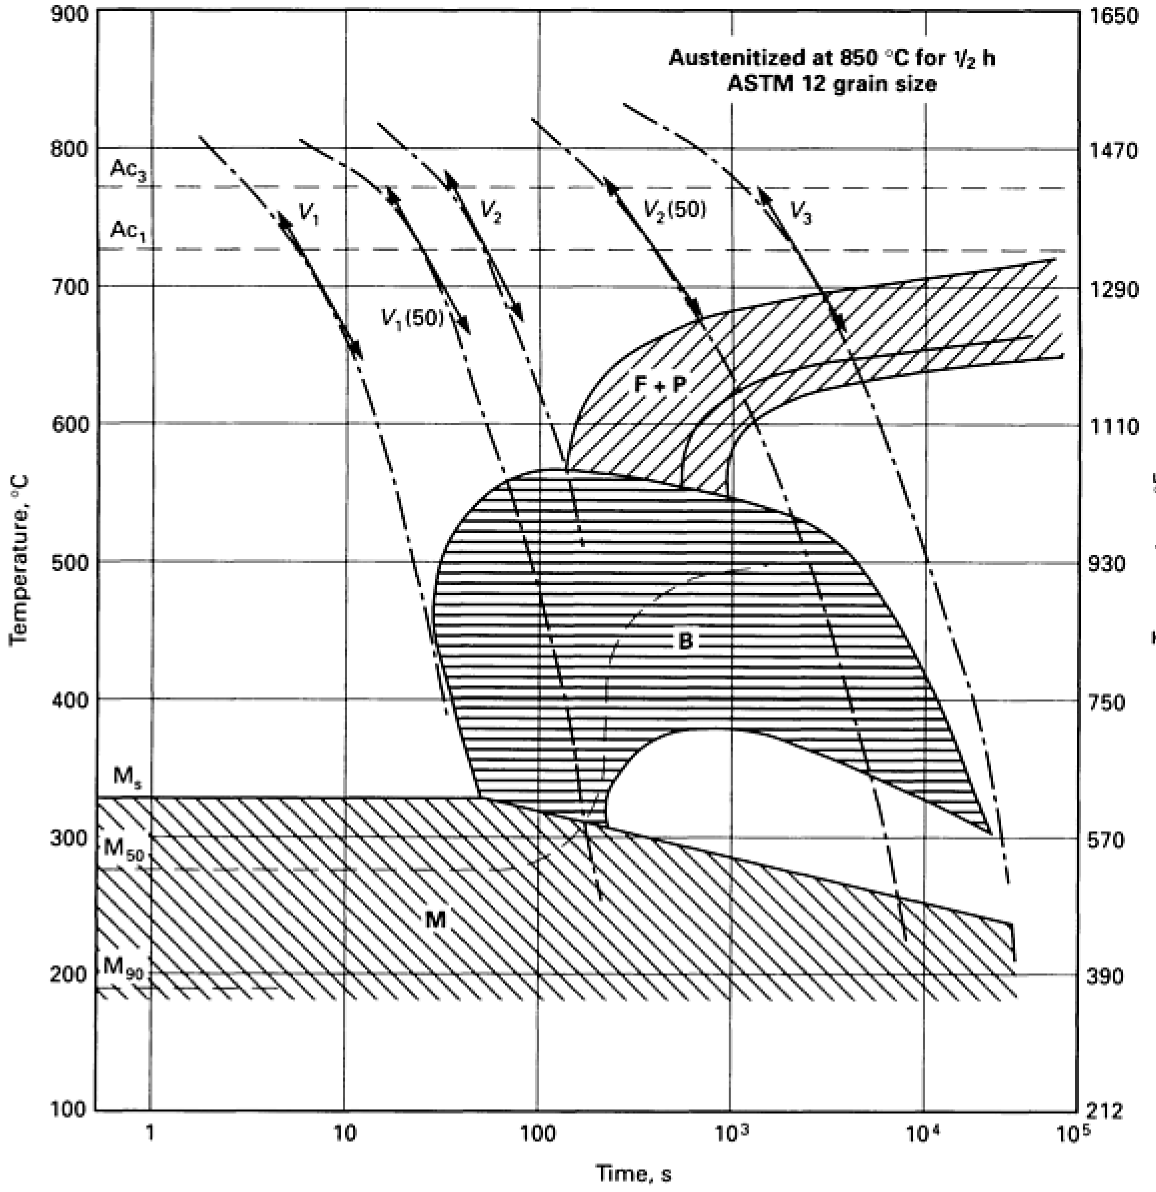

Fig. 7 CCT diagram showing critical cooling curves of 30 NC11 steel (0.32% C, 0.3% Mn, 0.2% Si, 0.008% S, 0.017% P, 2.95% Ni, 0.69% Cr, 0.10% Mo, 0.31% Cu, 0.056% As). Source: Ref 3

Residual Stress Estimates from CCT Curves. If for the purpose of estimating residual stresses (Fig. 4), the data set was systematized to all temperatures and times, at least 40 regression formulas would be required together with a greatly expanded number of interpolation and mixing formulas. (See, for example, some of the references listed in the article "Computerized Properties Prediction and Technology Planning in Heat Treatment of Steels" in this Volume.) However, in view of inconsistencies between techniques and the many independent data sets, an alternative based on systematization of IT curves (Fig. 5) has considerable merit and is explored elsewhere in this article.

The Creusot-Loire systematization of CCT curves involves explicit formulas, which allow the estimation of microstructure and hardness distributions in various shapes, including a Jominy bar. The formulas can be incorporated within an algorithm that is simple and short enough for programming on a quality hand calculator. They are already available in a

user-friendly form within a personal computer software package HAZ CALCULATOR developed by Mat-Weld-Soft of Graz, Austria (Ref 12).

The allowed inputs cover the ranges 0.2 to 0.5% C; Si $\leq$1%; Mn $\leq$2%; Ni $\leq$4%; Cr $\leq$3%; Mo $\leq$1%; V $\leq$0.2% together with the austenitizing temperature (T) and time (t). The latter parameters (T in degrees Kelvin and t in hours) are taken to define a thermally activated grain growth parameter (P_a):

$$P_a^{'} = \left[\frac{1}{T(K)} - \frac{nR}{H_a}\log t(h)\right]^{-1} \quad \textbf{(Eq 1)}$$

or

$$P_a\ (°C) = P'_a - 273$$

which enters the regression analysis along with the composition. All logs are to the base 10, n = 2.303, R = 1.986 as the gas constant, and H_a = 110,000 cal/mole as the activation enthalpy. There are eight critical cooling velocities V_i (in °C/h), which as log V_i have been linearly regressed against compositions in wt% and P_a. The logarithmic term reflects the usual convenient time normalization for plotting IT or CCT curves and has roughly the same combinatory effect as Grossmann multiplying factors in hardenability calculations. These two qualitative devices greatly increase the effectiveness of performing linear regression analysis on what is in fact a highly nonlinear and empirically sparse manifold. The formulas are:

$$\log V_1 = 9.81\text{-}4.62\text{C}\text{-}1.05\text{Mn}\text{-}0.54\text{Ni}\text{-}0.5\text{Cr}\text{-}0.66\text{Mo}\text{-}0.00183P_a \quad \textbf{(Eq 2)}$$

$$\log V_1(10) = 8.76\text{-}4.04\text{C}\text{-}0.96\text{Mn}\text{-}0.49\text{Ni}\text{-}0.58\text{Cr}\text{-}0.97\text{Mo}\text{-}0.0010P_a \quad \textbf{(Eq 3)}$$

$$\log V_1(50) = 8.50\text{-}4.13\text{C}\text{-}0.86\text{Mn}\text{-}0.57\text{Ni}\text{-}0.41\text{Cr}\text{-}0.94\text{Mo}\text{-}0.0012P_a \quad \textbf{(Eq 4)}$$

$$\log V_2 = 10.17\text{-}3.80\text{C}\text{-}1.07\text{Mn}\text{-}0.70\text{Ni}\text{-}0.57\text{Cr}\text{-}1.58\text{Mo}\text{-}0.0032P_a \quad \textbf{(Eq 5)}$$

$$\log V_2(90) = 10.55\text{-}3.65\text{C}\text{-}1.08\text{Mn}\text{-}0.77\text{Ni}\text{-}0.61\text{Cr}\text{-}1.49\text{Mo}\text{-}0.0040P_a \quad \textbf{(Eq 6)}$$

$$\log V_2(50) = 8.74\text{-}2.23\text{C}\text{-}0.86\text{Mn}\text{-}0.56\text{Ni}\text{-}0.59\text{Cr}\text{-}1.60\text{Mo}\text{-}0.0032P_a \quad \textbf{(Eq 7)}$$

$$\log V_3(90) = 7.51\text{-}1.38\text{C}\text{-}0.35\text{Mn}\text{-}0.93\text{Ni}\text{-}0.11\text{Cr}\text{-}2.31\text{Mo}\text{-}0.0033P_a \quad \textbf{(Eq 8)}$$

$$\log V_3 = 6.36\text{-}0.43\text{C}\text{-}0.49\text{Mn}\text{-}0.78\text{Ni}\text{-}0.26\text{Cr}\text{-}0.38\text{Mo}\text{-}0.0019P_a\text{-}2\sqrt{Mo} \quad \textbf{(Eq 9)}$$

where the smallest rate for 100% martensite is V_1; the rate for 90% martensite-10% bainite is $V_1(90)$; the rate for 50% martensite-50% bainite is $V_1(50)$; the smallest rate for no ferrite-pearlite is V_2; the rate for 90% bainite-10% ferrite-pearlite is $V_2(90)$; the rate for 50% bainite-50% ferrite-pearlite is $V_2(50)$; the rate for 90% ferrite-pearlite-10% bainite is $V_3(90)$; and the largest rate for 100% ferrite-pearlite is V_3. Note that all but V_2 give a unique volume fraction of the three designated constituents, so a law of mixtures for hardnesses is easily programmed (see below). In this odd case it is easy to interpolate the volume percents of bainite at log V_2 from log $V_2(90)$ and log $V_1(50)$, yielding an estimate of the bainite and martensite phase fractions at log V_2. Table 2 gives the computed critical cooling rates and microstructure for an 8620 carburizing steel of composition in wt%, 0.20C-1Mn-0.5Ni-0.5Cr-0.2Mo.

Table 2 Computed critical cooling rates and microstructure for an 8620 steel

Austenitization parameter, P_a = 917(°C - 1 h)

Critical cooling rates		**Microstructure, %**		
***v*(°C/h)**	**log *v***	**M**	**B**	**F + P**
321,067	5.507	100	0	0
222,017	5.346	90	10	0
108,658	5.036	50	50	0
28,565	4.456	10	90	0
12,177	4.086	0	90	10
4,035	3.606	0	50	50
754	2.877	0	10	90
352	2.547	0	0	100

Note: In the SAE-AISI designation the last two numbers refer to the weight percent of carbon in hundredths (that is, 20 $\equiv$ 0.2%) while the first two or three numbers refer to the alloy class (for example, Cr-Mo-Ni).

Supposing now that for a given part either the mean cooling rate $\dot{T} = dT/dt$ between 800 °C (1470 °F) and 500 °C (930 °F) is known as a function of depth *x* or the inverse function (x):

$$x = x(\dot{T}) \quad \textbf{(Eq 10)}$$

is known, and then the substitutions

$$\dot{T} = V_i \quad \textbf{(Eq 11)}$$

associate an explicit microstructure with a given depth profile. The empirical regression formulas for Vickers hardness (HV) versus composition and cooling rate developed by Creusot-Loire for martensite (M), bainite (B), and ferrite-pearlite (FP) are:

$$HV_M = 127 + 949C + 27Si + 11Mn + 8Ni + 16Cr + 21 \log \dot{T} \quad \textbf{(Eq 12)}$$

$$HV_B = 323 + 185C + 330Si + 153Mn + 65Ni + 144Cr + 191Mo + (89 + 53C - 55Si - 22Mn - 10Ni - 20Cr - 33Mo) \log \dot{T} \quad \textbf{(Eq 13)}$$

$$HV_{FP}=42+223C + 53Si + 30Mn + 13Ni + 7Cr + 19Mo + (10-19Si + 4Ni + 8Cr + 130V) \log \dot{T} \qquad \textbf{(Eq 14)}$$

Graphs in the form of Eq 10 are given for bars and plates subject to different quench media (Fig. 8 and 9) so an estimation of hardness distributions can be obtained in a more general context.

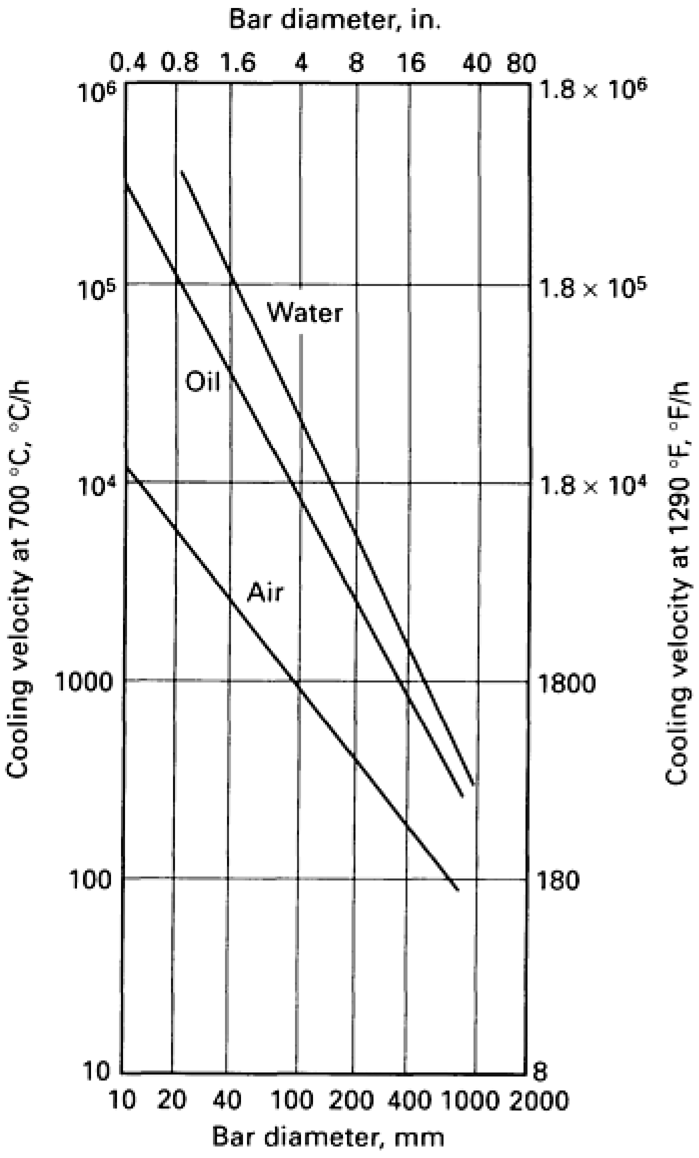

Fig. 8 Cooling rate at the center of bars cooled in air, water, or oil as a function of diameter. Source: Ref 13

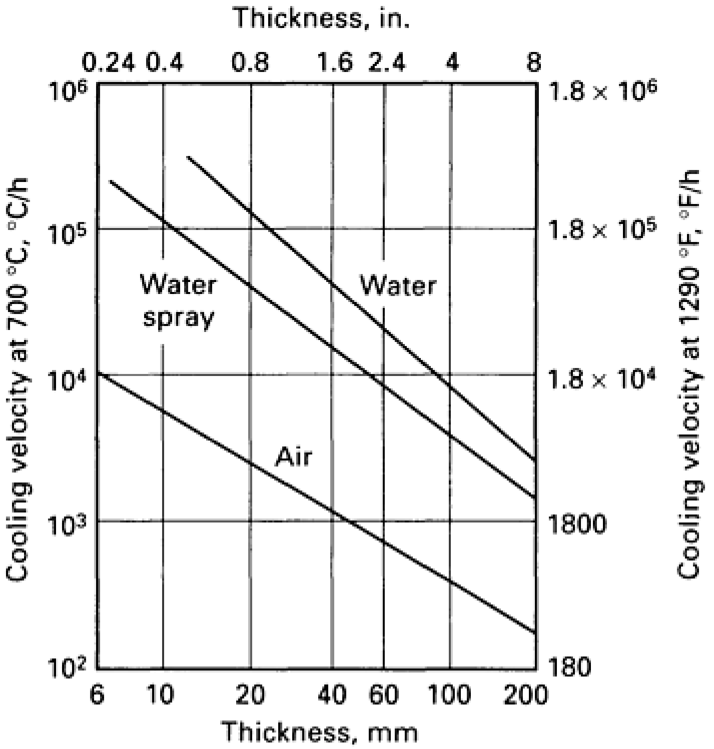

Fig. 9 Cooling rates at center of plates in air, and water, as a function of thickness. Source: Ref 13

Table 3 shows center hardness versus diameter of a water quenched rod of the 8620 composition introduced above. This was derived by a program which incorporated Eq 10, 11, 12, 13, 14 and Fig. 8 together with a weighted summation rule for hardnesses according to Table 1 and linear interpolations of log *V* between critical values (see also Fig. 10).

Table 3 Water-quenched 8620 bar center line hardness as a function of diameter

d, mm	Hardness, HV	*d*, mm	Hardness, HV
10	473	100	252
20	455	150	225
30	401	300	193
40	356	400	184
50	323	500	179
75	277		

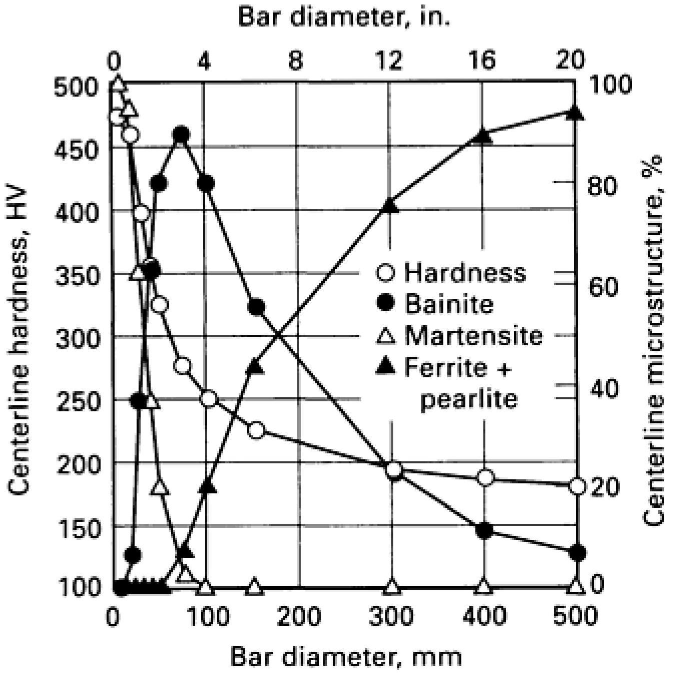

Fig. 10 Center-line hardness and microstructure of water-quenched 8620-type steel bar as predicted by the Creusot-Loire formulas. Composition inputs: 0.2% C, 1% Mn, 0.5% Ni, 0.5% Cr, 0.2% Mo

A quite effective Jominy curve predictor has been developed along these lines using the appropriate form of Eq 10 (see the section on Jominy curves). The main limitation of this methodology lies in its emphasis on room-temperature hardnesses and microstructures, which precludes residual stress calculations.

CCT Curves Derived from IT Curves. Isothermal transformation diagrams (Fig. 5) are deemed to be more accurate and definitive than CCT diagrams since most are micrographically determined under reproducible thermal conditions and the volumetric distribution of products is not nearly so complicated. The data set is smaller since preparation of the diagrams by metallography is expensive, and to the technologist they apply directly only to a few heat treatment processes like austempering; however, it is nonetheless adequate for calibrating nucleation and growth formulas which have an established theoretical basis. As with CCT curves the set could be stored in its entirety for selective recall along with appropriate interpolation rules. More economically, a typical IT curve for fraction transformed X (as in Fig. 5) can be fitted to a Johnson-Mehl nucleation and growth formula (Ref 14, 15) of the form:

$$X = 1 - \exp(-bt^n) \quad \textbf{(Eq 15)}$$

Reference 15 pertains to work on eutectoid steels in Germany, expressing the coefficients b and n as smooth functions of composition and temperature through curve-fitting on a set of 5 steels from the Atlas zur Wärmebehandlung der Stähle (Ref 16). A similar procedure has been used by Hildenwall and Ericsson in Sweden (see the article "Principles of Heat Treating of Steels" in this Volume). Following the suggestion of Kennon (Ref 17), Sakamoto *et al.* (Ref 18) have fitted C-curves for ferrite start, pearlite start and finish, and bainite start and finish to the relevant part of the U.S. Steel compendium (Ref 19, 20) involving the composition ranges, C = 0.06 to 0.79%, Si < 2.1%, Mn = 0.2 to 1.9%, Ni < 3.5%, Cr < 0.2%, Mo < 0.8%, and Cu < 1.5%. Intermediate volume fractions are also interpolated according to a logarithmic formula which is equivalent to Eq 15.

The author and coworkers have reported a predictor for IT curves based on rigorous Fe-C-X thermodynamics (which is accessible as multicomponent phase diagrams, and isothermal phase transformation kinetics for ferrite, pearlite, and bainite) and have calibrated this to the U.S. Steel compendium with a few adjustable parameters (Ref 7). While it is quantitatively similar to the method of Sakamoto *et al.*, it accounts for explicit synergistic alloying effects. Volume fractions also terminate at finite times (compare with Eq 15), and intermediate volume fractions are inherently defined. It is this procedure which underlies the comprehensive system described in Fig. 4. All three procedures have been offered in

elaborate detail in the open literature and limited space precludes repetition here. If the aim is for comprehensiveness, one of the two procedures based on the U.S. Steel Atlas is recommended.

A martensite start (M_s) formula, as for example given by Andrews (Ref 21), completes an information set that is capable of giving good estimates of entire CCT diagrams. The applicability of these procedures is limited to what has been previously designated by AISI-SAE as hardenability steels (H-steels) with alloying ranges 0.15 to 0.65% C, 0 to 0.4% Si, 0.4 to 2% Mn, 0 to 5% Ni, 0 to 1.8% Cr, 0 to 0.5% Mo. All the simple formulas fail outside these ranges because of the complicating effects of alloy carbides. Obviously, the software must be automatically disabled when the concentration inputs extend beyond the acceptable or proven ranges. As already noted, it is assumed that an integrating or weighting factor can be found for the time until each fraction (X) transformed. The best estimate of this quantity is generally agreed to be equal to the isothermal time $_{IT}(X)$ until a fixed X transformed so that along a given cooling curve (Ref 9):

$$\int_{T_{Ac3}}^{TCCT(X)} \frac{dt}{t_{IT}} = \int_{T_{Ac3}}^{TCCT(X)} \frac{dT}{t_{IT}(dT/dt)} = 1 \qquad \textbf{(Eq 16)}$$

where it is understood that the solution of the integral equation, T_{CCT}, together with the corresponding time on the selected cooling curve, gives one point on the CCT curve which is then designated by $_{CCT}(X)$. Although Eq 16, which is variously known as the *Scheil* or *Avrami Rule,* is more general (Ref 9), it is helpful to contemplate steady state growth of pearlite colonies at velocity V from a state of nucleation site saturation at time zero where the dimension l of a colony is simply:

$$l = \nu\ _{IT} \qquad \textbf{(Eq 17)}$$

Substituting this on the left of Eq 16, the unit value of this integral is confirmed for fixed X (or l) irrespective of the path of integration. The term after the first equal expression in Eq 16 is the more convenient one, because the independent variable, T, corresponds directly to the temperature limits. When a given cooling curve generates mixed structures such as ferrite-bainite or pearlite-bainite, Eq 16 evidently requires a detailed interpolative algorithm (Ref 7). Not surprisingly, there is some consensus that this procedure becomes quantitatively more successful as the steels became leaner.

Grange and Kieffer (Ref 22) have offered a useful approximation to the Scheil-Avrami Rule which represents a geometric method of conversion of IT to CCT diagrams. Here the integral (Eq 16) is evaluated by changing the Ae_3 limit to the cooling curve temperature of intersection T_{IT} on the X curve, and averaging the integrand, so that:

$$\frac{t_{CCT}(T_m) - t_{IT}(T_{IT})}{1/2[t_{IT}(T_m) + t_{CCT}(T_m)]} = 1 \qquad \textbf{(Eq 18)}$$

where T_m is the unknown on the cooling curve at $_{CCT}$. This can be found graphically by trial and error as indicated in Fig. 11 or by computer as described by Markowitz and Richman (Ref 23).

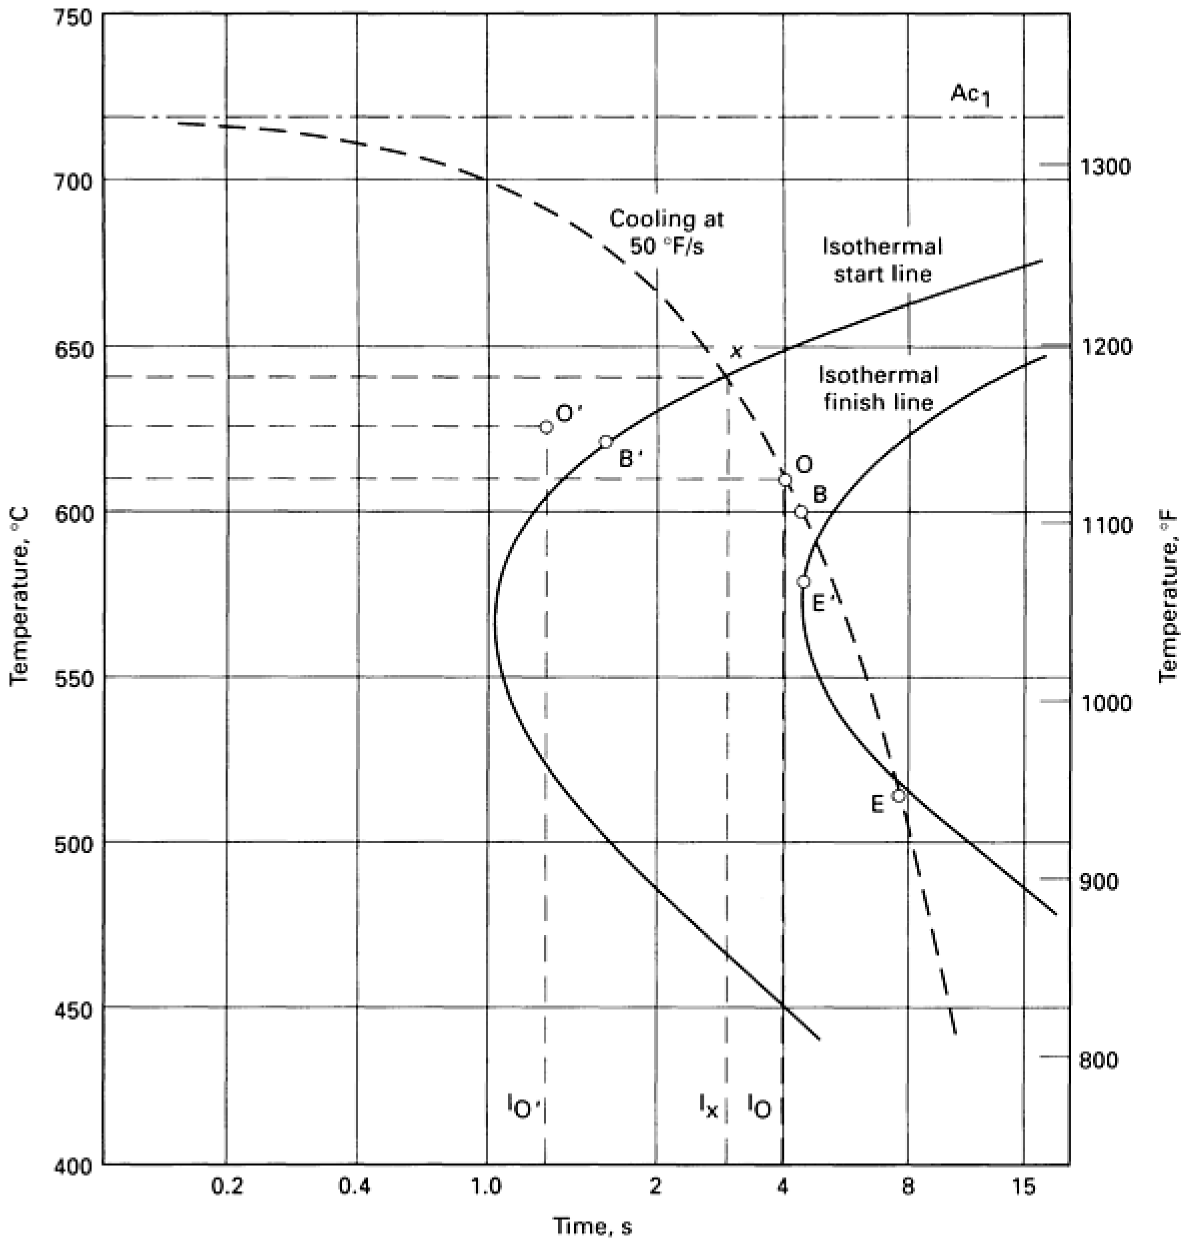

Fig. 11 A portion of the IT diagram for a plain carbon eutectoid steel, illustrating the graphical construction for obtaining the CCT diagram. In accordance with Eq 18, the time $_{CCT}$ at the unknown temperature (T_m) minus the time at *x* must equal the mean of $_{CCT}$ and that on the IT line at T_m.

The existence of an IT-to-CCT transformation procedure raises the question as to whether the process can be inverted. The answer is positive, as Eq 18 implies. This provides a basis for converting CCT curves (which are evaluated for natural, exponential-like cooling conditions) to those for constant cooling rates which are universal (Ref 9). This could be used to rationalize the international CCT data set for greater self-consistency and comprehensiveness and thus expand the knowledge base of an empirical system.

The precision of the various procedures for generating IT and CCT curves has often, and properly been criticized in the literature (Ref 4, 24), but what is being offered here is the art of the possible. It is generally sufficient in this kind of modelling to get all of the broad functional dependencies correct, and then, when the highest precision is demanded, to make empirical amendments.

The Jominy Hardenability Data Set

The historical definition of "hardenability" as the "relative ability of steels to be deep-hardened" has various quantitative measures such as "ideal critical diameter" (D_I), or the depth of the Jominy inflection point (where the inflection point often corresponds to 50% martensite). It is clearly understood that hardenability is unique to a given steel composition and grain size. The effects of shape and cooling rates are another matter, as discussed below and in the article "Principles of Heat Treating of Steels" in this Volume. All dissolved alloying element additions (with the possible exception of cobalt) and grain size increase the hardenability. Sulfur decreases hardenability slightly by reducing the soluble manganese.

The measure which has been adopted almost universally is the Jominy end-quench hardenability test (Ref 25, 26, 27 and Fig. 3, 12). Given an alloy and its Jominy curve, there is no ambiguity concerning the end hardness value, which corresponds to fully hardened martensite of the given composition. The hardness for different martensite fractions depends on carbon content (Table 1), and data such as in Table 1 can be used to choose reference points during the

formulation of specifications of hardenability for steels of different carbon contents (Ref 28). With such relations of hardness to martensite, the steepness of a Jominy curve at the inflection point (50% martensite) is also of interest, because it relates to the intensity of internal stresses and to distortion. Together with the inflection point or mean depth of hardening there are at least four important pieces of information contained in a Jominy curve. Because the test is acceptably, if not ideally, reproducible (Fig. 13 and 14; Ref 25 and 29) under controlled conditions, and because it is informative and relatively economical, it is not surprising that the Jominy test has become the standard of the industry.

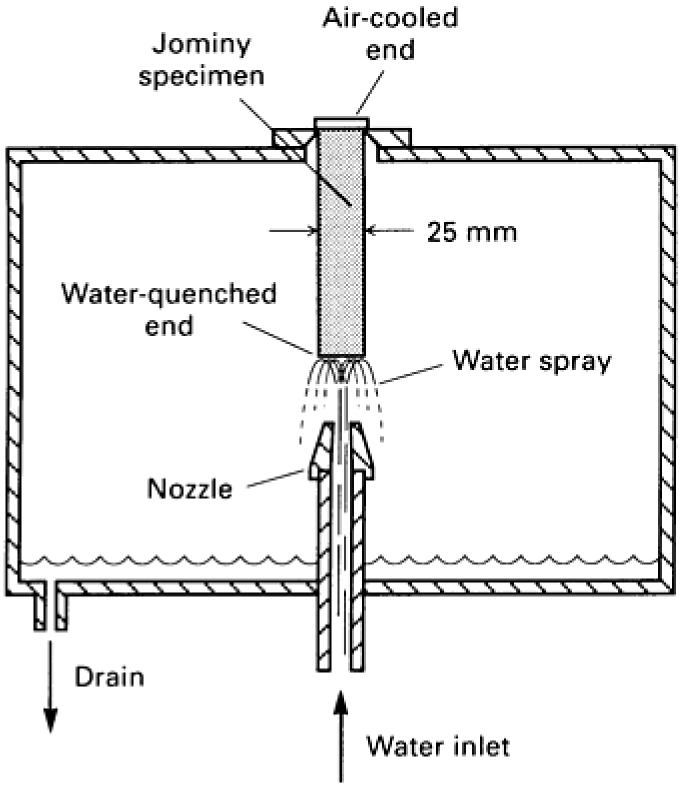

Fig. 12 Hardening procedure for Jominy end-quench specimen

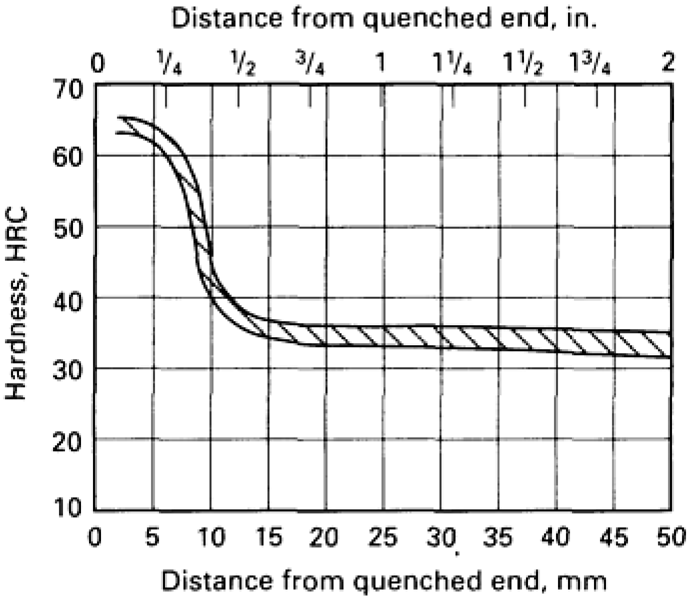

Fig. 13 Reproducibility of Jominy test by nine laboratories on one heat of 4068 steel. Source: Ref 25

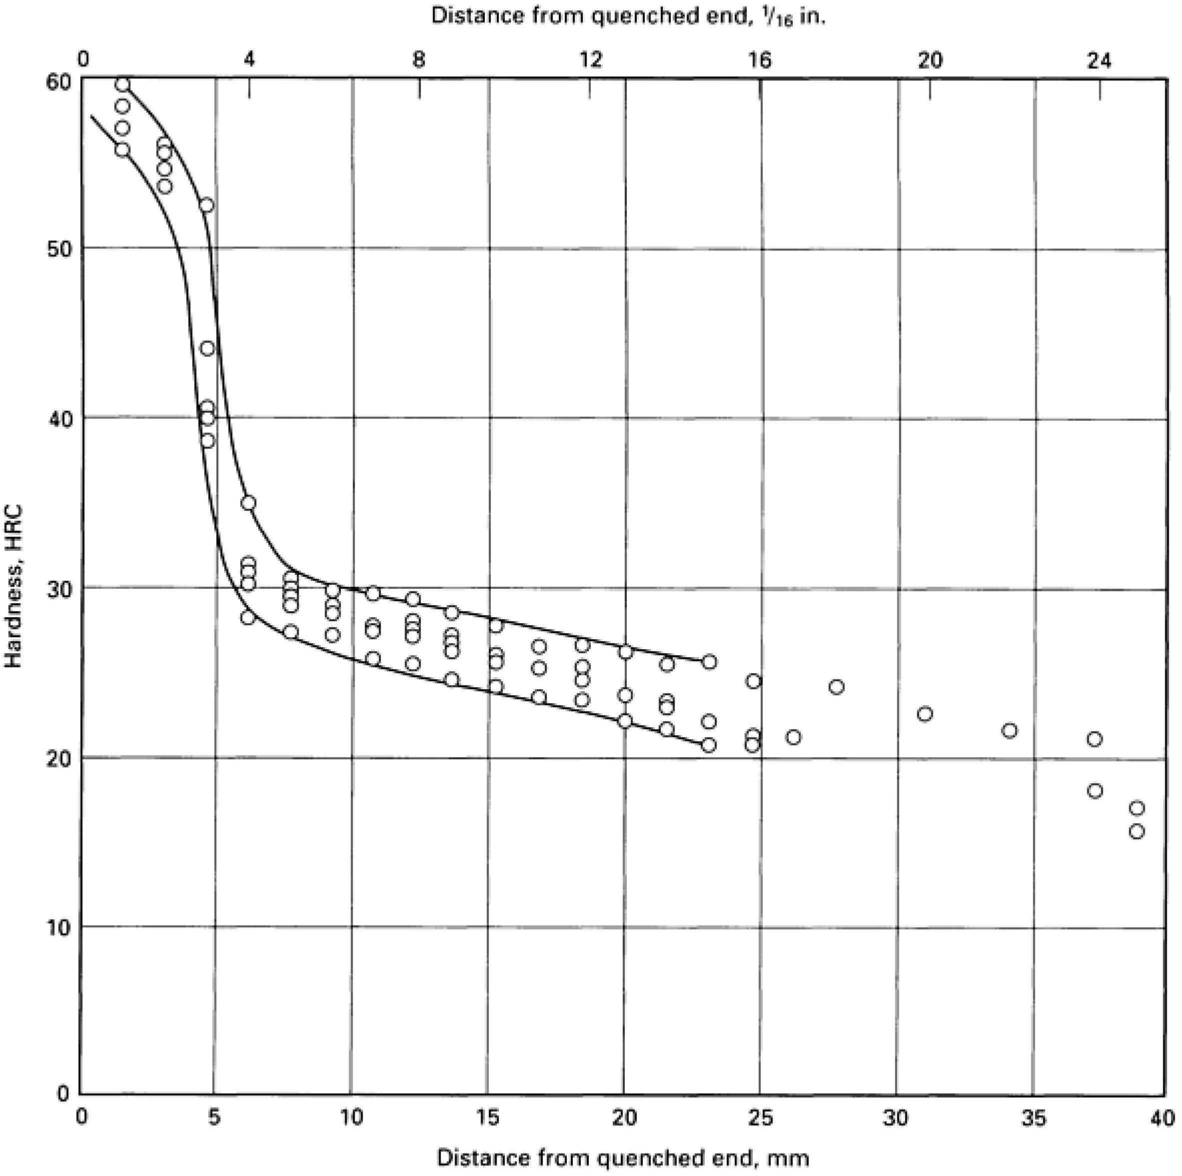

Fig. 14 Scatter band illustrating reproducibility between different organizations using standard Jominy system. Source: Ref 29

The main objectionable feature of the test lies in its impractical shape and quench configuration. Radially quenched bars are by far the most common configuration, a fact which was recognized in earlier test procedures. Unfortunately, to ascertain a unique hardenability measure such as the "ideal critical diameter" (D_I), it is necessary to examine an uneconomically large set of samples. One is therefore forced to conjecture, and hopefully establish the existence of a unique correlation between a Jominy measure (such as the inflection point) and D_I.

What are the grounds for expecting such a correlation which is independent of composition? The justification, which is far from rigorous, lies in the Lamont transformations (Ref 30, Fig. 15), that are based on an idealized but rigorous heat transfer model involving constant thermal conductivities k and surface heat transfer coefficients C as expressed in the Russell tables. They are prepared by numerical integration of the appropriate differential equations for heat transfer (Ref 31). It is assumed that for all low-alloy steels the main indices of phase partitioning are established near 700 °C (1300 °F) so that locations of equal cooling rates at 700 °C (1300 °F) will possess the same room-temperature structures (Fig. 7). The Carney empirical correlation (Ref 32) of Fig. 16 relating Jominy 50% martensite points (interpreted as the inflection point) to D_I (50% martensite at the center) should correspond roughly to the imposition of an infinite severity of quench ($H = \infty$) as indicated in the Lamont transformation of Fig. 15. The agreement here is an encouraging confirmation of the conjecture.

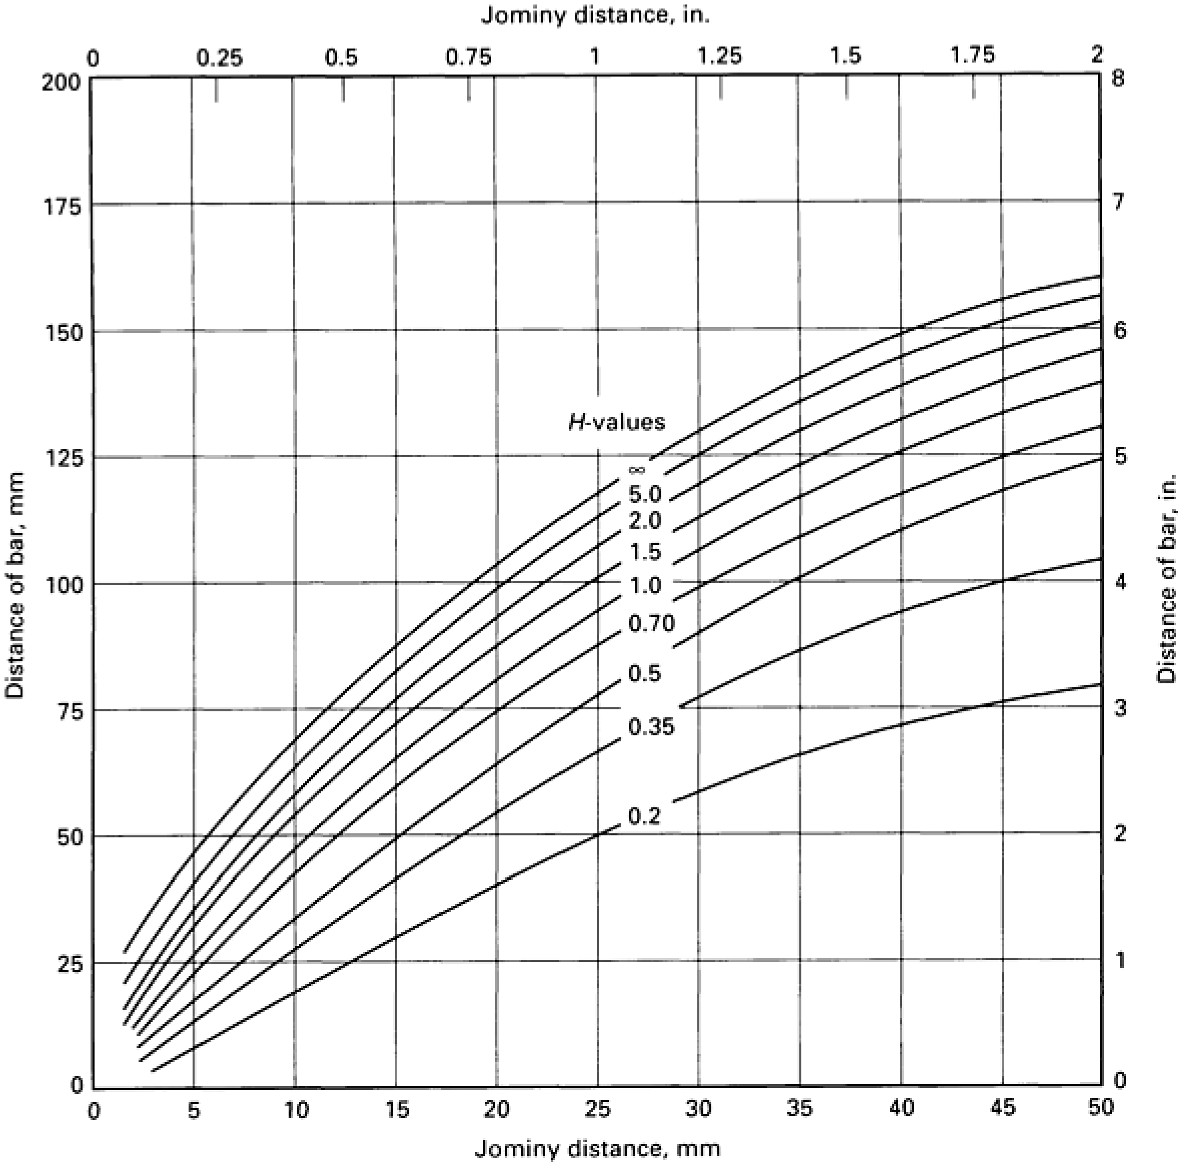

Fig. 15 Curves showing correlation of quench severity (expressed as Grossmann *H*-values) for Jominy specimens. The diagrams apply to points situated at a distance of one-tenth a radius (0.1 *R*) from the center of a round bar. Source: Ref 30

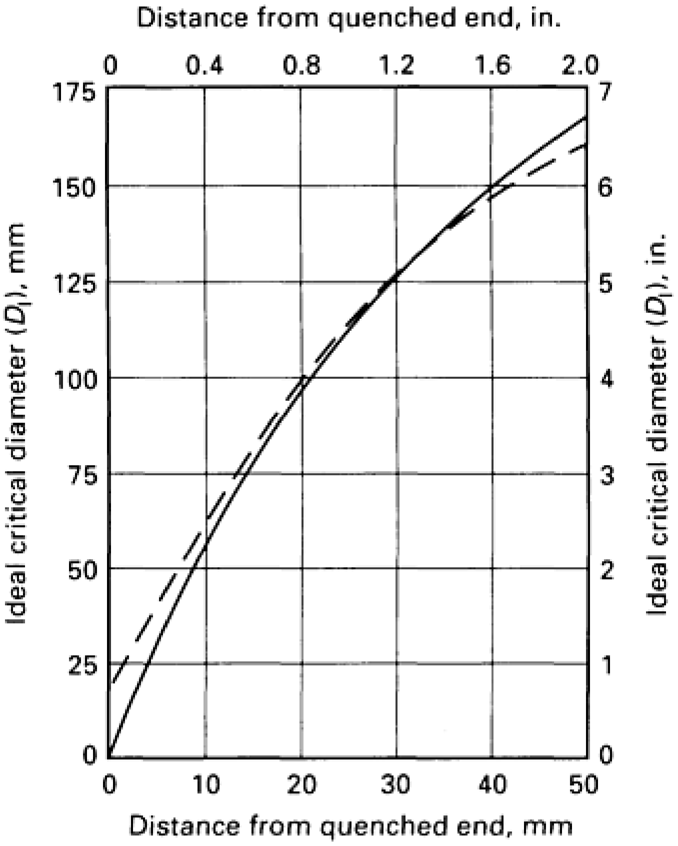

Fig. 16 Results from two similar studies showing the correlation between ideal critical diameter (D_I) and the distance to 50% martensite on an end-quench bar. Source: Ref 32

As Fig. 13 and 14 show, experimental reproducibility of hardness at a fixed Jominy depth near the inflection point of an H-steel in controlled tests can typically be ±6 HRC. It should be appreciated that the actual observed or predicted values of the hardness value at the inflection point are of very little intrinsic interest to the quality control officer or the heat treater. Rather, it is the upper or lower limits of surface (J1) and core (J32) hardness, the "half-hardness" *location*, and the slope of the hardness curve at this location which represent valuable information.

The foregoing comments pertain mainly to shallow and medium hardening steels. Focusing upon deeper hardening steels such as 4340 (Fig. 17), the idea of a Jominy depth of hardening becomes rather indefinite. Even though determination of D_I from an experimental set of critical diameters (*D*) remains a valid concept, this test option for deep hardening steels is not considered for cost reasons. The specification and interpretation problem in this case is not strongly associated with the shape of the curve, but with the extreme sensitivity of the hardnesses to the austenitizing temperature and time actually used in the Jominy test. To a lesser extent this is also true for low-alloy steels. This problem arises from the fact that the higher carbon hardenable steels are invariably hypereutectoid and therefore possess a substantial volume fraction of very unstable, undissolved carbides in the as-rolled condition. The quality control officer and heat treater should be critical of both the hardenability specifications and the experimental Jominy curves received for such grades. On the positive side, the heat treater should be cognizant of the flexibility afforded by minor variations in the austenitizing temperature.

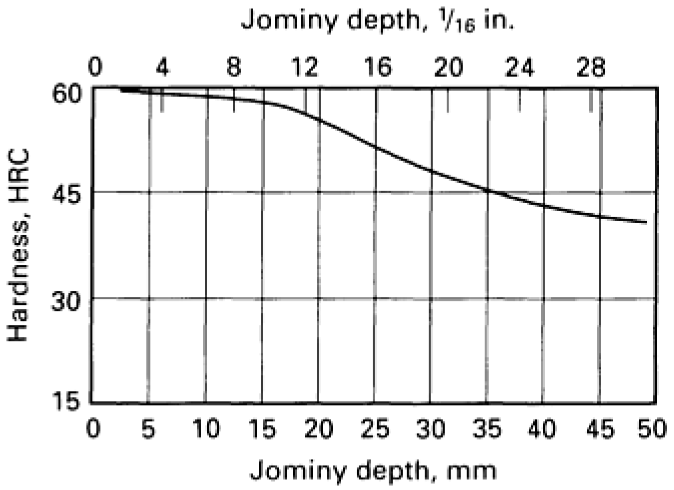

Fig. 17 Typical Jominy curve for a high hardenability (4340) steel. Source: Ref 1

The precision and reproducibility of the Jominy test is appreciably worse than indicated thus far. The test is a complex procedure which is carried out in most laboratories as though it were routine. Although the ASTM specification A 255-89 is highly specific, there are many instances whereby significant deviations from the specified practice are not preventable within the most disciplined laboratory situations. There are often five levels of uncoordinated servicing involved in the completion of the test: sampling, chemical analysis, heat treating, grinding, and hardness testing. The expectation of random and systematic errors, even when staff discipline is optimal, is obviously high and this is reflected in the strictly controlled reproducibility tests of Fig. 13 and 14 compiled by Jominy (Ref 25) and Brown (Ref 29). Such expectations led Caterpillar Tractor to undertake the regular auditing of the laboratory procedures of all of their suppliers and to establish their own specifications for test procedures (Ref 33). In England, others have been equally critical of routine Jominy testing (Ref 29, 34). To illustrate once more, Fig. 1 and 2 show a worldwide collection of Jominy curves for grades 8620 and 4140 of nearly the same reported individual chemistries and grain sizes. The scatter here reflects not only the exigencies of inadequate test procedures, but also the variations in melt shop practices which determine the inclusion content and therefore the effective grain size. The question is raised whether a carefully calibrated predictor might have advantages over routine, unaudited testing.

Prediction of Jominy Hardenability. This section gives alternatives to the set of Grossmann factors offered annually for many years in the June issue of *Metal Progress* and which are now included in the Appendices to ASTM Code A255-89 and SAE Standard J406. Such general systematizations run counter to the common intelligence that a different set of factors is required for each narrow class of steels (Ref 33, 35).

As with CCT diagrams a large compendium of observed Jominy curves spanning the composition and grain size range of interest can be stored. This can be accessed according to a composition and grain size input by near-matching to produce an empirically expected Jominy curve. At least one major steel producer proceeds in this way. The pitfalls in this methodology have been made evident by data sets such as those shown in Fig. 1 and 2. The methodology is computationally inefficient.

The development of linear regression formulas to a set of hardnesses corresponding to selected Jominy depths has been widely explored. This can be fairly effective for a single grade provided the data set densely covers the chemistry limits and hardness bands (Ref 29, 34). Such formulas, however, cannot be used outside of this single grade context (Ref 34), so comprehensive information or "expert" systems based on such procedures are inherently inflexible and exaggerated. However, producers or users of a limited number of grades may find this appropriate as an alternative to grade-selected Grossmann factors.

A comprehensive, if relatively crude system has been given for the HRC distribution in a Jominy bar by Just (Ref 36) who developed a universal Jominy curve shape in terms of penetration "E" in sixteenths of an inch and linearly regressed the coefficients for the weight percents of all of the constituents except carbon. As a consequence of the observed trends, carbon is accorded a square root rather than linear dependence. The main data set is taken as the center-line of the SAE-

AISI bands at the mean chemical composition specifications. The resulting formula for Rockwell C hardnesses (HRC) as a function of depth (4-25 sixteenths of an inch), independent of grain size, is:

$$\begin{aligned} J4\text{-}25 = {} & 98\sqrt{C} - 0.025E^2\sqrt{C} + 20Cr \\ & + 6.4Ni + 19Mn + 34Mo + 28V \\ & - 24\sqrt{E} + 2.86E - 7 \end{aligned} \quad \textbf{(Eq 19)}$$

Regression to 37 steels from the U.S. Steel Atlas, for which ASTM grain sizes A are given, yields the similar formula:

$$\begin{aligned} & J4\text{-}40 \\ & = 88\sqrt{C} - 0.0135E^2\sqrt{C} + 19Cr \\ & + 6.3Ni + 16Mn + 35Mo + 5Si - 0.82A \\ & - 20\sqrt{E} + 2.11E - 2 \end{aligned} \quad \textbf{(Eq 20)}$$

Together these suggest a more general composite formula:

$$\begin{aligned} & J4\text{-}32 \\ & = 98\sqrt{C} - 0.025E^2C + 20Cr + 6.4Ni \\ & + 19Mn + 34Mo + 28V + 5Si - \\ & 24\sqrt{E} + 2.86E - 0.82A - 1 \end{aligned} \quad \textbf{(Eq 21)}$$

The quenched end hardness (depth 0) is given empirically by:

$$J0 = 60\sqrt{C} + 20 \quad \textbf{(Eq 22)}$$

The combination of Eq 21 and 22 can be evaluated by hand-held calculators. Just also offers regression formulas which take into account higher powers of carbon-alloy interactions, but it is by no means clear that the rather subjective data set formulation justifies this extra sophistication. On the other hand, his partition of the data set into case-hardening and strongly hardenable steels seems justified, so the special formulas offered will probably improve on the predictive capabilities of Eq 21 in context. This methodology has been favorably tested by Jernkontorets in Sweden (Ref 35) and *in the general context* is expected to give better Jominy curves than those generated by slide rules or tables based on Grossmann multiplying factors (Ref 35) for the alloys 0.1 to 0.6% C, 0 to 1% Si, 0 to 2% Mn, 0 to 5% Ni, 0 to 2% Cr, 0 to 0.5(%Mo + %V). On the other hand, precise curve shapes are not expected to be reproduced.

As already indicated, the systematization of CCT diagrams due to Creusot-Loire is also a sound foundation for predicting Jominy curves (Ref 3, 13). For a Jominy specimen an explicit expression for Eq 10 is obtained by inverting the Timken estimate (Ref 37):

$$\dot{T} \text{ (in °C/h)} = 2.1298 \times 10^{26} \exp[-46.6254x^{0.03}] \quad \textbf{(Eq 23)}$$

where x is in sixteenths of an inch. Figure 18 shows a typical calculation of a Jominy curve based on this and the Creusot-Loire equation in relation to a typical observation. Any of the foregoing procedures can be calibrated to the user's data set by the simple device of a dummy correction to the carbon input and grain size parameter.

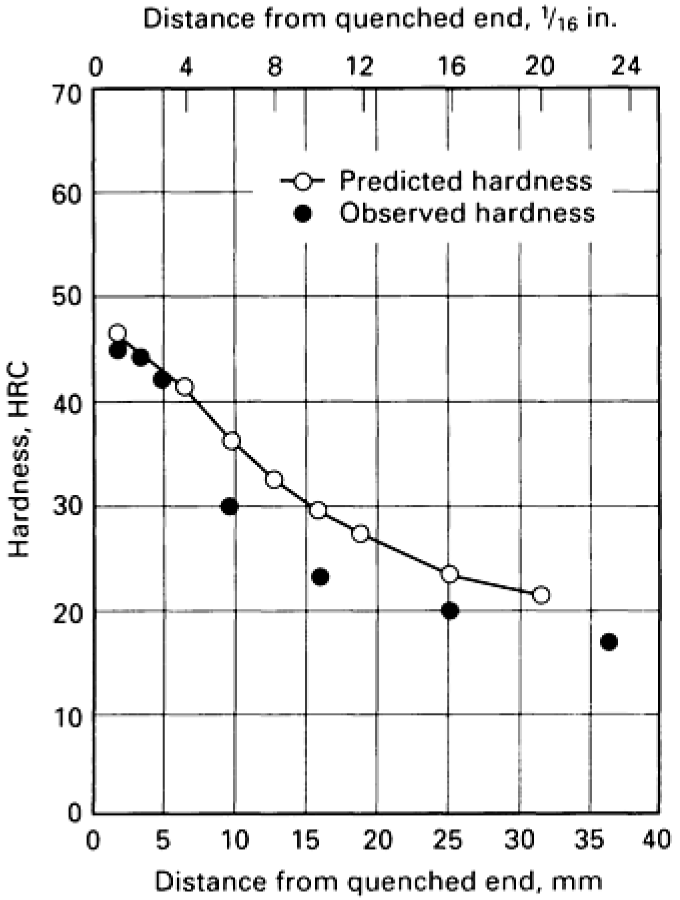

Fig. 18 Observed and predicted Jominy curve for the 8620-type steel of Fig. 10. Composition inputs (0.2% C, 1% Mn, 0.5% Cr, and 0.2% Mo) for the program has manganese slightly above the range for 8620 steel (0.7 to 0.9% Mn).

Evidently the set of TTT curves systematized by the Sakamoto *et al.* (Ref 18) or the Kirkaldy *et al.* (Ref 7) methods can be converted to CCT curves via the Scheil-Avrami Rule and room-temperature volume fractions and hardnesses can be calculated for various shapes, sizes, and cooling regimes, including the Jominy configuration. Accuracies comparable to those obtained by the Creusot-Loire method are undoubtedly obtainable.

None of the foregoing methods is capable of predicting in any generality the detailed shapes of the full range of Jominy curves because of the smoothing by averaging or the approximations and inherent errors in the various subsidiary formulas, such as for cooling rates and hardnesses. The proprietary system developed by Kirkaldy *et al.* (Ref 6) overcomes this defect by classifying the Jominy curves of steels into ten shape categories and correcting a data-based universal shape predictor accordingly. The Jominy inflection point depth is predicted directly from operations on theoretically systematized TTT-CCT start curves as above, and this and the shapes are calibrated against approximately 1000 well-characterized Jominy curves from an industry-provided set. It can be further calibrated to the user's data set, guaranteeing predictions at every Jominy point to a root mean square better than 2 HRC Operating in its most general format, all of the SAE-AISI and EX-Steel bands are generated to good precision. On the other hand, this predictive device offers only limited information about microstructure.

Relative Reliability of Jominy Measurements and Predictions (Ref 1). At this point, the question is raised as to whether calibrated predictors have reached the stage where chemistry-based outputs can be relied upon for decision-making by both the producer and user of hardenability steels. Although a number of corporations have already made a positive decision in this respect, the following statistical analysis compares the relative reliability of Jominy measurements and predictions (Ref 1).

An ideal Jominy hardness curve is defined by J_n where n designates the indentation location. The J_n curve is obtained by a precise Jominy measurement (per ASTM specification) on a forged bar which is sampled so as to best represent the performance of heats (or partial heats) of a particular grade from the user's point of view. A J'_n value will represent the

Jominy curve reported for an actual sample (which may or may not correspond to the ideal specification) and J''_n will represent the predicted Jominy curve based on the measured chemistry and grain size of a standard melt or bar sample. The formula which predicts J''_n has previously been calibrated to a large random set (N > 10; preferably 30) of measured Jominy curves (of form J_n or J'_n) from extended production or laboratory runs which span the expected or known production run band. It is therefore statistically established as a reliable average.

We now ask the question as to the respective expected deviations of J'_n and J''_n from J_n (the presumed actual) in application to a single heat. Regarding J''_n the first errors to consider are random and systematic chemical errors. Modern procedures and technology together with the expected chemical laboratory discipline allow the assignment of a zero systematic error and a random chemistry error (σ_c) less than 1 HRC. Secondly, the calibration errors (σ_n) must be considered. Ideally the calibrations would be based on a J_n set of N samples where N > 10. Figures 13 and 14 and our experience suggest that σ_n < 4 HRC would be typical, so the predictive error on a single heat would be $\sigma_n \div \sqrt{N-1}$ from this cause. There are random and systematic errors σ_0 and δ_0 due to the hardenability factors which are not represented by the chemistry. These are primarily systematic errors arising from plant or vessel practice and inadequate control of inclusions. Assuming a well-controlled standard practice, δ_0 will be stationary over long periods of time and thus eliminated from the predictor error by the calibration. The residual random error is estimated as $\sigma_0 \leq 1$ HRC. Finally, for conservatism, a random sampling error (σ_s) of 1 HRC and a systematic sampling error (δ_s) are introduced, which are assumed to be eliminated through the calibration. The net maximum predictive error for a single heat is accordingly:

$$e_n = \sqrt{s_c^2 + s_0^2 + s_s^2 + s_n^2/(N-1)} < \sqrt{1+1+1+16/10} = 2.2 HRC \qquad \textbf{(Eq 24)}$$

This figure, as an upper limit at an n location on the steep portions of the Jominy curve, is in complete accord with our general experience. It should be appreciated that if hardenability predictions are being taken seriously the principals will pay close attention to the quality of the input data sets, J_n.

Regarding J'_n, which pertains to routine Jominy testing, the situation is highly variable from producer to producer (Fig. 1 and 2). Under strictly controlled trials, such as in Fig. 13 and 14, on the steep portions of the curves, $_n$ generally exceeds 3 HRC and can be as high as 6 HRC. In routine testing, where there are often systematic errors as well, these values may be expected to be even higher, therefore, properly calibrated predictors offer a strong advantage over testing in routine applications (compare 6 HRC with ε_n in Eq 24). A properly calibrated hardenability formula will also anticipate the results of a check test at every hardness point better than an actual Jominy test. Thus, if spot testing for recalibration is maintained to allow for possible long-term changes in the systematic errors, or if standard practice is rigid enough to prevent such changes, confidence can be placed in a calibrated prediction formula based on final melt or bar chemistry.

Application of Jominy Predictors. In many cases decisions on the release of heats for rolling and/or delivery are now made on the basis of prediction from bar or melt-down chemistry alone. As such, a comprehensive formula, which is accurately calibrated to a grade range and a particular plant practice, can be used within this context. However, prior austenite grain size must be considered since, unlike chemistry as a hardenability determinant, it is not routinely reported.

Prior austenite grain size usually becomes an adjustable parameter in theoretical or empirical predictors which can be altered for different grades and for local conditions. (In the Creusot-Loire procedure it is estimated by a calculation based on the austenitizing parameter P_a.) This element of the calibration procedure operates on the assumption that typically the effective grain size is repeatable as a consequence of standardized melt shop practices. When standard melt practice is grossly altered through scheduling breaks, nonstandard preheats, refractory defects and/or large changes in unreported residuals (which alter the inclusion count), the effective grain size may change so as to alter detectably the Jominy curves. As a warning here, the modern trend toward cleaner heats necessarily generates larger grain sizes and concomitant hardenability, a result often counteracted by microalloying.

Unscheduled production variations, together with gross errors in the Jominy test procedure, are the sources of what is known as "maverick" heats. These may be recognized when the observed measure lies outside of the calibrated predictor measure by more than 2μ. Upon mandatory retesting with special care, it can be immediately established whether or not the deviation is due to a testing error or other cause. If the latter is the case then we must agree with the common view of producers (Ref 1) that a systematic change in practice should be suspected and identified as the source of the problem.

Through private communication with parties in three countries other than the U.S., it is known that Jominy predictions are being used for release to rolling mills and substituted for tests in both critical and noncritical applications. The

replacement of Jominy testing by equivalent predictions has long been the case with very shallow hardening steels where hardenability testing is difficult or impossible (Ref 1). Great savings can be realized by producers and users by adopting this kind of computer-aided technology.

Modelling of Post-Hardening Treatments

Predicting the Tempering Characteristics of Quenched Low-Alloy Steels. While the theory of temper softening of martensite is now advanced to the point of accurate predictions (Ref 38), the same cannot be said for mixed structures found at the center of thicker parts. The Creusot-Loire system overcomes this problem through empiricism and a plausible hypothesis that a low-temperature version of the austenitizing grain growth parameter (P_a) designated as (Ref 39):

$$Pc = \left[\frac{1}{T} - \frac{nR}{H_a}.\log\frac{t}{t_0}\right]^{-1} \qquad \textbf{(Eq 25)}$$

controls the coarsening and therefore the hardness of all room-temperature microstructural mixtures. It is claimed that the activation enthalpy H_a = 57,500 cal/mole for carbon steels with Mo < 0.04% and H_a = 100,000 for all steels with Mo > 0.04% with the time unit t_0 = 1 h. The first regression formula pertains to the temperature-time dependence of the deflection or softening point (Fig. 19), that is:

$$10^3/P_c = 1.365 -(0.205C+0.233Mo+0.135V) \qquad \textbf{(Eq 26)}$$

and this relates to the time and temperature of the sharp deflection in Fig. 19. The term $10^3/P_c$ from Eq 25 is also input to hardness formulas for martensite and bainite of the form:

$$HV_M = -74 - 434C - 368Si = 25Mn + 37Ni - 335Mo$$
$$-2235V + \frac{10^3}{P_c}(260 + 616C + 321Si - 21Mn - 35Ni - 11Cr + 352Mo + 2354V) \qquad \textbf{(Eq 27)}$$

and

$$HV_B = 262 + 163C _ 349Si - 64Mn - 6Ni - 186Cr - 458Mo - 857V$$
$$+\frac{10^3}{Pc}(-149 + 43C + 446Si + 79Mn + 16Ni + 196Cr + 498Mo + 1094V) \qquad \textbf{(Eq 28)}$$

and

$$HV_{F-P} = 152 - 493C - 10Mn - 19Mo + \frac{10^3}{Pc}(-37 + 726C + 14Mn + 17Mo) \qquad \textbf{(Eq 29)}$$

The softening of ferrite-pearlite is almost negligible, so the usual rule of mixing can now be employed and the time or temperature dependent process of softening generated. A nomographic summary for a particular steel is given in Fig. 19. For example, none of the structures in French steel 20CND6 contribute softening at 550 °C (1020 °F) for times up to 100 h. On the other hand they all show significant softening after 60 s at 700 °C (1300 °F). Figure 20 shows the computed softening after 1 h at 600 °C (1110 °F) from the center line hardnesses of the alloy recorded in Fig. 10. Generally, the observational validations are impressive (Ref 13).

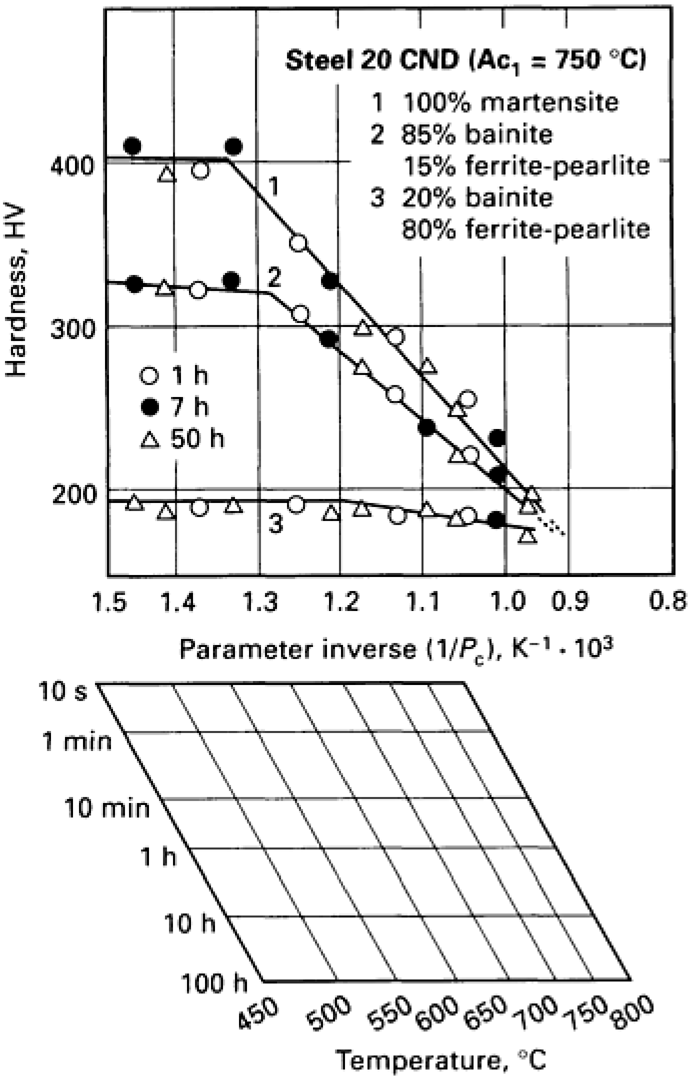

Fig. 19 Hardness variation as a linear function of the inverse of the tempering parameter (P_c) in Eq 25. The activation enthalpy (H_a) was 1 × 10^5 cal/mole. Source. Ref 13

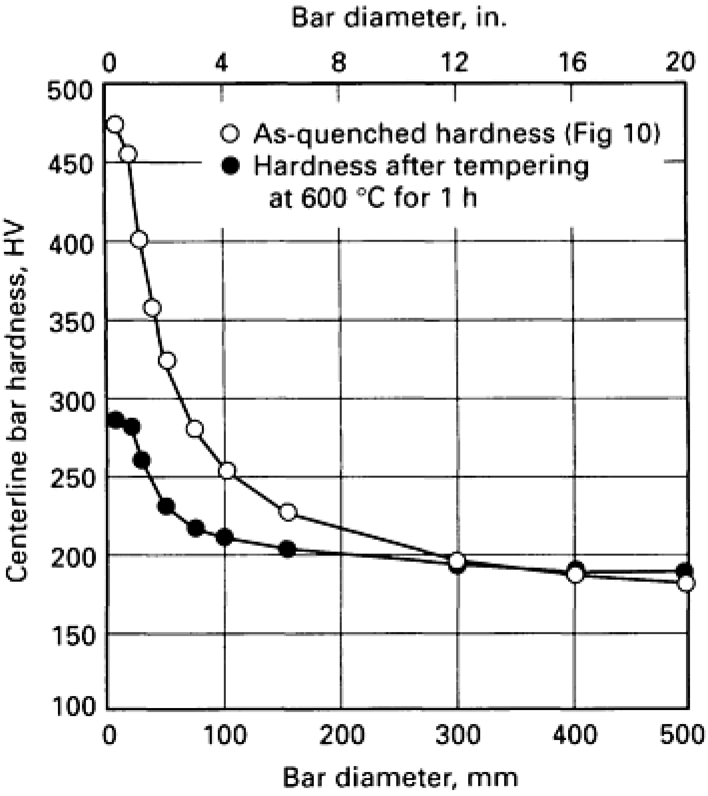

Fig. 20 Hardness after tempering predicted by the Creusot-Loire system for the 8620-type steel composition of Fig. 10

It must be emphasized that the estimates from all the previous formulas are based upon incomplete information pertaining to the original data set and the theoretical bases, and upon inaccurate or incomplete inputs. To achieve predictive precision, all formulas should be calibrated by the user within narrowed contexts and checked against outcomes on a regular basis to remove systematic inadequacies. The best formulas are those with valid functional dependencies which are amenable to easy calibration against historical data, and these will prove to be indispensable within a viable, quantitative information system. The grain size or coarsening parameters and the carbon content which enter into most of the preceding formulas are effective parameters for calibration adjustment.

Elements of a Comprehensive Quantitative Information System for Heat-Treated Low-Alloy Steel Parts. A survey of about thirty international corporations using hardenability and heat treatment software identifies the following cost-saving functions:

- Aid to dispatching heats for rolling or to a particular customer, together with control of inventory
- Diversion of heats to particular sizes and product lines and subsequent rolling schedules
- On-line cost-optimal calculation of alloy vessel and ladle additions to meet hardenability and mechanical specifications. Cost savings of greater than $2/ton have been demonstrated
- Aid in customer service to reduce risks in accepting orders where chemistry and hardenability requirements may not be compatible, to help meet very narrow hardenability specifications, and to suggest alternate steels which meet customer's hardenability requirements
- On-line control in bar and plate heat-treating facilities based on chemistry. A major reduction of rejects has been reported
- Substitution of calculations where possible for costly Jominy and other mechanical testing. Annual savings of $100,000 have been reported for a medium-sized steel-making shop
- Scientific aid to design and development, taking account of mechanical properties and residual stresses
- Development of new hardenable steel grades together with specifications and bands
- Development of a research tool to match hardenability requirements and compositions to stress levels imposed on various components
- Simulation of product heat-treat operations

- Incorporation in a comprehensive material selection program
- Quality control of steel deliveries including their chemistry, hardenability, mechanical properties, and heat-treat response. Auditing incoming heats in relation to received and historical data
- On-line control of heat treatment and multistage gas carburization processes

Modelling of Carburization Response. The chart in Fig. 4 contemplates an accurate predictor which goes beyond the main features of quenching and tempering discussed in this article. In particular, carburization response, residual stresses, and stress relief are areas of further modelling and program complication. Carburization, for example, includes the distribution of carbon content as an additional variable to the basic quench and temper program, which must be adjusted to accommodate hypereutectoid compositions. This obviously increases running time and expands the time scale of the stress-strain calculations. Furthermore, an on-line capability, which accounts for largescale multistage operations, must also take into account atmosphere control and furnace and charge configurations so as to provide a correctly predicted carbon injection level. Research towards this goal is well advanced through the efforts of Stickels (Ref 40) and others.

Prediction of Residual Stress and Distortion. The inclusion of mechanical response to a complex temperature field and variation in chemical composition to allow prediction of internal stresses, strains, and overall dilatation represents the most severe complication because finite element methods must be used. (See the article "Computerized Properties Prediction and Technology Planning in Heat Treatment of Steels" in this Volume for a listing of various finite element analysis programs.)

The preliminary program being investigated by the author and coworkers requires at least one hour running time on a mainframe computer or work station and generates tabular information pertaining to a sample part (the Jominy bar) which consumes approximately 1000 pages of printout. In the latter outcome the modeler must confront the problem of generating too much information for the needs of the average industrial software user. Thus much programming effort and memory must be devoted to aiding the user in selection for brevity and clarity. Figures 21 and 22 are two examples of processed predictions from a finite element analysis program.

Stress-Relief Heat Treating of Steel

Domenic A. Canonico, ABB Combustion Engineering Services

Introduction

STRESS-RELIEF HEAT TREATING is used to relieve stresses that remain locked in a structure as a consequence of a manufacturing sequence. This definition separates stress-relief heat treating from postweld heat treating in that the goal of postweld heat treating is to provide, in addition to the relief of residual stresses, some preferred metallurgical structure or properties (Ref 1, 2). For example, most ferritic weldments are given postweld heat treatment to improve the fracture toughness of the heat-affected zones (HAZ). Moreover, austenitic and nonferrous alloys are frequently postweld heat treated to improve resistance to environmental damage.

Stress-relief heat treating is the uniform heating of a structure, or portion thereof, to a suitable temperature below the transformation range (Ac_1 for ferritic steels), holding at this temperature for a predetermined period of time, followed by uniform cooling (Ref 2, 3). Care must be taken to ensure uniform cooling, particularly when a component is composed of variable section sizes. If the rate of cooling is not constant and uniform, new residual stresses can result that are equal to or greater than those that the heat-treating process was intended to relieve.

Stress-relief heat treating can reduce distortion and high stresses from welding that can affect service performance. The presence of residual stresses can lead to stress-corrosion cracking (SCC) near welds and in regions of a component that has been cold strained during processing. Furthermore, cold strain per se can produce a reduction in creep strength at elevated temperatures.

Residual stresses in a ferritic steel cause significant reduction in resistance to brittle fracture. In a material that is not prone to brittle fracture, such as an austenitic stainless steel, residual stresses can be sufficient to provide the stress necessary to promote SCC even in environments that appear to be benign (Ref 4).

Sources of Residual Stress

There are many sources of residual stress; they can occur during processing of the material from ingot to final product form (Ref 4, 5). Residual stresses can be generated during rolling, casting, or forging; during forming operations such as shearing, bending, drawing, and machining; and during fabrication, in particular, welding. Residual stresses are present whenever a component is stressed beyond its elastic limit and plastic flow occurs. Additional information on residual stresses can be found in the article "Defects and Distortion in Heat-Treated Parts" in this Volume.

Bending a bar during fabrication at a temperature where recovery cannot occur (cold forming, for example) will result in one surface location containing residual tensile stresses, whereas a location 180° away will contain residual compressive stresses (Ref 6).

Quenching of thick sections results in high residual compressive stresses on the surface of the material. These high compressive stresses are balanced by residual tensile stresses in the internal areas of the section (Ref 7).

Grinding is another source of residual stresses; these can be compressive or tensile in nature, depending on the grinding operation. Although these stresses tend to be shallow in depth, they can cause warping of thin parts (Ref 8).

Welding. The cause of residual stresses that has received the most attention in the open literature is welding. The residual stresses associated with the steep thermal gradient of welding can occur on a macroscale over relatively long distances (reaction stresses) or can be highly localized (microscale) (Fig. 1). Welding usually results in localized residual stresses that approach levels equal to or greater than the yield strength of the material at room temperature.

Alleviation of Residual Stresses

A number of factors influence the relief of residual stresses, including level of stress, permissible (or practicable) time for their relief, temperature, and metallurgical stability.

Time-Temperature Factors. The relief of residual stresses is a time-temperature-related phenomenon (Fig. 2), parametrically correlated by the Larson-Miller equation:

$$\text{Thermal effect} = T(\log t + 20)10^{-3} \qquad \textbf{(Eq 1)}$$

where T is temperature (Rankin), and t is the time in hours. It is evident in Fig. 2 that similar relief of residual stresses can be achieved by holding a component for longer periods at a lower temperature. For example, holding a piece at 595 °C (1100 °F) for 6 h provides the same relief of residual stress as heating at 650 °C (1200 °F) for 1 h.

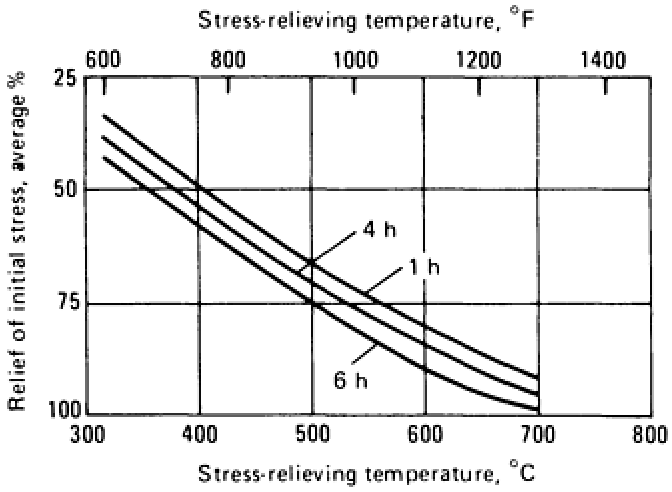

Fig. 2 Relationship between time and temperature in the relief of residual stresses in steel. Source: Ref 3

Alloy Considerations. Relief of residual stresses represents typical stress-relaxation behavior, in which the material undergoes microscopic (sometimes even macroscopic) creep at the stress-relief temperature. Creep-resistant materials, such as the chromium-bearing low-alloy steels and the chromium-rich high-alloy steels, normally require higher stress-relief heat-treating temperatures than conventional low-alloy steels. Typical stress-relief temperatures for low-alloy ferritic steels are between 595 and 675 °C (1100 and 1250 °F). For high-alloy steels, these temperatures may range from 900 to 1065 °C (1650 to 1950 °F).

For high-alloy steels, such as the austenitic stainless steels, stress relieving is sometimes done at temperatures as low as 400 °C (750 °F). However, at these temperatures, only modest decreases in residual stress are achieved. Residual stresses can be significantly reduced by stress-relief heat treating those austenitic materials in the temperature range from 480 to 925 °C (900 to 1700 °F). At the higher end of this range, nearly 85% of the residual stresses may be relieved. Stress-relief heat treating in this range, however, may result in sensitizing susceptible material. This metallurgical effect can lead to SCC in service (Ref 9). Frequently, solution-annealing temperatures of about 1065 °C (1950 °F) are used to achieve a reduction of residual stresses to acceptably low values.

Some copper alloys may fail by SCC due to the presence of residual stresses. These stresses are usually relieved by mechanical or thermal stress-relief treatments. Stress-relief heat treating tends to be favored because it is more controllable, less costly, and also provides a degree of dimensional stability. Stress-relief heat treating of copper alloys is usually carried out at relatively low temperatures, in the range from 200 to 400 °C (390 to 750 °F) (Ref 5).

Resistance of a material to the reduction of its residual stresses by thermal treatment can be estimated with a knowledge of the influence of temperature on its yield strength. Figure 3 provides a summary of the yield strength to temperature relationship for three generic classes of steels. The room-temperature yield strength of these materials provides an excellent estimate of the level of localized residual stress that can be present in a structure. To relieve the residual stress requires that the component be heated to a temperature where its yield strength approaches a value that corresponds to an acceptable level of residual stress. Holding at this temperature can further reduce the residual stress through the reduction of strain due to creep. Uniform cooling after residual-stress heat treating is mandatory if these levels of residual stress are to be maintained.

Normalizing of Steel

Revised by Thomas Ruglic, Hinderliter Heat Treating, Inc.

Introduction

NORMALIZING OF STEEL is a heat-treating process that is often considered from both thermal and microstructural standpoints. In the thermal sense, normalizing is an austenitizing heating cycle followed by cooling in still or slightly agitated air. Typically, the work is heated to a temperature about 55 °C (100 °F) above the upper critical line of the iron-iron carbide phase diagram, as shown in Fig. 1; that is, above Ac_3 for hypoeutectoid steels and above A_{cm} for hypereutectoid steels. To be properly classed as a normalizing treatment, the heating portion of the process must produce a homogeneous austenitic phase (face-centered cubic, or fcc, crystal structure) prior to cooling. Figure 2 compares the time-temperature cycle of normalizing to that of full annealing. Typical normalizing temperatures for many standard steels are given in Table 1.

Table 1 Typical normalizing temperatures for standard carbon and alloy steels

Grade	Temperature[a]	
	°C	°F

(a) Based on production experience, normalizing temperature may vary from as much as 27 °C (50 °F) below, to as much as 55 °C (100 °F) above, indicated temperature. The steel should be cooled in still air from indicated temperature.

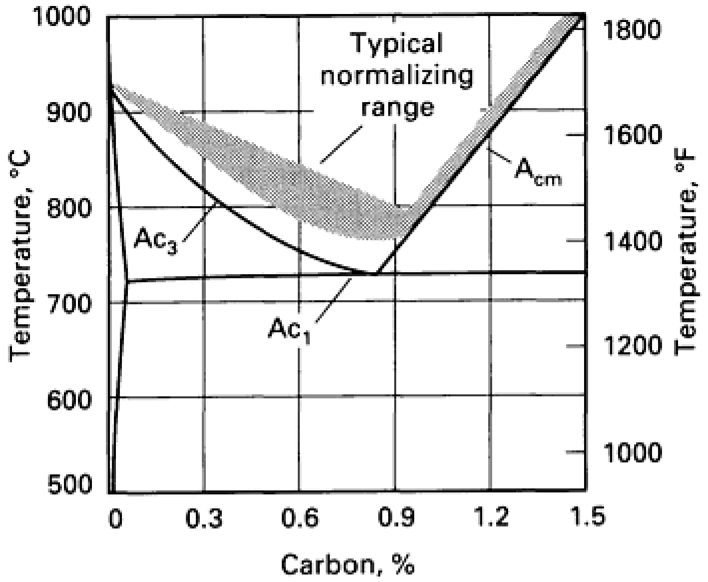

Fig. 1 Partial iron-iron carbide phase diagram showing typical normalizing range for plain carbon steels

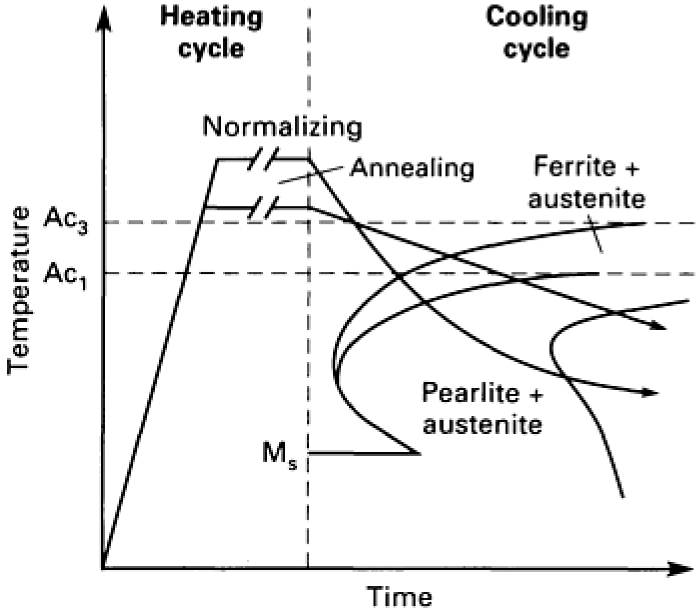

Fig. 2 Comparison of time-temperature cycles for normalizing and full annealing. The slower cooling of annealing results in higher temperature transformation to ferrite and pearlite and coarser microstructures than does normalizing. Source: Ref 1

Normalizing is also frequently thought of in terms of microstructure. The areas of the microstructure that contain about 0.8% C are pearlitic (lamellae of ferrite and iron carbide). The areas that are low in carbon are ferritic (body-centered cubic, or bcc, crystal structure). In hypereutectoid steels, proeutectoid iron carbide first forms along austenite grain boundaries. This transformation continues until the carbon level in the austenite reaches approximately 0.8%, at which time a eutectoid reaction begins as indicated by the formation of pearlite. Air-hardening steels are excluded from the class of normalized steels because they do not exhibit the normal pearlitic microstructure that characterizes normalized steels.

Applications of Normalizing Based on Steel Classification

A broad range of ferrous products can be normalized. All of the standard low-carbon, medium-carbon, and high-carbon wrought steels can be normalized, as well as many castings. Many steel weldments are normalized to refine the structure within the weld-affected area. Austenitic steels, stainless steels, and maraging steels either cannot be normalized or are not usually normalized. Tool steels are generally annealed by the steel supplier.

The purpose of normalizing varies considerably. Normalization may increase or decrease the strength and hardness of a given steel in a given product form, depending on the thermal and mechanical history of the product. Actually, the functions of normalizing may overlap with or be confused with those of annealing, hardening, and stress relieving. Improved machinability, grain-structure refinement, homogenization, and modification of residual stresses are among the reasons normalizing is done. Homogenization of castings by normalizing may be done in order to break up or refine the dendritic structure and facilitate a more even response to subsequent hardening. Similarly, for wrought products, normalization can help reduce banded grain structure due to hot rolling, as well as large grain size or mixed large and small grain size due to forging practice. The details of normalizing treatments applied to three typical production parts are given in Table 2, which also lists the reasons for normalizing and gives some of the mechanical properties obtained in the normalized and tempered condition. Comparisons of typical hot-rolled or annealed mechanical properties versus typical normalized properties are presented in Table 3.

Table 2 Typical applications of normalizing and tempering of steel components

Part	Steel	Heat treatment	Properties after treatment	Reason for normalizing
Cast 50 mm (2 in.) valve body, 19 to 25 mm ($\frac{3}{4}$ to 1 in.) in section thickness	Ni-Cr-Mo	Full annealed at 955 °C (1750 °F), normalized at 870 °C (1600 °F), tempered at 665 °C (1225 °F)	Tensile strength, 620 MPa (90 ksi); 0.2% yield strength, 415 MPa (60 ksi); elongation in 50 mm, or 2 in., 20%; reduction in area, 40%	To meet mechanical-property requirements
Forged flange	4137	Normalized at 870 °C (1600 °F), tempered at 570 °C (1060 °F)	Hardness, 200 to 225 HB	To refine grain size and obtain required hardness
Valve-bonnet forging	4140	Normalized at 870 °C (1600 °F) and tempered	Hardness, 220 to 240 HB	To obtain uniform structure, improved machinability, and required hardness

(a) All grades are fine grained except for those in the 1100 series, which are coarse grained

(b) In 50 mm or 2 in.

Figure 3 shows that high-carbon steels with large amounts of pearlite have high transition temperatures and therefore will fail in a brittle manner even well above room temperature. On the other hand, low-carbon steels have subzero transition temperatures and are quite tough at room temperature (Ref 1).

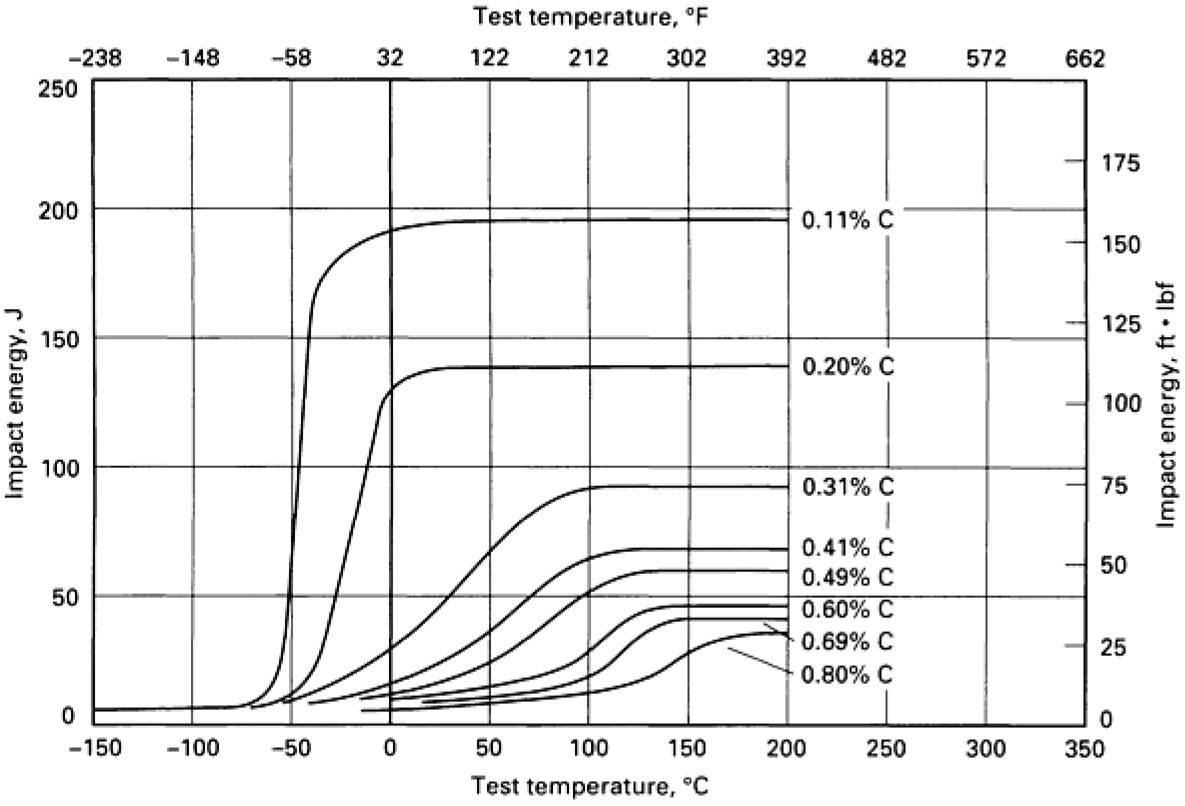

Fig. 3 Change in impact transition curves with increasing pearlite content in normalized carbon steels. Source: Ref 1

Depending on the mechanical properties required, normalizing may be substituted for conventional hardening when the size or shape of the part is such that liquid quenching might result in cracking, distortion, or excessive dimensional changes. Thus, parts that are of complex shape or that incorporate sharp changes in section may be normalized and tempered, provided that the properties obtained are acceptable.

The rate of heating generally is not critical for normalizing; on an atomic scale, it is immaterial. In parts having great variations in section size, however, thermal stress can cause distortion.

Time at temperature is critical only in that it must be sufficient to cause homogenization. Sufficient time must be allowed for solution of thermodynamically stable carbides, or for diffusion of constituent atoms. Generally, time sufficient for complete austenitization is all that is required. One hour at temperature, after the furnace recovers, per inch of part thickness, is considered to be standard. Parts often can be austenitized adequately in much less time (with a saving of energy). In cases where normalizing is done to homogenize segregated structures, longer times may be required.

The rate of cooling significantly influences both the amount of pearlite and the size and spacing of the pearlite lamellae. At higher cooling rates, more pearlite forms, and the lamellae are finer and more closely spaced. Both the increased amount of pearlite and the greater fineness of the pearlite result in higher strength and higher hardness. Conversely, lower cooling rates result in softer parts. The effect of mass on hardness (via its effect on cooling rate) is illustrated by the data in Table 4. In any part having both thick and thin sections, the potential exists for variations in cooling rate, and thus for variations in strength and hardness as well. This can also increase the probability of distortion or even cracking. Cooling rate sometimes is enhanced with fans to increase strength and hardness of parts or to decrease the time required, following the furnace operation, for sufficient cooling of parts to permit convenient handling.¨

After parts have cooled uniformly through their cross section to black heat below Ar_1 (the parts are no longer red, as when they were removed from the furnace), they may be water or oil quenched to decrease the total cooling time. In heavy sections, cooling of the center material to black heat may require considerable time. Thermal shock, residual thermally induced stress, and resultant distortions are factors to be considered. The microstructure remains essentially unaffected by the increased cooling rate, provided that the entire mass is below the lower critical temperature, Ar_1, although changes involving precipitates may occur.

Carbon Steels. Table 1 lists typical normalizing temperatures for some standard grades of carbon steel. These temperatures can be interpolated to obtain values for carbon contents not listed.

Steels containing 0.20% C or less usually receive no treatment subsequent to normalizing. However, medium-carbon or high-carbon steels are often tempered after normalizing to obtain specific properties such as a lower hardness for straightening, cold working, or machining. Whether tempering is desirable depends on specific property requirements and not on carbon content and section size requirements. Table 3 presents typical mechanical properties of selected carbon and alloy steels in the hot-rolled, normalized, and annealed conditions. Because of pearlite lamellae and spacing, a low-carbon or medium-carbon steel of thin section may be harder after normalizing than a high-carbon steel of large section size subjected to the same treatment.

Alloy Steels. For alloy steel forgings, rolled products, and castings, normalizing is commonly used as a conditioning treatment before final heat treatment. Normalizing also refines the structures of forgings, rolled products, and castings that have cooled nonuniformly from high temperatures. Table 1 lists typical normalizing temperatures for some standard alloy steels.

Alloy carburizing steels such as 3310 and 4320 usually are normalized at temperatures higher than the carburizing temperature to minimize distortion in carburizing and to improve machining characteristics. Carburizing steels of the 3300 series sometimes are double normalized with the expectation of minimizing distortion; these steels are tempered at about 650 °C (1200 °F) for intervals of up to 15 h to reduce hardness to below 223 HB for machinability. Carburizing steels of the 4300 and 4600 series usually can be normalized to a hardness not exceeding 207 HB and therefore need not be tempered for machinability.

Hypereutectoid alloy steels such as 52100 are normalized for partial or complete elimination of carbide networks, thus producing a structure that is more susceptible to 100% spheroidization in the subsequent spheroidize annealing treatment. The spheroidized structure provides improved machinability and a more uniform response to hardening.

Some alloy grades require more care in heating to prevent cracking from thermal shock. They also require longer soaking times because of lower austenitizing and solution rates. For many alloy steels, rates of cooling in air to room temperature must be carefully controlled. Certain alloy steels are forced-air cooled from the normalizing temperature in order to develop specific mechanical properties. This is a normalizing treatment only in the microstructural sense discussed in the introduction to this article.

Forgings

When forgings are normalized before carburizing or before hardening and tempering, the upper range of normalizing temperatures is used. However, when normalizing is the final heat treatment, use is made of the lower range of temperatures.

Furnaces. Any appropriately sized furnace may be utilized for normalizing. Furnace type and size will depend upon the specific need. In a continuous furnace, forgings to be normalized are usually placed in shallow pans, and a pusher mechanism at the loading end of the furnace transports the pans through the furnace. Furnace burners located on both sides of the furnace fire below the hearth, and combustion products rise along the walls of the work-zone muffle and exhaust into the roof of the furnace. No atmosphere control is used. Combustion products enter the work zone through ports lining both sides of the entire hearth. A typical furnace is 9 m (30 ft) long and has 18 gas burners (or 9 oil burners) on each side. For purposes of temperature control, such a furnace is divided into three 3 m (10 ft) zones, each having a vertical thermocouple extending into it through the roof of the furnace.

Processing. Small forgings are usually normalized as received from the forge shop. A typical furnace has five pans in each of the three furnace zones. Heating is adjusted so that the work reaches normalizing temperature in the last zone. After passing through the last zone, the pans are discharged onto a cooling conveyor. The work, while still in the pans, is cooled in still air to below 480 °C (900 °F); it is then discharged into tote boxes, where it cools to room temperature. Total furnace time is approximately $3\frac{1}{2}$ h, but during this period the work is held at the normalizing temperature for only 1 h.

Normalizing of large open-die forgings usually is performed in batch-type furnaces pyrometrically controlled to narrow temperature ranges. Forgings are held at the normalizing temperature long enough to allow complete austenitizing and carbide solution to occur (usually one hour per inch of section thickness), and then are cooled in still air.

Axle-Shaft Forging. In forging an axle shaft made of fine-grained 1049 steel, only one end of the forging bar was heated to upset the wheel-flange section. When the part was examined in cross section from the flanged end to the cold end, the metallurgical conditions discussed below were revealed.

The hot-worked flanged area of the axle exhibited a fine-grained structure as a result of the hot working at the forging temperature (approximately 1095 °C, or 2000 °F). However, a section adjacent to the flange, which also had been heated to the forging temperature but which had not been hot worked, exhibited a coarse-grained structure. Nearer the cool end of the shaft, a zone that reached a temperature of about 705 °C (1300 °F) exhibited a spheroidized structure. The cold end of the shaft retained its initial fine grain size throughout the forging operation.

In subsequent operations, this shaft was to be mechanically straightened, machined, and induction hardened. Because of the mixed grain structure, these operations posed several problems. The coarse-grained area adjacent to the flange was extremely weak in the transverse direction, and there was a possibility that fracture would occur if this section were subjected to a severe straightening operation. The spheroidized area would not respond adequately to induction hardening because the solution rate of this type of carbide formation was too sluggish for the relatively rapid rate of induction heating. Furthermore, the mixed metallurgical structure would present difficulties in machining. Consequently, normalizing was required in order to produce a uniformly fine-grained structure throughout the axle shaft prior to straightening, machining, and induction hardening.

Low-Carbon Steel Forgings. In contrast to the medium-carbon axle shaft discussed in the preceding paragraphs, forgings made of carbon steels containing 0.25% C or less are seldom normalized. Only severe quenching from above the austenitizing temperature will have any significant effect on their structure or hardness.

Structural Stability. Normalizing and tempering is also a preferred treatment for promoting the structural stability of low-alloy heat-resistant alloys, such as AMS 6304 (0.45% C, 1% Cr, 0.5% Mo, and 0.3% V), at temperatures up to 540 °C (1000 °F). Wheels and spacer rings used in the cold ends of aircraft gas-turbine engine compressors are typical of parts subjected to such treatment to promote structural stability.

Multiple normalizing treatments are employed to obtain complete solution of all lower-temperature constituents in austenite by the use of high initial normalizing temperatures (for example, 925 °C, or 1700 °F), and to refine final pearlite grain size by the use of a second normalizing treatment at a temperature closer to the Ac_3 temperature (for example, 815 °C, or 1500 °F) without destroying the beneficial effects of the initial normalizing treatment.

Double normalizing is usually applied to carbon and low-alloy steels of large dimension where extremely high forging temperatures have been used (Ref 4). Locomotive-axle forgings made of carbon steel to Association of American Railroads (AAR) Specification M-126, Class F (ASTM A 236, Class F), containing 0.45 to 0.59% C and 0.60 to 0.90% Mn, are double normalized to obtain a uniformly fine grain structure along with other exacting mechanical-property requirements. Forgings made of a low-carbon steel (0.18% C) with 1% Mn intended for low-temperature service are double normalized to meet subzero impact requirements.

Bar and Tubular Products

Frequently, the finishing stages of hot-mill operations employed in making steel bar and tube produce properties that closely approximate those obtained by normalizing. When this occurs, normalizing is unnecessary and may even be inadvisable. Nevertheless, the reasons for normalizing bar and tube products are generally the same as those applicable to other forms of steel.

The machinability of steel bars and tubular products depends on a combination of hardness properties and microstructure. For a low-carbon alloy steel, a coarse pearlitic structure obtained by normalizing or annealing maximizes machinability. In the case of medium-carbon alloy steel, a lamellar pearlitic structure obtained by annealing is desirable in order to optimize machinability. For a high-carbon alloy steel, a spheroidized structure lowers the hardness and increases the machinability of the alloy. Prior processing, part configuration, and processing following machining should be taken into consideration when determining the need for annealing or normalization.

In general, annealing improves machinability more than normalization does. Normalizing is used to correct the effects of spheroidization, but the steel bar or tube still needs to be annealed. Multiple anneals and tempering are normally used on only small-diameter parts such as wire gage products. Type 4340 is one of the few steels that is typically delivered to the customer with a normalized heat treatment due to machining specifications standard in the aircraft industry.

Tubes are easier to normalize than bars of equivalent diameter because the lighter section thickness of tubes permits more rapid heating and cooling. These advantages help minimize decarburization and promote more nearly uniform microstructures in tube products.

Furnaces Requirements. Continuous furnaces of the roller-hearth type are widely used for normalizing tube and bar products, especially in long lengths. Batch-type furnaces or other types of continuous furnaces are satisfactory if they provide some means for rapid discharge and separation of the load to permit free circulation of air around each tube as it cools. Continuous furnaces should have at least two zones, one for heating and one for soaking. Cooling facilities should be ample so that uniform cooling can proceed until complete transformation has occurred. If tubes are packed or bundled during cooling from a high temperature, the purpose of normalizing is defeated, and a semiannealed or a tempered product results.

Generally, protective atmospheres are not used in roller-hearth continuous furnaces for normalizing bar or tube products. The scale that forms during normalizing is removed by acid pickling or abrasive blast cleaning.

Castings

In industrial practice, steel castings may be normalized in car-bottom, box, pit, or continuous furnaces. The same heat-treating principles apply to each type of furnace.

Furnace Loading. Furnaces are loaded with castings in such a manner that each casting will receive an adequate and uniform heat supply. This may be accomplished by stacking castings in regular order or by interspersing large and small castings so that load concentration in any one area is not excessive. At normalizing temperatures, the tensile strength of steel is greatly reduced, and heavy unequal sections may become distorted unless bracing and support are provided. Accordingly, small and large castings may be arranged so that they support each other.

Loading Temperature. When castings are charged, the temperature of the furnace should be such that the thermal shock will not cause metal failure. For the higher-alloy grades of steel castings, such as C5, C12, and WC9, a safe furnace temperature for charging is 315 to 425 °C (600 to 800 °F). For lower-alloy grades, furnace temperatures may be as high as 650 °C (1200 °F). For cast carbon steels and low-alloy steels with low carbon contents (low hardenability), castings may be charged into a furnace operating at the normalizing temperature.

Heating. After the furnace has been charged, the temperature is increased at a rate of approximately 225 °C/h (400 °F/h) until the normalizing temperature is reached. Depending on steel composition and casting configuration, a reduction in the rate of heating to approximately 28 to 55 °C/h (50 to 100 °F/h) may be necessary to avoid cracking. Extremely large castings should be heated more slowly to prevent development of extreme temperature gradients.

Soaking. After the normalizing temperature has been reached, castings are soaked at this temperature for a period that will ensure complete austenitization and carbide solution. The duration of the soaking period may be predetermined by microscopic examination of specimens held for various times at the normalizing temperature.

Cooling. After the soaking period, the castings are unloaded and allowed to cool in still air. Use of fans, air blasts, or other means of accelerating the cooling process should be avoided.

Sheet and Strip

Hot-rolled steel sheet and strip (about 0.10% C) are normalized primarily to refine grain size, to minimize directional properties, and to develop desirable mechanical properties. Uniformly fine equiaxed ferrite grains are normally obtained in hot-rolled sheet and strip by finishing the final hot-rolling operation above the upper transformation temperature. However, if part of the hot-rolling operation is performed on steel that has transformed partially to ferrite, the deformed ferrite grains usually will recrystallize and form abnormally coarse-grained patches during the self-anneal induced by coiling or piling at temperatures of 650 to 730 °C (1200 to 1350 °F). Also, relatively thin hot-rolled material, if it is inadvertently finished well below the upper transformation temperature and coiled or piled while it is too cold to self-anneal, may possess directional properties. These conditions are unsuitable for some types of severe press-drawing applications and may be corrected by normalizing.

Normalizing also may be used to develop high strength in alloy steel sheet and strip if the products are sufficiently high in carbon and alloy contents to enable them to transform to fine pearlite or martensite when cooled in air from the normalizing temperature. In general, the hardened material is tempered to attain an optimum combination of strength and ductility. Typical mechanical properties of normalized 4130, modified 4335, and modified 4340 steel sheet are given in Table 5.

Table 5 Typical mechanical properties of normalized alloy steel sheet

Grade	Thickness		Tensile strength		Yield strength[a]		Elongation[b], %	Hardness, HRC
	mm	in.	MPa	ksi	MPa	ksi		

4130	4.9	0.193	835	121	585	85	14	25
4335[(c)]	4.6	0.180	1725	250	1240	180	8	48
4340[(c)]	2.0	0.080	1860	270	1345	195	7	50

(a) At 0.2% offset.

(b) In 50 mm or 2 in.

(c) Modified: 0.40% Mo, 0.20% V

Processing. The normalizing operation consists of passing the sheet or strip through an open, continuous furnace where the material is heated to a temperature approximately 55 to 85 °C (100 to 150 °F) above its upper transformation temperature, 845 to 900 °C (1550 to 1650 °F), thus obtaining complete solution of the original structure with the formation of austenite and then air cooling the material to room temperature.

Furnace Equipment. Normalizing furnaces are designed to heat and cool sheets singly or two in a pile. They are built in the form of long, low chambers and usually comprise three sections: a preheating zone (12 to 20% of the total length); a heating, or soaking, zone (about 40% of the total length); and a cooling zone, which occupies the remaining 40 to 50% of the length.

Heating Arrangements. Normalizing furnaces usually are heated with gas or oil and do not employ protective atmospheres. Therefore, sheets are scaled during heat treatment. Burners are arranged along each side of the heating zone; they usually are above the conveyor, but occasionally are both above and below it. The furnace roof, which is higher in the preheating and soaking zones than in the cooling zone, is usually built in sections. In most furnaces, both the preheating zone and the cooling zone are heated by the hot gases from the heating zone. However, both of these zones may be equipped with burners for more accurate temperature control. Air is excluded by regulating the draft to maintain a slight pressure within all zones.

Conveyor-Type Furnaces. In modern furnaces of the conveyor type (the only type suitable for treating short lengths), sheets are carried through each of the three zones on rotating disks made of heat-resistant alloys. These disks have polished surfaces, which prevent them from scratching the sheets, and are staggered to ensure uniform heating. The disks are mounted on water-cooled shafts, which are driven by variable-speed motors through chains and sprockets or shafts and gears. These furnaces may be up to 2.5 m (100 in.) wide and from 27 to 61 m (90 to 200 ft) long. Fuel consumption is 2.3 to 5.2×10^6 kJ/tonne (2.0 to 4.5×10^6 Btu/ton) of steel treated, and production rates vary from 2.7 to 10.9 tonnes (3 to 12 tons) per hour.

Normalizing in a three-zone conveyor-type furnace equipped with pyrometric controls is a relatively simple operation. If scratching of sheets is to be avoided, the sheets are brought to the charging table and hand laid, one or more at a time, on a rider or conveyor sheet. Heavy sheets are normalized singly, but lighter sheets may be stacked two in a pile. To control heating and retard scaling, single sheets may be laid on a rider sheet and covered with a cover sheet. Sheets are carried by disk-rollers into the preheating zone, where they absorb heat rapidly because of the large temperature differential between the sheets and the interior of the furnace and because of the large surface-to-volume ratio. As the sheets become heated and the temperature differential is reduced, the rate of heat absorption slackens. After traveling $4\frac{1}{2}$ to 6 m (15 to 20 ft), the sheets enter the soaking zone at a temperature several degrees below the normalizing temperature. Heating is completed in the soaking zone, which is maintained at a constant temperature, and sheets are held at the required temperature for a time sufficient to convert the microstructure to austenite before they are passed into the cooling zone. The sheets emerge from the cooling zone at a temperature that can be varied between 150 and 540 °C (300 and 1000 °F), and are conveyed for a short distance on the runout table, where, after being cooled rapidly in air, they are carefully

removed from the rider sheet. The trip through such a furnace is carried out at a uniform speed of 0.03 to 0.10 m/s (5 to 20 ft/min) and requires 5 to 20 min to complete.

Catenary Furnaces. The catenary, or freeloop, type of furnace is designed for continuous normalizing of cold-reduced steel unwound from coils; it does not have rolls or any other type of conveyor for supporting the material passing through the heating zone. The heating zones of catenary furnaces range in length from 6 to 15 m (20 to 50 ft). The preheating and cooling zones usually are shorter than those in conveyor-type furnaces, and for some kinds of work may be omitted entirely. At their exit ends, catenary furnaces may incorporate pickling or other descaling equipment for removing surface oxides formed on the steel during normalizing.

Annealing of Steel

Revised by B.L. Bramfitt, Bethlehem Steel Corporation; and Anil K. Hingwe, Molloy Manufacturing Company

---

Introduction

ANNEALING is a generic term denoting a treatment that consists of heating to and holding at a suitable temperature followed by cooling at an appropriate rate, primarily for the softening of metallic materials. Generally, in plain carbon steels, annealing produces a ferrite-pearlite microstructure (Fig. 1). Steels may be annealed to facilitate cold working or machining, to improve mechanical or electrical properties, or to promote dimensional stability. The choice of an annealing treatment that will provide an adequate combination of such properties at minimum expense often involves a compromise. Terms used to denote specific types of annealing applied to steels are descriptive of the method used, the equipment used, or the condition of the material after treatment.

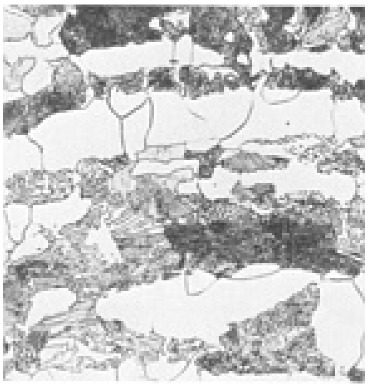

Fig. 1 A fully annealed 1040 steel showing a ferrite-pearlite microstructure. Etched in 4% picral plus 2% nital. 5OO×

Metallurgical Principles

The iron-carbon binary phase diagram (Fig. 2) can be used to better understand annealing processes. Although no annealing process ever achieves true equilibrium conditions, it can closely parallel these conditions. In defining the various types of annealing, the transformation temperatures or critical temperatures are usually used. (See the article "Principles of Heat Treating of Steels" in this Section.)

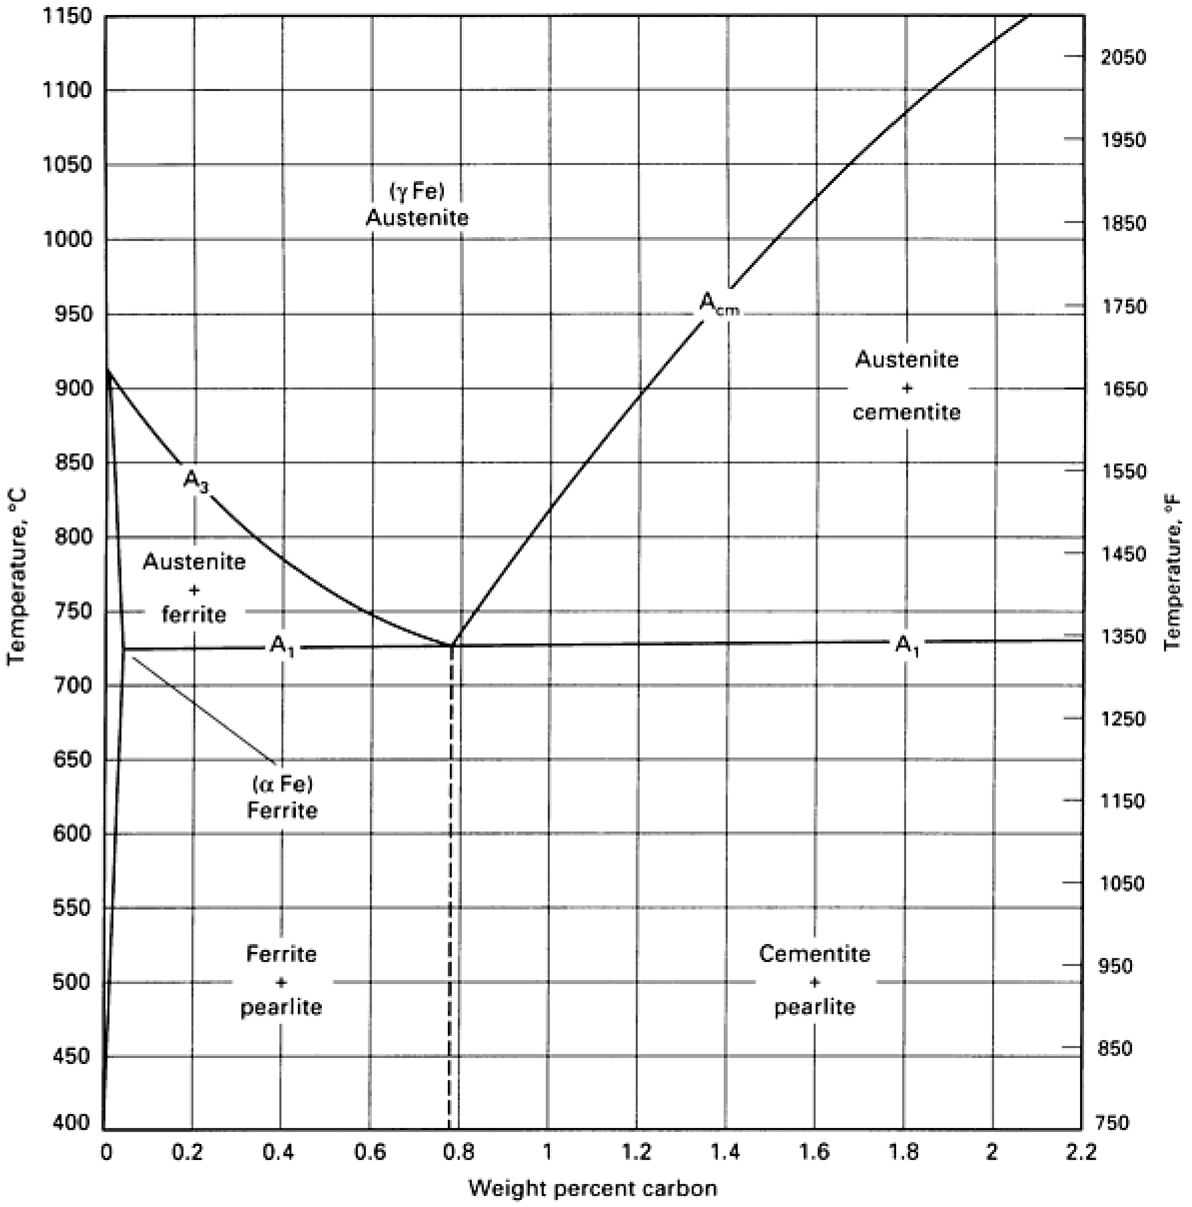

Fig. 2 Iron-carbon binary phase diagram.

Critical Temperatures. The critical temperatures that must be considered in discussing annealing of steel are those that define the onset and completion of the transformation to or from austenite. For a given steel, the critical temperatures depend on whether the steel is being heated or cooled. Critical temperatures for the start and completion of the transformation to austenite during heating are denoted, respectively, by Ac_1 and Ac_3 for hypoeutectoid steels and by Ac_1 and Ac_{cm} for hypereutectoid steels. These temperatures are higher than the corresponding critical temperatures for the start and completion of the transformation from austenite during cooling, which are denoted, respectively, by Ar_3 and Ar_1 for hypoeutectoid steels and by Ar_{cm} and Ar_1 for hypereutectoid steels. (The "c" and "r" in the symbols are derived from the French words *chauffage* for heating and *refroidissement* for cooling.) These critical temperatures converge to the equilibrium values Ae_1, Ae_3, and Ae_{cm} as the rates of heating or cooling become infinitely slow. The positions of the Ae_1, Ae_3, and Ae_{cm} lines are close to the more general (that is, near equilibrium) A_1, A_3, and A_{cm} lines on the iron-carbon binary phase diagram shown in Fig. 2. Various alloying elements markedly affect these critical temperatures. For example, chromium raises the eutectoid temperature, A_1, and manganese lowers it.

It is possible to calculate upper and lower critical temperatures using the actual chemical composition of the steel. The following equations will give an approximate critical temperature for a hypoeutectoid steel (Ref 1):

$$Ac_1(°C) = 723 - 20.7(\% Mn) - 16.9(\%Ni) + 29.1(\%Si) - 16.9(\%Cr)$$
Standard deviation = ± 11.5 °C

$$Ac_3(°C) = 910 - 203\sqrt{\%C} - 15.2(\% Ni) + 44.7(\% Si) + 104(\% V) + 31.5(\% Mo)$$
Standard deviation = ± 16.7 °C

The presence of other alloying elements will also have marked effects on these critical temperatures.

Table 1 provides approximate critical temperatures for selected steels, measured at heating and cooling rates of 28 °C/h (50 °F/h). The equilibrium critical temperatures generally lie about midway between those for heating and cooling at equal rates. Because annealing may involve various ranges of heating and cooling rates in combination with isothermal treatments, the less specific terms A_1, A_3, and A_{cm} are used here in discussing the basic concepts.

Table 1 Approximate critical temperatures for selected carbon and low-alloy steels

Annealing Cycles

In practice, specific thermal cycles of an almost infinite variety are used to achieve the various goals of annealing. These cycles fall into several broad categories that can be classified according to the temperature to which the steel is heated and the method of cooling used. The maximum temperature may be below the lower critical temperature, A_1 (subcritical annealing); above A_1 but below the upper critical temperature, A_3 in hypoeutectoid steels, or A_{cm} in hypereutectoid steels (intercritical annealing); or above A_3 (full annealing).

Because some austenite is present at temperatures above A_1, cooling practice through transformation is a crucial factor in achieving desired microstructure and properties. Accordingly, steels heated above A_1 are subjected either to slow continuous cooling or to isothermal treatment at some temperature below A_1 at which transformation to the desired microstructure can occur in a reasonable amount of time. Under certain conditions, two or more such cycles may be combined or used in succession to achieve the desired results. The success of any annealing operation depends on the proper choice and control of the thermal cycle, based on the metallurgical principles discussed in the following sections.

Subcritical Annealing

Subcritical annealing does not involve formation of austenite. The prior condition of the steel is modified by such thermally activated processes as recovery, recrystallization, grain growth, and agglomeration of carbides. The prior history of the steel is, therefore, an important factor.

In as-rolled or forged hypoeutectoid steels containing ferrite and pearlie, subcritical annealing can adjust the hardnesses of both constituents, but excessively long times at temperature may be required for substantial softening. The subcritical treatment is most effective when applied to hardened or cold-worked steels, which recrystallize readily to form new ferrite grains. The rate of softening increases rapidly as the annealing temperature approaches A_1. Cooling practice from the subcritical annealing temperature has very little effect on the established microstructure and resultant properties. A more detailed discussion of the metallurgical processes involved in subcritical annealing is provided in Ref 2.

lntercritical Annealing

Austenite begins to form when the temperature of the steel exceeds A_1. The solubility of carbon increases abruptly (nearly 1%) near the A_1 temperature. In hypoeutectoid steels, the equilibrium structure in the intercritical range between A_1 and A_3 consists of ferrite and austenite, and above A_3 the structure becomes completely austenitic. However, the equilibrium mixture of ferrite and austenite is not achieved instantaneously. For example, the rate of solution for a typical eutectoid steel is shown in Fig. 3. Undissolved carbides may persist, especially if the austenitizing time is short or the temperature is near A_1, causing the austenite to be inhomogeneous. In hypereutectoid steels, carbide and austenite coexist in the intercritical range between A_1 and A_{cm}; and the homogeneity of the austenite depends on time and temperature. The degree of homogeneity in the structure at the austenitizing temperature is an important consideration in the development of annealed structures and properties. The more homogeneous structures developed at higher austenitizing temperatures tend to promote lamellar carbide structures on cooling, whereas lower austenitizing temperatures in the intercritical range result in less homogeneous austenite, which promotes formation of spheroidal carbides.

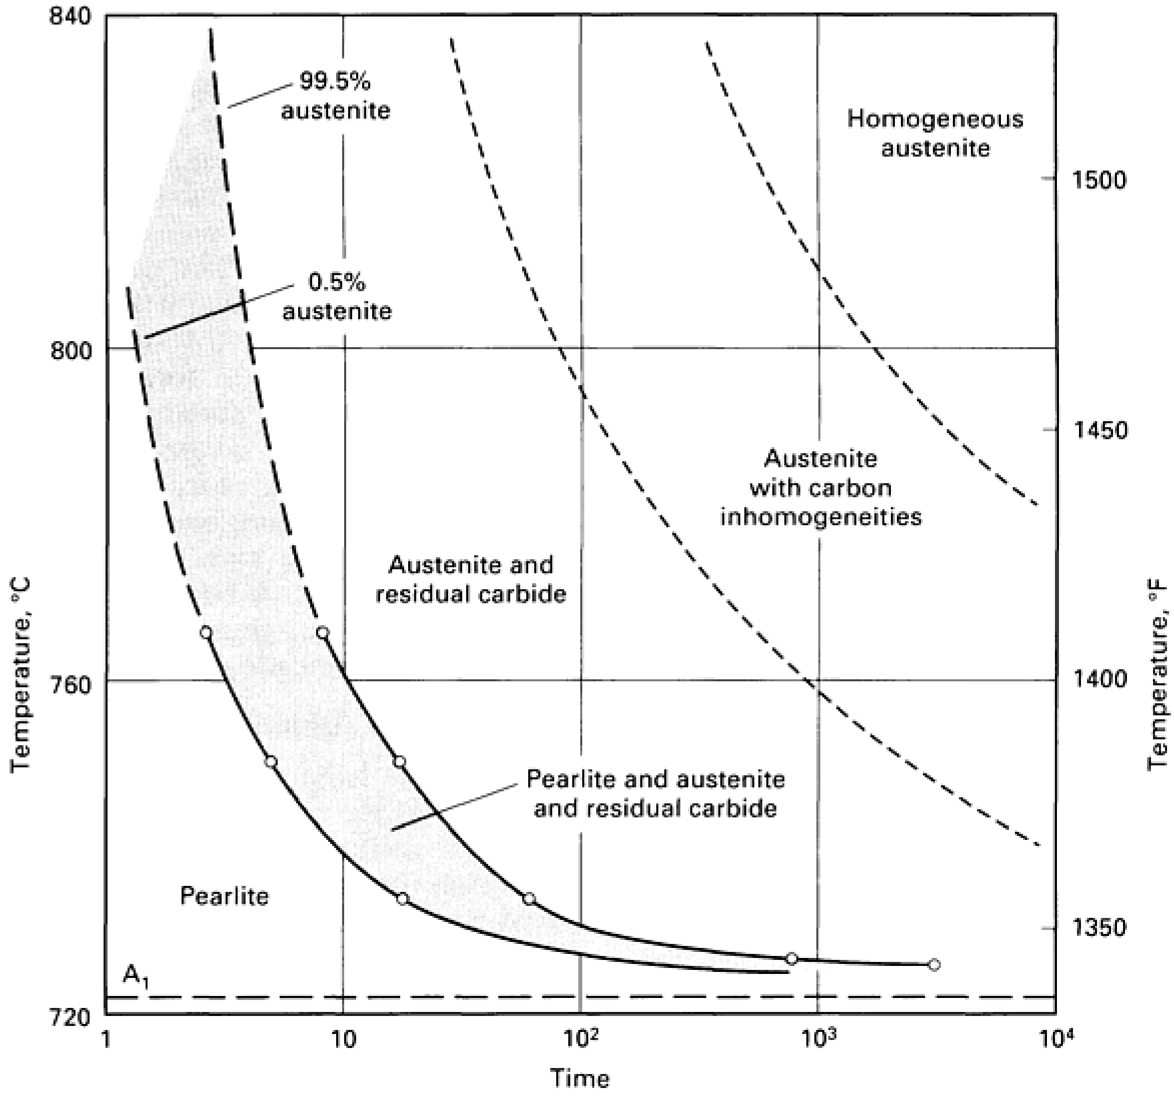

Fig. 3 Austenitizing rate-temperature curves for commercial plain carbon eutectoid steel. Prior treatment was normalizing from 875 °C (1610 °F); initial structure, fine pearlite. First curve at left shows beginning of disappearance of pearlite; second curve, final disappearance of pearlite; third curve, final disappearance of carbide; fourth curve, final disappearance of carbon concentration gradients.

Austenite formed when steel is heated above the A_1 temperature transforms back to ferrite and carbide when the steel is slowly cooled below A_1. The rate of austenite decomposition and the tendency of the carbide structure to be either lamellar or spheroidal depend largely on the temperature of transformation. If the austenite transforms just below A_1, it will decompose slowly. The product then may contain relatively coarse spheroidal carbides or coarse lamellar pearlite, depending on the composition of the steel and the austenitizing temperature. This product tends to be very soft. However, the low rate of transformation at temperatures just below A_1 necessitates long holding times in isothermal treatments, or very slow cooling rates in continuous cooling, if maximum softness is desired. Isothermal treatments are more efficient than slow continuous cooling in terms of achieving desired structures and softness in the minimum amount of time. Sometimes, however, the available equipment or the mass of the steel part being annealed may make slow continuous cooling the only feasible alternative.

As the transformation temperature decreases, austenite generally decomposes more rapidly, and the transformation product is harder, more lamellar, and less coarse than the product formed just below A_1. At still lower transformation temperatures, the product becomes a much harder mixture of ferrite and carbide, and the time necessary for complete isothermal transformation may again increase.

Temperature-time plots showing the progress of austenite transformation under isothermal (IT) or continuous transformation (CT) conditions for many steels have been widely published (Ref 3, 4) and illustrate the principles just

discussed. These IT or CT diagrams may be helpful in design of annealing treatments for specific grades of steel, but their usefulness is limited because most published diagrams represent transformation from a fully austenitized, relatively homogeneous condition, which is not always desirable or obtainable in annealing.

In the continuous annealing process, which is discussed in detail in the following article in this Section, an intercritical annealing practice is used to develop dual-phase and tri-phase microstructures. In this practice, the steel is rapidly cooled from the intercritical temperature. The rapid cooling results in the transformation of the pools of austenite to martensite. The final microstructure consists of islands of martensite in a ferritic matrix. Depending upon the alloy content of the austenite pools and the cooling conditions, the austenite may not fully transform and the microstructure will consist of martensite/retained austenite regions in a ferritic matrix.

Cooling after Full Transformation. After the austenite has been completely transformed, little else of metallurgical consequence can occur during cooling to room temperature. Extremely slow cooling may cause some agglomeration of carbides, and consequently, some slight further softening of the steel, but in this regard such slow cooling is less effective than high-temperature transformation. Therefore, there is no metallurgical reason for slow cooling after transformation has been completed, and the steel may be cooled from the transformation temperature as rapidly as feasible in order to minimize the total time required for the operation.

If transformation by slow continuous cooling has been used, the temperature at which controlled cooling may be stopped depends on the transformation characteristics of the steel. However, the mass of the steel or the need to avoid oxidation are practical considerations that may require retarded cooling to be continued below the temperature at which the austenite transformation ceases.

Effect of Prior Structure. The finer and more evenly distributed the carbides in the prior structure, the faster the rate at which austenite formed above A_1 will approach complete homogeneity. The prior structure, therefore, can affect the response to annealing. When spheroidal carbides are desired in the annealed structure, preheating at temperatures just below A_1 sometimes is used to agglomerate the prior carbides in order to increase their resistance to solution in the austenite on subsequent heating. The presence of undissolved carbides or concentration gradients in the austenite promotes formation of a spheroidal, rather than lamellar, structure when the austenite is transformed. Preheating to enhance spheroidization is applicable mainly to hypoeutectoid steels but also is useful for some hypereutectoid low-alloy steels.

Supercritical or Full Annealing

A common annealing practice is to heat hypoeutectoid steels above the upper critical temperature (A_3) to attain full austenitization. The process is called full annealing. In hypoeutectoid steels (under 0.77% C), supercritical annealing (that is, above the A_3 temperature) takes place in the austenite region (the steel is fully austenitic at the annealing temperature). However, in hypereutectoid steels (above 0.77% C), the annealing takes place above the A_1 temperature, which is the dual-phase austenite-cementite region. Figure 4 shows the annealing temperature range for full annealing superimposed in the iron-carbon binary phase diagram from Fig. 2. In general, an annealing temperature 50 °C (90 °F) above the A_3 for hypoeutectic steels and A_1 for hypereutectoid steels is adequate.

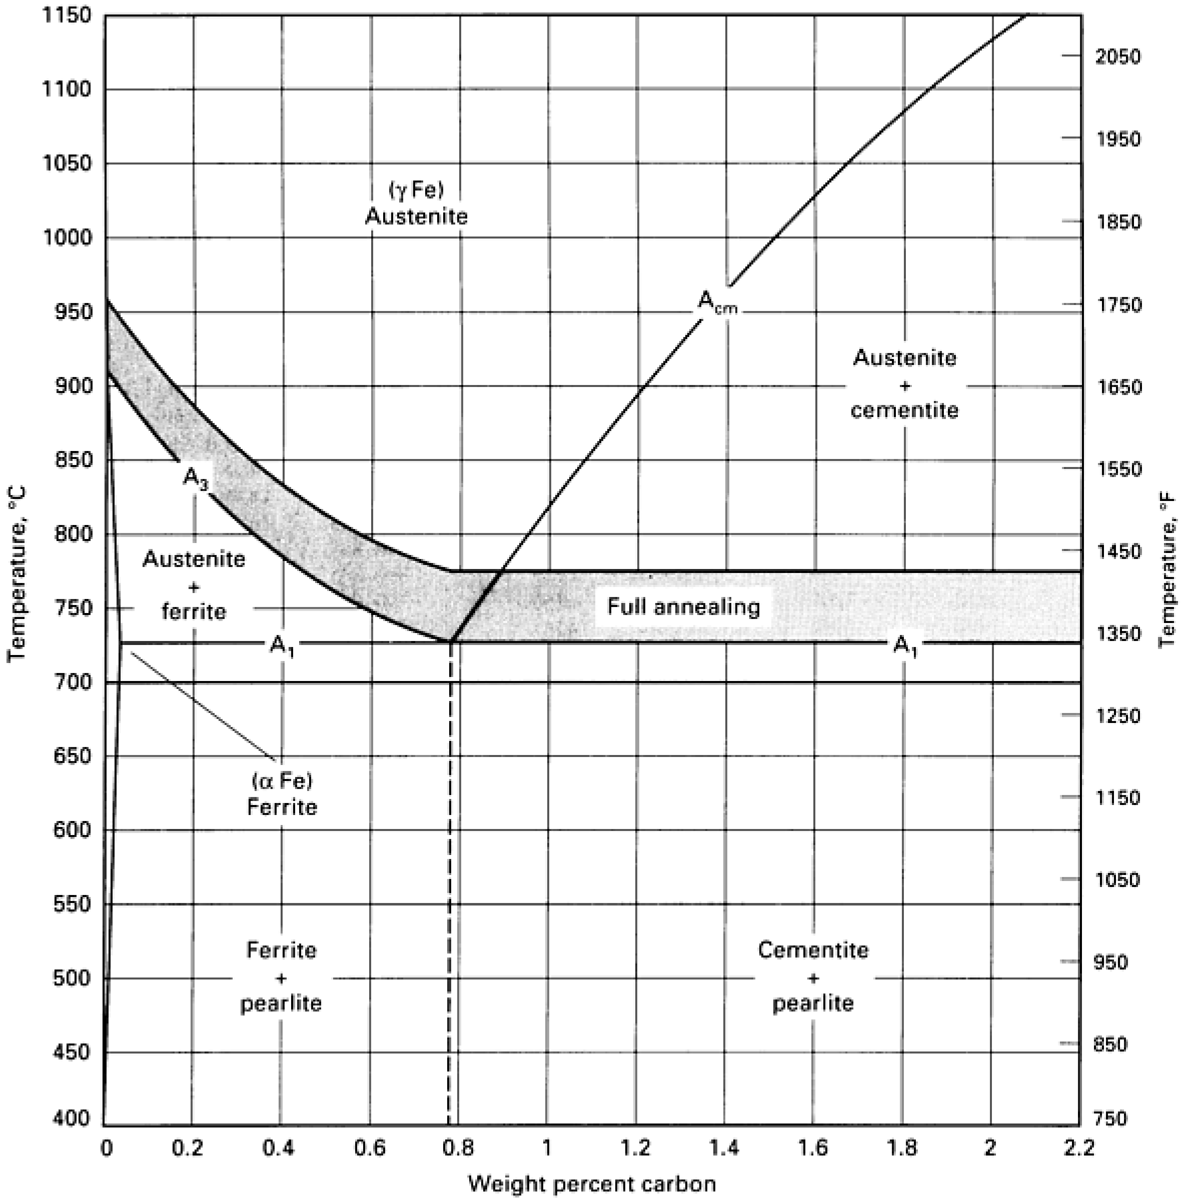

Fig. 4 The iron-carbon binary phase diagram showing region of temperatures for full annealing (Ref 5)

Austenitizing Time and Dead-Soft Steel. Hypereutectoid steels can be made extremely soft by holding for long periods of time at the austenitizing temperature. Although the time at the austenitizing temperature may have only a small effect on actual hardnesses (such as a change from 241 to 229 HB), its effect on machinability or cold-forming properties may be appreciable.

Long-term austenitizing is effective in hypereutectoid steels because it produces agglomeration of residual carbides in the austenite. Coarser carbides promote a softer final product. In lower-carbon steels, carbides are unstable at temperatures above A_1 and tend to dissolve in the austenite, although the dissolution may be slow.

Steels that have approximately eutectoid carbon contents generally form a lamellar transformation product if austenitized for very long periods of time. Long-term holding at a temperature just above the A_1 temperature may be as effective in dissolving carbides and dissipating carbon-concentration gradients as is short-term holding at a higher temperature.

Guidelines for Annealing

The metallurgical principles discussed above have been incorporated by Payson (Ref 6) into the following seven rules, which may be used as guidelines for development of successful and efficient annealing schedules:

- *Rule 1:* The more homogeneous the structure of the as-austenitized steel, the more completely lamellar will be the structure of the annealed steel. Conversely, the more heterogeneous the structure of the as-austenitized steel, the more nearly spheroidal will be the annealed carbide structure
- *Rule 2:* The softest condition in the steel is usually developed by austenitizing at a temperature less than 55 °C (100 °F) above A_1 and transforming at a temperature (usually) less than 55 °C (100 °F) below A_1
- *Rule 3:* Because very long times may be required for complete transformation at temperatures less than 55 °C (100 °F) below A_1, allow most of the transformation to take place at the higher temperature, where a soft product is formed, and finish the transformation at a lower temperature, where the time required for completion of transformation is short
- *Rule 4:* After the steel has been austenitized, cool to the transformation temperature as rapidly as feasible in order to minimize the total duration of the annealing operation
- *Rule 5:* After the steel has been completely transformed, at a temperature that produces the desired microstructure and hardness, cool to room temperature as rapidly as feasible to decrease further the total time of annealing
- *Rule 6:* To ensure a minimum of lamellar pearlite in the structures of annealed 0.70 to 0.90% C tool steels and other low-alloy medium-carbon steels, preheat for several hours at a temperature about 28 °C (50 °F) below the lower critical temperature (A_1) before austenitizing and transforming as usual
- *Rule 7:* To obtain minimum hardness in annealed hypereutectoid alloy tool steels, heat at the austenitizing temperature for a long time (about 10 to 15 h), then transform as usual

These rules are applied most effectively when the critical temperatures and transformation characteristics of the steel have been established and when transformation by isothermal treatment is feasible.

Annealing Temperatures

From a practical sense, most annealing practices have been established from experience. For many annealing applications, it is sufficient simply to specify that the steel be cooled in the furnace from a designated annealing (austenitizing) temperature. Temperatures and associated Brinell hardnesses for simple annealing of carbon steels are given in Table 2, and similar data for alloy steels are presented in Table 3.

Table 2 Recommended temperatures and cooling cycles for full annealing of small carbon steel forgings

Data are for forgings up to 75 mm (3 in.) in section thickness. Time at temperature usually is a minimum of 1 h for sections up to 25 mm (1 in.) thick; $\frac{1}{2}$ h is added for each additional 25 mm (1 in.) of thickness.

Heating cycles that employ austenitizing temperatures in the upper ends of the ranges given in Table 3 should result in pearlitic structures. Predominantly spheroidized structures should be obtained when lower temperatures are used.

When an alloy steel is annealed to obtain a specific microstructure, greater precision is required in specifying temperatures and cooling conditions for annealing. Table 4 presents, for a variety of standard alloy steels, typical schedules for such annealing operations.

Table 4 Recommended temperatures and time cycles for annealing of alloy steels

(a) The steel is cooled in the furnace at the indicated rate through the temperature range shown.

(b) The steel is cooled rapidly to the temperature indicated and is held at that temperature for the time specified.

(c) In isothermal annealing to obtain pearlitic structure, steels may be austenitized at temperatures up to 70 °C (125 °F) higher than temperatures listed.

(d) Seldom annealed. Structures of better machinability are developed by normalizing or by transforming isothermally after rolling or forging.

(e) Annealing is impractical by the conventional process of continuous slow cooling. The lower transformation temperature is markedly depressed, and excessively long cooling cycles are required to obtain transformation to pearlite.

(f) Predominantly pearlitic structures are seldom desired in this steel.

In isothermal annealing to produce a pearlitic structure, particularly in forgings, an austenitizing temperature as much as 70 °C (125 °F) higher than that indicated in Table 4 may be selected in order to decrease the austenitizing time.

For most steels, as indicated in Table 4, annealing may be accomplished by heating to the austenitizing temperature and then either cooling in the furnace at a controlled rate or cooling rapidly to, and holding at, a lower temperature for isothermal transformation. Both procedures result in virtually the same hardness; however, considerably less time is required for isothermal transformation.

Uniformity of Temperature. One potential contribution to the failure of an annealing operation is a lack of knowledge of the temperature distribution within the load of steel in the furnace. Furnaces large enough to anneal 18 Mg (20 tons) of steel at a time are not uncommon. In some large forging shops, workpieces can weigh in excess of 270 Mg (300 tons). The larger the furnace, the more difficult it is to establish and maintain uniform temperature conditions throughout the load, and the more difficult it is to change the temperature of the steel during either heating or cooling.

Furnace thermocouples indicate the temperature of the space above, below, or beside the load, but this temperature may differ by 28 °C (50 °F) or more from the temperature of the steel itself, especially when the steel is in a pipe or box, or when bar or strip is packed in a dense charge in a quiescent atmosphere. When these conditions exist, the distribution of temperature throughout the load during heating and cooling should be established by placing thermocouples among the bars, forgings, coils, and so on. A good practice is to spot weld a thermocouple to the workpiece or to use embedded thermocouples (thermocouples placed in holes drilled into the workpiece). Regulation of the furnace during the annealing operation should be based on the temperatures indicated by these thermocouples, which are in actual contact with the steel, rather than on the temperatures indicated by the furnace thermocouples.

Spheroidizing

The majority of all spheroidizing activity is performed for improving the cold formability of steels. It is also performed to improve the machinability of hypereutectoid steels, as well as tool steels. A spheroidized microstructure is desirable for cold forming because it lowers the flow stress of the material. The flow stress is determined by the proportion and distribution of ferrite and carbides. The strength of the ferrite depends on its grain size and the rate of cooling. Whether the carbides are present as lamellae in pearlite or spheroids radically affects the formability of steel.

Steels may be spheroidized, that is, heated and cooled to produce a structure of globular carbides in a ferritic matrix. Figure 5 shows 1040 steel in the fully spheroidized condition. Spheroidization can take place by the following methods:

- Prolonged holding at a temperature just below Ae_1
- Heating and cooling alternately between temperatures that are just above Ac_1 and just below Ar_1
- Heating to a temperature just above Ac_1, and then either cooling very slowly in the furnace or holding at a temperature just below Ar_1
- Cooling at a suitable rate from the minimum temperature at which all carbide is dissolved to prevent reformation of a carbide network, and then reheating in accordance with the first or second methods above (applicable to hypereutectoid steel containing a carbide network)

It should be noted that it is difficult to establish consistent designations for critical temperatures. In discussions about heating with prolonged holding, the critical temperatures of interest should be the equilibrium temperatures Ae_1 and Ae_3. Terminology becomes more arbitrary in discussions of heating and cooling at unspecified rates and for unspecified holding times.

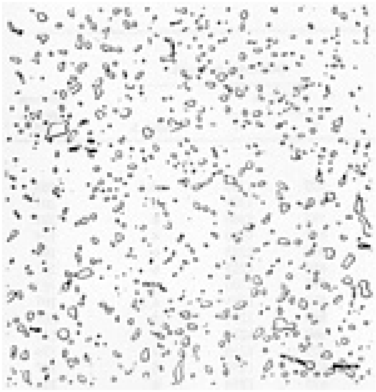

Fig. 5 Spheroidized microstructure of 1040 steel after 21 h at 700 °C (1290 °F). 4% picral etch. 1000×

Figure 6 shows the range of temperatures used for spheroidization of hypoeutectoid and hypereutectoid steels. The rates of spheroidizing provided by these methods depend somewhat on prior microstructure, being greatest for quenched structures in which the carbide phase is fine and dispersed. Prior cold work also increases the rate of the spheroidizing reaction in a subcritical spheroidizing treatment.

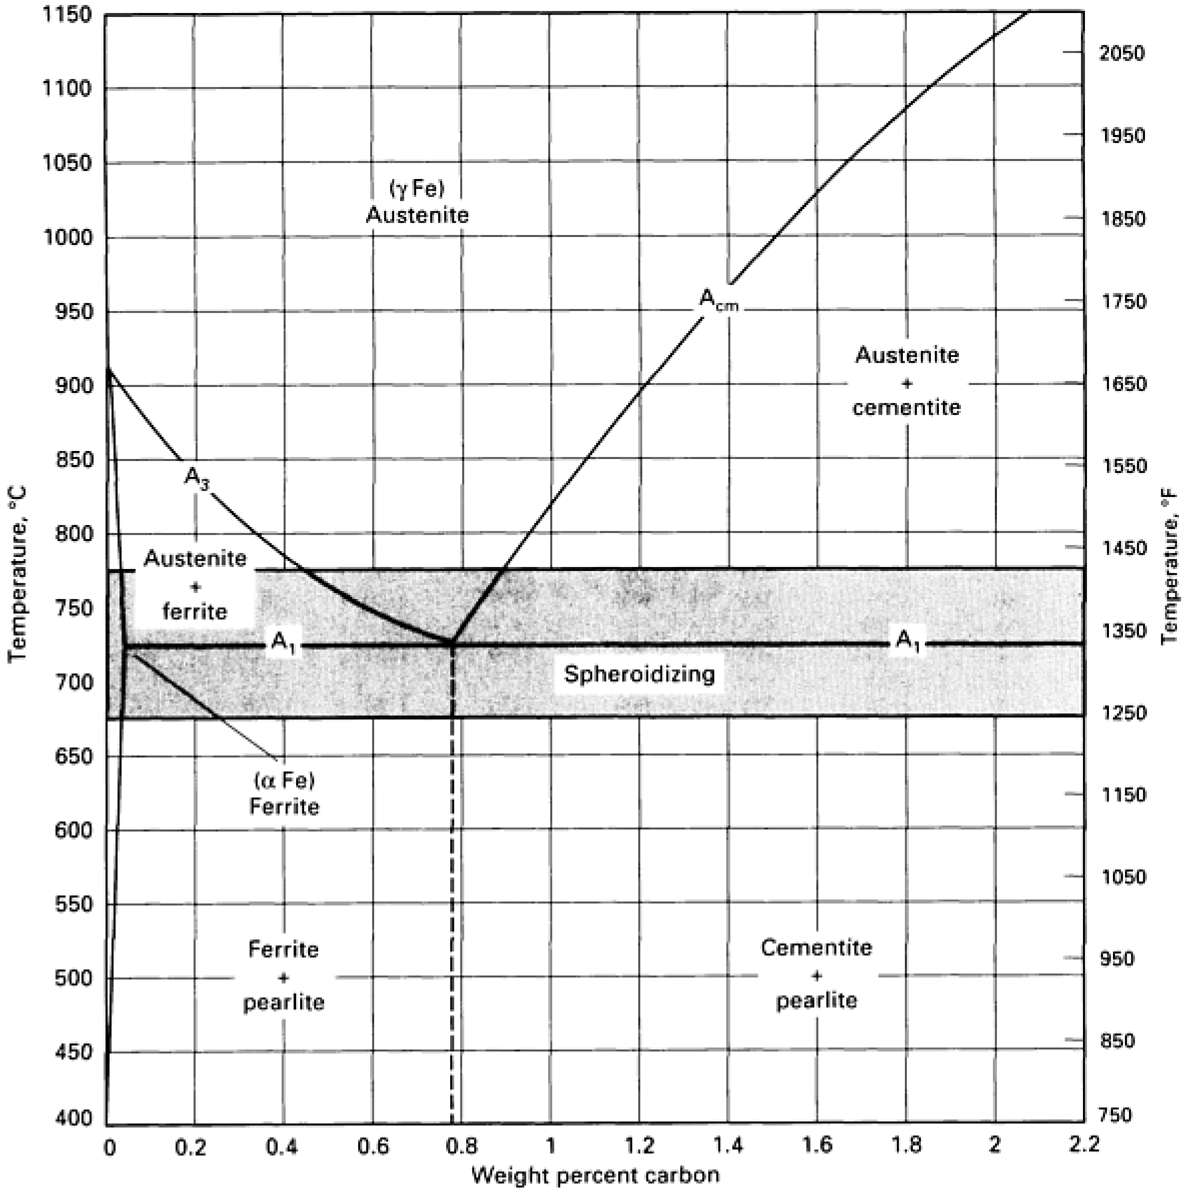

Fig. 6 The iron-carbon binary phase diagram showing region of temperatures for spheroidizing (Ref 5)

An example of the effect of prior microstructure on spheroidization is given in Fig. 7 for the same 1040 steel shown in Fig. 1 (further examples are found in Ref 7). The photomicrograph in Fig. 7(a) shows the extent of spheroidization of the 1040 steel with a prior martensitic microstructure after holding 21 h at 700 °C (1290 °F). Figure 7(b) shows the extent of spheroidization after the same time/temperature heating cycle with a prior ferrite-pearlite microstructure. Spheroidization has occurred in the 1040 steel with the prior martensitic microstructure. On the other hand, it has only just begun in the same steel with the prior fenite-pearlite microstructure. Figure 8 shows that after 200 h at 700 °C (1290 °F) the spheroidization process is almost completed in the prior ferrite-pearlite steel; however, traces of the pearlitic areas can still be seen.

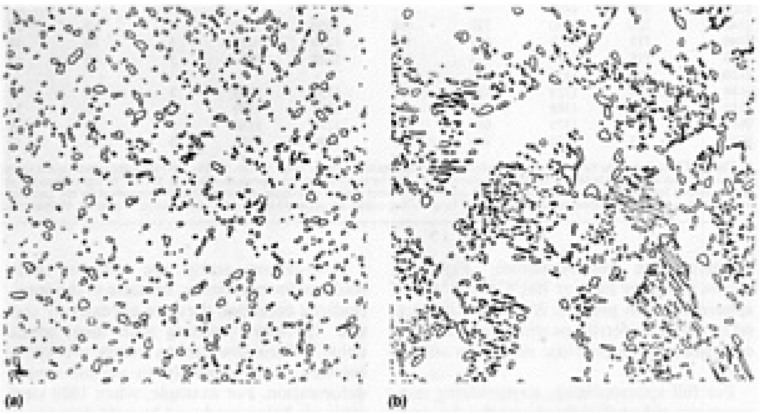

Fig. 7 Effect of prior microstructure on spheroidizing a 1040 steel at 700 °C (1290 °F) for 21 h. (a) Starting from a martensitic microstructure (as-quenched). (b) Starting from a ferrite-pearlite microstructure (fully annealed). Etched in 4% picral plus 2% nital. 1000×

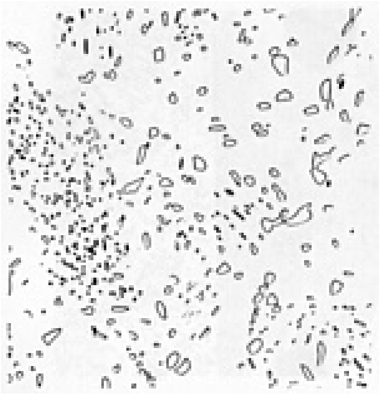

Fig. 8 The extent of spheroidization at 700 °C (1290 °F) for 200 h for the 1040 steel starting from a ferrite-pearlite microstructure etched in 4% picral. 1000×

For full spheroidizing, austenitizing temperatures either slightly above the Ac_1 temperature or about midway between Ac_1 and Ac_3 are used. If a temperature slightly above Ac_1 is to be used, good loading characteristics and accurate temperature controls are required for proper results; otherwise, it is conceivable that Ac_1 may not be reached and that austenitization may not occur.

Low-carbon steels are seldom spheroidized for machining, because in the spheroidized condition they are excessively soft and "gummy," cutting with long, tough chips. When low-carbon steels are spheroidized, it is generally to permit severe deformation. For example, when 1020 steel tubing is being produced by cold drawing in two or three passes, a spheroidized structure will be obtained if the material is annealed for $\frac{1}{2}$ to 1 h at 690 °C (1275 °F) after each pass. The final product will have a hardness of about 163 HB Tubing in this condition will be able to withstand severe deformation during subsequent cold forming.

As with many other types of heat treatment, hardness after spheroidizing depends on carbon and alloy content. Increasing the carbon or alloy content, or both, results in an increase in the as-spheroidized hardness, which generally ranges from 163 to 212 HB (Table 4).

Process Annealing

As the hardness of steel increases during cold working, ductility decreases and additional cold reduction becomes so difficult that the material must be annealed to restore its ductility. Such annealing between processing steps is referred to as in-process or simply process annealing. It may consist of any appropriate treatment. In most instances, however, a subcritical treatment is adequate and least costly, and the term "process annealing" without further qualification usually refers to an in-process subcritical anneal. Figure 9 shows the range of temperatures typically used for process annealing. It is often necessary to specify process annealing for parts that are cold formed by stamping, heading, or extrusion. Hot-worked high-carbon and alloy steels also are process annealed to prevent them from cracking and to soften them for shearing, turning, or straightening.

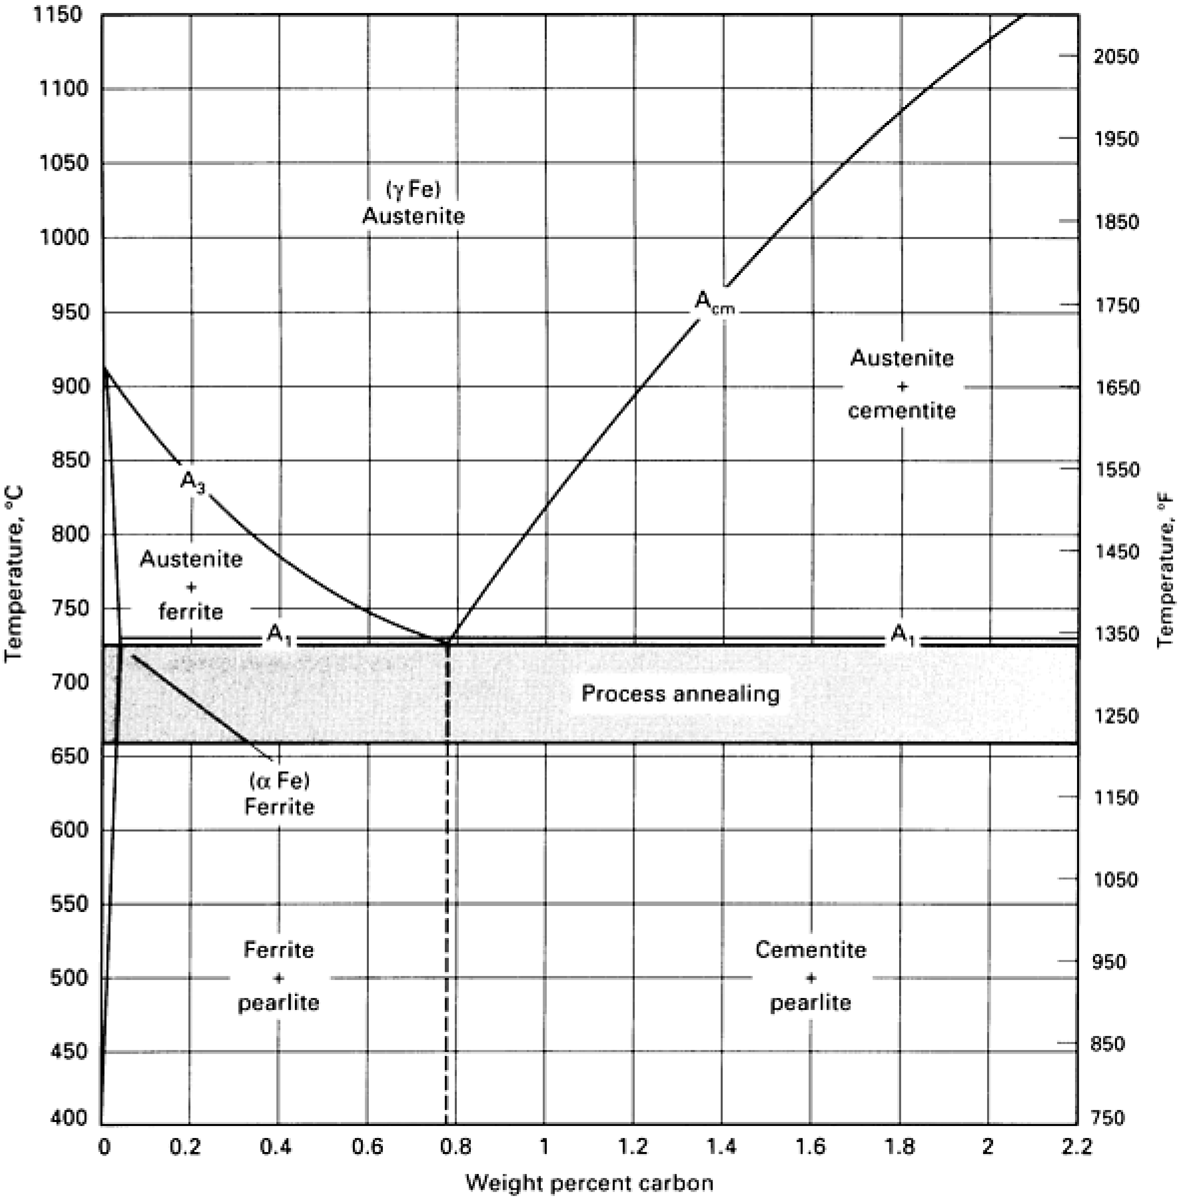

Fig. 9 The iron-carbon binary phase diagram showing region of temperature for process annealing (Ref 5)

Process annealing usually consists of heating to a temperature below Ae_1, soaking for an appropriate time and then cooling, usually in air. In most instances, heating to a temperature between 10 and 20 °C (20 and 40 °F) below Ae_1 produces the best combination of microstructure hardness, and mechanical properties. Temperature controls are necessary only to prevent heating the material above Ae_1 and thus defeating the purpose of annealing.

When process annealing is performed merely to soften a material for such operations as cold sawing and cold shearing, temperatures well below Ae_1 normally are used and close controls are unnecessary.

In the wire industry, process annealing is used as an intermediate treatment between the drawing of wire to a size slightly larger than the desired finished size and the drawing of a light reduction to the finished size. Wire thus made is known as annealed in process wire. Process annealing is used also in the production of wire sufficiently soft for severe upsetting and to permit drawing the smaller sizes of low-carbon and medium-carbon steel wire that cannot be drawn to the desired small size directly from the hot-rolled rod. Process annealing is more satisfactory than spheroidize annealing for a material that, because of its composition or size (or both), cannot be drawn to finished size because it either lacks ductility or does not meet physical requirements. Also, material that is cold sheared during processing is process annealed to raise the ductility of the sheared surface to a level suitable for further processing.

Annealed Structures for Machining

Different combinations of microstructure and hardness, considered together, are significant in terms of machinability. For instance, Fig. 10 shows that a partially spheroidized 5160 steel shaft was machined (by turning) with much less tool wear and better surface finish than the same steel in the annealed condition with a pearlitic microstructure and a higher hardness. Based on many observations, optimum microstructure for machining steels of various carbon contents are usually as follows:

Carbon, %	Optimum microstructure
0.06-0.20	As-rolled (most economical)
0.20-0.30	Under 75 mm (3 in.) diameter, normalized; 75 mm diameter and over, as-rolled
0.30-0.40	Annealed, to produce coarse pearlite, minimum ferrite
0.40-0.60	Coarse lamellar pearlite to coarse spheroidized carbides
0.60-1.00	100% spheroidized carbides, coarse to fine

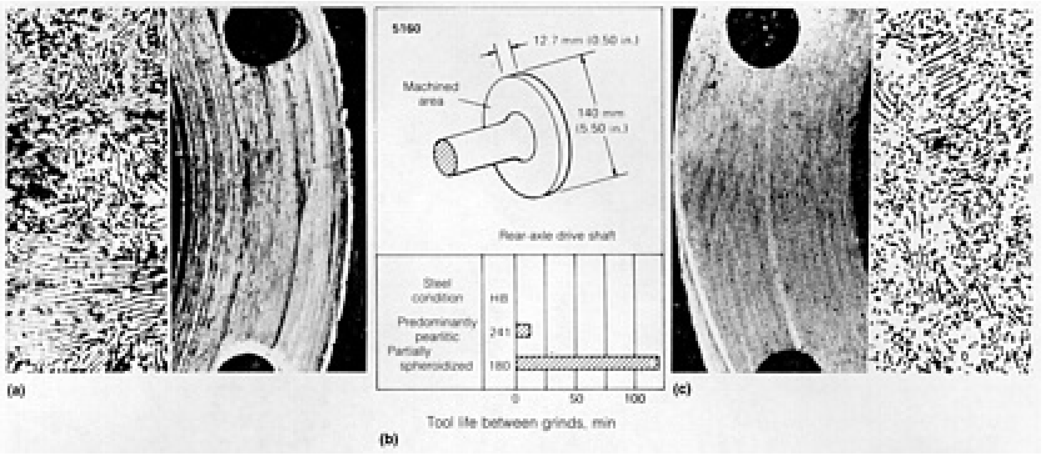

Fig. 10 The effect of partial spheroidization on surface finish and tool life in subsequent machining of 5160 steel. (a) Annealed (pearlitic) microstructure (hardness: 241 HB), and surface finish of flange after machining of eight pieces. (b) Tool life between grinds, min. (c) Partially spheroidized microstructure (hardness: 180 HB) and surface finish of flange after machining of 123 pieces

The type of machining operation is also a factor. For example, certain gears were made from 5160 steel tubing by the dual operation of machining in automatic screw machines and broaching of cross slots. The screw-machine operations were easiest with thoroughly spheroidized material, but a pearlitic structure was more suitable for broaching. A semispheroidized structure proved to be a satisfactory compromise.

Semispheroidized structures can be achieved by austenitizing at lower temperatures, and sometimes at higher cooling rates, than those used for achieving pearlitic structures. The semispheroidized structure of the 5160 steel tubing mentioned above was obtained by heating to 790 °C (1450 °F) and cooling at 28 °C/h (50 °F/h) to 650 °C (1200 °F). For this steel, austenitizing at a temperature of about 775 °C (1425 °F) results in more spheroidization and less pearlite.

Medium-carbon steels are much more difficult to fully spheroidize than are high-carbon steels such as 1095 and 52100. In the absence of excess carbides to nucleate and promote the spheroidizing reaction, it is more difficult to achieve complete freedom from pearlite in practical heat-treating cycles.

At lower carbon levels, structures consisting of coarse pearlite in a ferrite matrix often are found to be the most machinable. In some alloy steels, this type of structure can best be achieved by heating to temperatures well above Ac_3 to establish a coarse austenite grain size, then holding below Ar_1 to allow coarse, lamellar pearlite to form. This process sometimes is referred to as cycle annealing or lamellar annealing. For example, forged 4620 steel gears were heated rapidly in a five-zone furnace to 980 °C (1800 °F), cooled to 625 to 640 °C (1160 to 1180 °F) in a water-cooled zone, and held at that temperature for 120 to 150 min. The resulting structure--coarse, lamellar pearlite in a ferrite matrix--had a hardness of 140 to 146 HB (Ref 8).

Types of Furnaces

Furnaces for annealing are of two basic types: batch furnaces and continuous furnaces. Within either of these two types, furnaces can be further classified according to configuration, type of fuel used, method of heat application, and means by which the load is moved through, or supported in, the furnace. Other factors that must be considered in furnace selection are cost, type of annealing cycle, required atmosphere, and physical nature of parts to be annealed. In many cases, however, the annealing cycle used is dictated by the available equipment.

Batch-type furnaces are necessary for large parts such as heavy forgings and often are preferred for small lots of a given part or grade of steel and for the more complex alloy grades requiring long cycles. Specific types of batch furnaces

include car-bottom, box, bell, and pit furnaces. Annealing in bell furnaces can produce the greatest degree of spheroidization (up to 100%). However, the spheroidizing cycles in bell furnaces are long and last from 24 to 48 h depending on the grade of material being annealed and the size of the load.

Continuous furnaces such as roller-hearth, rotary-hearth, and pusher types are ideal for isothermal annealing of large quantities of parts of the same grade of steel. These furnaces can be designed with various individual zones, allowing the work to be consecutively brought to temperature, held at temperature, and cooled at the desired rate. Continuous furnaces are not able to give complete spheroidization and should not be used for products that require severe cold forming. For more detailed discussion of the types of furnaces available for annealing, see Ref 9 and the article "Types of Heat-Treating Furnaces" in this Volume.

Furnace Atmospheres

Electric furnaces used with air atmospheres, and gas furnaces used with atmospheres consisting of the products of combustion, cannot be regulated for complete elimination of oxidation of the steel being treated. Only atmospheres independent of the fuel are generally considered satisfactory for clean or bright annealing. Excessive oxidation during annealing usually is prevented by the use of controlled atmospheres in conjunction with a suitable furnace that is designed to exclude air and combustion gases from the heating chamber. The gases and gas mixtures used for controlled atmospheres depend on the metal being treated, the treatment temperature, and the surface requirements of the parts being annealed. The need to eliminate decarburization as well as oxidation is often a significant factor in the selection of annealing atmospheres.

The gas most widely used as a protective atmosphere for annealing is exothermic gas. This gas is inexpensive, the raw materials for making it are readily available, and the results obtained with it are generally excellent. Hydrocarbon gases such as natural gas, propane, butane, and coke-oven gas are commonly burned in an exothermic-gas producer, creating a self-supporting, heat-producing combustion reaction. A commonly used exothermic gas mixture contains 15% H_2, 10% CO, 5% CO_2, 1% CH_4, and 69% N_2. This gas is used for bright annealing of cold-rolled low-carbon steel strip. It will decarburize medium-carbon and high-carbon steels, however, because of the carbon dioxide and water vapor it contains.

Exothermic gas sometimes is refrigerated to reduce its moisture content, particularly in geographic areas where the temperature of the water used for cooling is high. When decarburization of workpiece surfaces must be prevented, water vapor and carbon dioxide must be completely removed from the gas. Purified exothermic gas, with its carbon dioxide and water vapor removed, has many applications in heat treatment of steel without decarburization.

Purified rich exothermic gas, formed by partial combustion, is used for short-cycle annealing and process annealing of medium- and high-carbon steels of the straight-carbon and alloy types. For long-cycle batch annealing, however, this gas is unsuitable because its high carbon monoxide content results in soot deposits on the work and because of the possibility of surface etching as a result of the relatively long time for which the work is in the critical low-temperature range where gas reactions can occur. In short-cycle annealing these effects are minimal, and the high-CO gas is then desirable because of its high carbon potential. The fairly lean purified gas formed by more complete combustion is used for long-cycle annealing of medium- and high-carbon steels of the straight-carbon and alloy types, and for batch and continuous annealing of low-carbon steel strip for tin plating.

Allowable decarburization on spheroidize annealed blanks or coiled rod can be quite restrictive. As long as the furnace has excellent sealing characteristics, low dewpoint exothermic gas can protect the steel from decarburization. Many commercial heat treaters compensate for the sealing problems of furnaces by using a blend of exothermic and endothermic gases. Depending on the carbon content of the stock that is being processed, the blend can be varied. A great deal of caution has to be exercised when such blends are used because endothermic gas forms an explosive mixture with air as the temperature drops below 760 °C (1400 °F).

Other atmospheres commonly used in annealing include endothermic-base, dissociated ammonia, and vacuum atmospheres. Nitrogen-base atmospheres became popular among heat treaters in the 1980s due in part to rising costs of utilities such as natural gas and water. The nitrogen is blended with small percentages of additives such as methane,

propane, propylene, and carbon monoxide. For more complete information, see the article "Furnace Atmospheres" in this Volume.

Annealing of Sheet and Strip

In terms of total tonnage of material processed, annealing of sheet and strip during production of steel-mill products represents the major use of annealing. Because such annealing is done to prepare the material for further processing (such as additional cold rolling or fabrication into parts), and because the temperatures employed are usually below the A_1 temperature, the more specific terms subcritical annealing and process annealing are appropriate, although common practice is to use the term annealing without qualification.

In annealing of sheet and strip, two techniques predominate: the batch process and the continuous process. In the batch process (also called box annealing), coils or cut lengths of sheet are placed on an annealing base and covered with containers that are sealed to hold the appropriate atmosphere. A furnace is then placed over the covered steel. A protective atmosphere is introduced within the inner covers to protect the steel from oxidation and is circulated through the coils by use of fans and convector plates. Heating is provided by the outer furnace and may be done either through the use of radiant tubes or by direct firing. The charge is heated to the required temperature and held for a period of time that will result in the desired properties. The outer furnace is then removed, and the coils are allowed to cool under the inner covers. When the temperature has been reduced to the point where oxidation of the steel will not occur, the inner covers are removed and the steel is forwarded for further processing.

In the continuous process, steel coils are uncoiled and drawn through a furnace where they are subjected to the annealing cycle under a protective atmosphere. After the sheet or strip has been cooled and removed from the furnace, further in-line processing (such as hot dip galvanizing) may be done, or the steel may be cut into sheets. In general, however, the steel is recoiled and then forwarded as in the batch process. For more detailed information, see the article "Continuous Annealing" that immediately follows in this Section.

In addition to the obvious differences in equipment, the batch process and the continuous process differ considerably in several other ways. Batch annealing may require up to a week because of the large mass of material being treated, whereas continuous annealing is accomplished in about five minutes. Differences are also evident in the temperatures employed, with the batch process generally being conducted at lower temperatures. Because in batch annealing it is difficult to ensure that the temperature is uniform throughout the charge (which may consist of several hundred tons of steel), the continuous process offers the potential of more uniform properties. The short annealing times of the continuous process, however, frequently result in hardness levels slightly higher than those of similar material annealed by the batch process.

Cold-Rolled Plain Carbon Sheet and Strip. The usual method of manufacturing cold-rolled sheet and strip is to produce a hot-rolled coil, pickle it to remove scale (oxide), and cold roll it to the desired final gage. Cold rolling may reduce the thickness of the hot-rolled material in excess of 90%, which increases the hardness and strength of the steel but severely decreases its ductility. If any large amount of subsequent cold working is to be done, the ductility of the steel must be restored.

Annealing of the cold-rolled steel normally is designed to produce a recrystallized ferrite microstructure from the highly elongated, stressed grains resulting from cold work. Figure 11 shows the effect of annealing on the microstructure of a low-carbon cold-rolled sheet steel. The cold-rolled microstructure is shown in Fig. 11(a) in contrast to the partially and fully recrystallized microstructure in Fig. 11(b) and 11(c). During heating of the steel, and in the first segment of the holding portion of the cycle, the first metallurgical process to occur is recovery. During this process, internal strains are relieved (although little change in the microstructure is evident), ductility is moderately increased, and strength is slightly decreased.

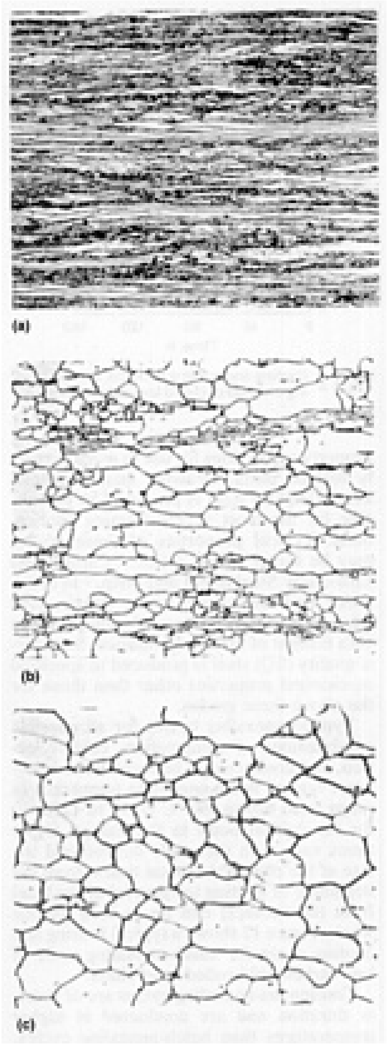

Fig. 11 A low-carbon sheet steel in the (a) as-cold-rolled unannealed condition, (b) partially recrystallized annealed condition, and (c) fully recrystallized annealed condition. Marshall's etch. 1000×

As annealing continues, the process of recrystallization occurs, and new, more equiaxed ferrite grains are formed from the elongated grains. During recrystallization, strength decreases rapidly, with a corresponding increase in ductility. Further time at temperature causes some of the newly formed grains to grow at the expense of other grains; this is termed grain growth and results in modest decreases in strength and small (but often significant) increases in ductility. Most plain carbon steels are given an annealing treatment that promotes full recrystallization, but care must be taken to avoid excessive grain growth, which can lead to surface defects (such as orange peel) in formed parts.

The rates at which the metallurgical processes noted above proceed are functions of both the chemical composition and the prior history of the steel being annealed. For example, small amounts of elements such as aluminum, titanium, niobium, vanadium, and molybdenum can decrease the rate at which the steel will recrystallize, making the annealing response sluggish and therefore necessitating either higher temperatures or longer annealing times to produce the same properties. Although the presence of these alloying elements is generally the result of deliberate additions intended to modify the properties of the sheet (as in the case of aluminum, titanium, niobium, and vanadium), some elements may be present as residual elements (molybdenum, for example) in quantities great enough to modify the response to annealing. Conversely, larger amounts of cold work (greater cold reductions) will accelerate the annealing response. Therefore, it is not possible to specify a single annealing cycle that will produce a particular set of mechanical properties in all steels; the chemical composition and the amount of cold work also must be taken into account.

Cold-rolled plain carbon steels are produced to a number of different quality descriptions. Commercial quality (CQ) steel is the most widely produced and is suitable for moderate forming. Drawing quality (DQ) steel is produced to tighter mechanical-property restrictions for use in more severely formed parts. Drawing quality special killed (DQSK) steel is

produced to be suitable for the most severe forming applications. Typical properties of these grades may be found in the article "Carbon and Low-Alloy Steel Sheet and Strip," in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.* Structural quality (SQ) steel is produced to specified mechanical properties other than those for the above three grades.

Typical annealing cycles for all possible combinations of composition, cold reduction, and grade cannot be listed here. However, typical batch-annealing temperatures range from 620 to 690 °C (1150 to 1270 °F) for the coldest point in the charge. Cycle times vary with the grade desired and the size of the charge, but total times (from the beginning of heating to removal of the steel from the furnace) can be as long as one week. Figure 12 shows a typical heating and cooling cycle for batch-annealing coils of low-carbon cold-rolled steel sheet.

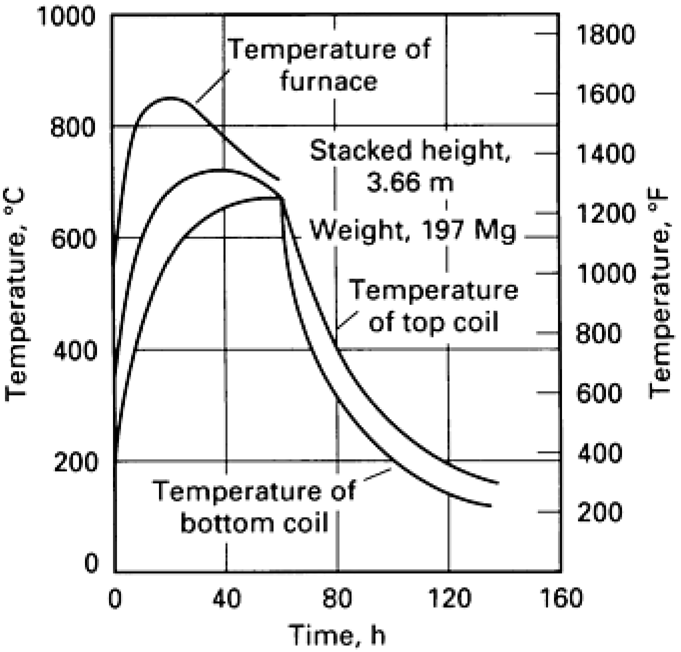

Fig. 12 Heating and cooling cycle for batch annealing of a load of coiled low-carbon steel sheet

Continuous-annealing cycles are of shorter duration and are conducted at higher temperatures than batch-annealing cycles. In some applications, the annealing temperature may exceed A_1. Typical cycles are 40 s at 700 °C (1290 °F) for cold-rolled commercial quality steel and 60 s at 800 °C (1470 °F) for drawing quality special killed sheet. Most continuous annealing of cold-rolled sheet includes an overaging treatment designed to precipitate carbon and nitrogen from solution in the ferrite and to reduce the likelihood of strain aging. Overaging for 3 to 5 min at 300 to 450 °C (570 to 840 °F) accomplishes the desired precipitation of carbon and nitrogen.

Batch annealing and continuous annealing differ slightly in the properties they produce. Typical average properties of batch-annealed and continuous-annealed commercial quality plain carbon steel are as follows:

Annealing process	**Yield strength**		**Elongation, %**
	MPa	**ksi**	
Batch	210	30.4	43.0

Continuous	228	33.0	41.7

High-strength cold-rolled sheet and strip are growing in importance due to their high load-bearing capacities. Strength of sheet and strip can be increased through modifications of chemical composition and/or selection of different annealing cycles, but these methods result in decreased ductility. Plain carbon steels, produced by conventional techniques, may be batch annealed or continuous annealed under conditions that result only in recovery or partial recrystallization. Typical batch-annealing cycles of this type employ soak temperatures of 425 to 480 °C (800 to 900 °F) and various soak times. High-strength low-alloy (HSLA) steels containing alloying elements such as niobium, vanadium, and titanium also may be produced as cold-rolled grades. The additional alloying produces a stronger hot-rolled steel, which is strengthened even more by cold rolling. Cold-rolled HSLA steels may be recovery annealed to produce higher-strength grades or recrystallization annealed to produce lower-strength grades. Successful production of cold-rolled HSLA steel requires selection of the appropriate combination of steel composition and hot-rolled strength, amount of cold reduction, and type of annealing cycle. For more information on HSLA steels, see the article "High-Strength Structural and High-Strength Low-Alloy Steels," in Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*

Another series of high-strength sheet steels are the dual-phase steels. These steels are generally annealed for a short period (usually less than 5 min) in the intercritical range, followed by rapid cooling. The resulting microstructure is 10 to 20% martensite by volume in a matrix of ferrite. The continuous-annealing process is ideal for producing dual-phase sheet grades (more details are in the next article in this Section). Dual-phase steels are unique in that they deform by a continuous yielding behavior because the martensite is a continuous source of dislocations during plastic deformation (see the article "Dual-Phase Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). Most other low-carbon steels that display a yield point upon deformation need to be skin passed or temper rolled to provide a source of dislocations for continuous yielding behavior. Steels displaying a yield point are undesirable for many forming operations because of the formation of Lüders bands that blemish the surface.

Hot dip galvanized products are produced on lines that process either preannealed (batch annealed) or full hard coils. Lines for processing full hard coils incorporate an in-line annealing capability so that annealing and hot dip galvanizing can be accomplished in a single pass through the line. This in-line annealing, like continuous annealing of uncoated steel, generally results in slightly higher strength and slightly lower ductility than batch annealing. Maximum strip temperatures are below the A_1 temperature for commercial quality steel, but temperatures in excess of 845 °C (1550 °F) are required for DQSK grades. Galvanizing of preannealed steel results in properties similar to those of ungalvanized material.

The atmosphere in a continuous galvanizing line, in addition to protecting the sheet from oxidation, must remove any oxides present on the strip to promote metallurgical bonding between the steel and the zinc or zinc alloy.

Tin mill products are distinguished from their cold-rolled sheet mill counterparts chiefly by the fact that they are produced in lighter gages (0.13 to 0.38 mm, or 0.005 to 0.015 in.) and by the fact that some of them are coated with tin or chromium and chromium oxide for corrosion resistance. The sequence used for processing single-reduced tin mill products is similar to that for cold-rolled sheet, that is, pickling, cold reducing, annealing, and temper rolling of hot-rolled coils. Double-reduced products are cold rolled an additional 30 to 40% following annealing (this step replaces temper rolling). Whereas much of the tonnage produced in tin mills is batch annealed, a considerable amount is continuous annealed (facilities for continuous annealing currently are more prevalent in tin mills than in sheet mills).

Because tin mill products traditionally have been produced at facilities separate from sheet mills and because applications for these products are different from those for cold-rolled sheet, tin mill products have been assigned separate designations for indicating the mechanical properties developed during annealing. A list of these temper designations is given in Table 5.

Table 5 Temper designations for steel tin mill products

Designation	**Hardness aim, HR30T**
Batch (box) annealed products	

T-1	52 max
T-2	50-56
T-3	54-60
Continuously annealed products	
T-4 CA	58-64
T-5 CA (TU)	62-68
T-6 CA	67-73
Double-reduced products	
DR-8	73
DR-9	76
DR-9M	77
DR-10	80

Open-coil annealing, which is done in batch furnaces, involves loose rewinding of a cold-reduced coil to provide open spaces between successive laps. This allows the controlled atmosphere gases to be drawn between the laps, providing faster and more uniform heating and cooling than are obtained with tightly wound coils. In addition, by control of the hydrogen content and dew point of the atmosphere, decarburizing conditions can be established. The carbon content of the steel can thereby be reduced to low levels for such materials as enameling steel and electrical steel.

Loose rewinding of coils for open-coil annealing is done on a turntable having a vertical mandrel. As the coil is wound, a twisted wire spacer is inserted between the laps. This spacer remains in the coil during annealing and is removed after the coil has been removed from the furnace. The coil is then tightly rewound and is ready for temper rolling.

Annealing of Steel Forgings

Annealing of forgings is most often performed to facilitate some subsequent operation, usually machining or cold forming. The type of annealing required is determined by the kind and amount of machining or cold forming to be done as well as the type of material involved. For some processes it is essential that the microstructure be spheroidal, whereas for others spheroidal structures may not be necessary or even desirable.

Annealing of Forgings for Machinability. In many cases, a structure suitable for machining can be developed in low-carbon steel forgings by transferring the forgings directly from the forging operation to a furnace heated to a proper transformation temperature, holding them at this temperature for a time sufficiently long to permit all the austenite to transform, then cooling in air. In this process, the effective austenitizing temperature is the finishing temperature of forging, not the initial forging temperature. This process is capable of producing reasonably uniform structures in forgings of uniform sections. However, in forgings shaped such that some portions are cooler than others, this difference in

finishing temperature will cause the structures to be dissimilar. This process generally will not produce a spheroidal structure except in high-alloy steels containing large amounts of carbide-forming elements. If a lamellar structure is suitable for subsequent operations, however, this process can minimize the energy usage and lower costs by reducing processing and handling time.

In many instances where the product or subsequent process requires a more consistent hardness, forgings can be subcritical annealed by heating to a temperature between 10 and 20 °C (20 and 40 °F) below Ae_1, holding sufficiently long (determined by degree of softening required), and then cooling in air (or equivalent). Care should be taken to maintain the temperature below Ae_1 to prevent formation of austenite, which would require a much lower cooling rate.

In forgings produced from higher-carbon steels with or without significant amounts of alloying elements, a spheroidal structure generally is preferable for high-speed machining operations. Direct transfer of high-carbon steel forgings to a furnace for transformation sometimes can be used as the preliminary step of an annealing cycle and as a means of preventing the possibility of cracking in deep-hardening steel parts, but seldom will produce satisfactory properties alone. Most annealing of high-carbon steel forgings is done either in a batch furnace or in a continuous tray pusher furnace. Typical schedules for spheroidizing 52100 steel in a batch furnace are as follows:

- Austenitize by holding at least 2 h at 790 °C (1450 °F), furnace cool at 17 °C/h (30 °F/h) to 595 °C (1100 °F), then air cool
- Austenitize by holding at least 2 h at 790 °C (1450 °F), cool as rapidly as practical to 750 °C (1380 °F), cool at 6 °C/h (10 °F/h) to 675 °C (1250 °F), then air cool
- Austenitize by holding at least 2 h at 790 °C (1450 °F), cool as rapidly as practical to 690 °C (1275 °F), transform isothermally by holding at this temperature for 16 h, then air cool

In all instances, the load should be distributed to promote uniform heating and cooling. Use of circulating fans in the furnace chamber will greatly aid in producing a product that is uniform in both hardness and microstructure.

A typical continuous furnace for annealing steel forgings might consist of five or six zones. An example of a specific spheroidize annealing treatment in such a furnace is given in the next section.

Annealing of Forgings for Cold Forming and Re-Forming. If a steel forging or blank requires further cold forming, it may be necessary to soften it in order to enhance its plastic-flow characteristics. In general, this type of annealing is done only to the extent that the forming operation requires, that is, to satisfy dimensional, mechanical, and tool-life requirements, as well as to prevent cracking and splitting. Much intermediate annealing is done successfully, but cold forming processes are best performed on parts with totally spheroidized microstructures, especially for parts made of high-carbon steels.

In one plant, both 5160 and 52100 steels have been successfully spheroidized with a common cycle in a six-zone tray pusher furnace. In this cycle, the temperatures in the six zones are 750, 750, 705, 695, 695, and 680 °C (1380, 1380, 1300, 1280, 1280, and 1260 °F). Time in each zone is 150 min. This process yields 5160 steel forgings with hardnesses of 170 to 190 RB and 52100 steel parts with hardnesses of 175 to 195 RB, both suitable for cold or warm restrike operations.

In another cold-forming plant, 15B35 steel is processed in either a continuous roller hearth furnace or a bell furnace depending on the severity of the cold-forging operation. The continuous furnace is a two-zone furnace with zone temperatures at 750 °C (1380 °F) and 695 °C (1280 °F). Annealing time in each zone is between 90 to 120 min. The parts then enter a water-cooled cooling bed and exit the furnace at about 260 °C (500 °F). Only a partially spheroidized structure is obtainable in this furnace. If a nearly full-spheroidized structure is required, bell furnaces are used (see Fig. 13). A typical cycle for a 4500 kg (10,000 lb) load involves soaking at 760 °C (1400 °F) for 8 h followed by a slow cool to 675 °C (1250 °F) and a rapid cool afterwards.

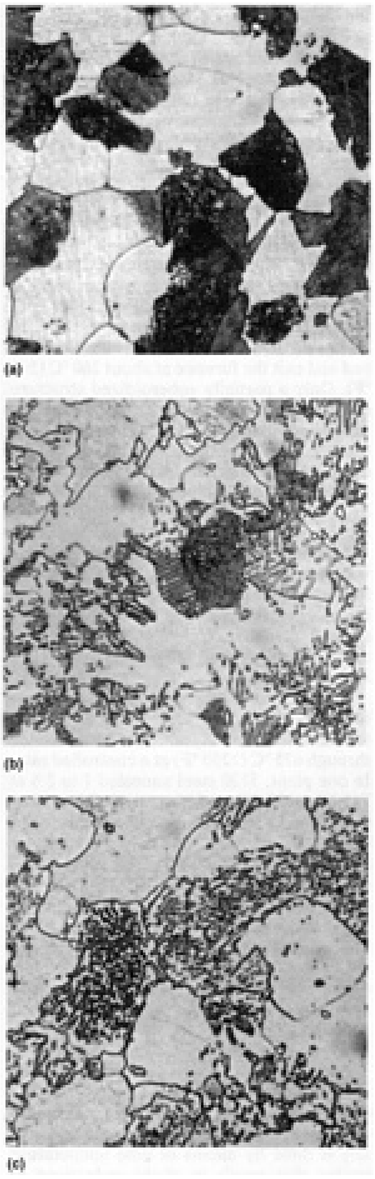

Fig. 13 Microstructures of 15B35 steel. (a) In the as-received hot-rolled condition, microstructure is blocky pearlite. Hardness is 87 to 88 HRB. (b) In the partially spheroidized condition following annealing in a continuous furnace. Hardness is 81 to 82 HRB. (c) In the nearly fully spheroidized condition following annealing in a bell furnace. Hardness is 77 to 78 HRB.

A commercial heat treater uses a further variation of the processing cycle in its bell furnaces. The cycle for a 14,000 kg (31,000 lb) load involves soaking at 765 °C (1410 °F) for 24 h, furnace cooling to 675 °C (1250 °F), and holding at that temperature for 16 h followed by a rapid cooling.

Low-carbon steels generally can be cold formed successfully after being heated to temperatures near A_1 and then being cooled through 675 °C (1250 °F) at a controlled rate. In one plant, 5120 steel annealed 1 to 2 h at 745 °C (1375 °F) and slow cooled has been cold formed successfully. Large quantities of 1008, 1513, 1524, 8620, and 8720 steels are being cold formed after annealing cycles consisting of 1 to 6 h at 720 °C (1325 °F) followed by slow cooling. The severity of the forming operation, as well as the grade of steel and history of the part, determines the extent of annealing required. Batch furnaces, continuous tray pusher furnaces, and continuous belt furnaces are being used successfully to perform these types of annealing operations on low-carbon steels.

Any part that contains significant stresses resulting from cold forming or restrike operations should be reviewed for some type of stress-relief process. Stress relieving usually is done by means of time-temperature cycles that result in slight reductions in hardness. These cycles often consist of 1 h at 425 to 675 °C (800 to 1250 °F).

Annealing to Obtain Pearlitic Microstructures. Forgings--especially plain and alloy high-carbon steel forgings--are isothermally annealed to produce a pearlitic microstructure that is preferred for a subsequent process. In steels that are to be induction hardened, for example, the carbide distribution of a fine pearlitic structure offers excellent preparation for optimum control in selective hardening while producing a reasonably machinable core structure. Isothermal annealing to obtain line pearlite can be performed in batch or continuous furnaces; however, temperature control and uniformity are more critical than in conventional slow cooling cycles because a particular microstructure and a particular hardness level usually are desired. In one plant, a continuous belt-type furnace is used for isothermal annealing of 1070 steel forgings. The forgings are uniformly heated for 30 min at 845 °C (1550 °F), cooled to 675 °C (1250 °F), and held for 20 min, then rapidly cooled. The microstructure produced is essentially fine lamellar pearlite with a hardness of 219 to 228 HB. The hardness and the structure can be modified by adjusting the transformation temperature.

Annealing of Bar, Rod, and Wire

Significant tonnages of bar, rod, and wire are subjected to thermal treatments that decrease hardness and prepare the material for subsequent cold working and/or machining. For low-carbon steels (up to 0.20% C), short-time subcritical annealing often is sufficient for preparing the material for further cold working. Steels with higher carbon and alloy contents require spheroidizing to impart maximum ductility.

Most carbon and alloy steel coiled products can be successfully spheroidized. In batch annealing, it is helpful to use higher-than-normal temperatures (for example, 650 °C, or 1200 °F) during initial heating for purging because the higher initial temperature promotes a lower temperature gradient in the charge during subsequent heating into the temperature range between A_1 and A_3. Use of a higher purge temperature also promotes agglomeration of the carbides in the steel, which makes them more resistant to dissolution in the austenite when the charge temperature is finally elevated. These undissolved carbides will be conducive to the formation of a spheroidal rather than a lamellar structure when transformation is complete.

A knowledge of the temperature distribution in the furnace and in the load can be a major factor in achieving a good, consistent response to spheroidization. Temperature distribution and control are much more critical in batch and vacuum furnaces, which may handle loads of up to 27 Mg (30 tons), than in continuous furnaces, in which loads of only 900 to 1800 kg (2000 to 4000 lb) may be transferred from zone to zone. Test thermocouples should be placed strategically at the top, middle, and bottom (inside and outside) of the charge during development of cycles. In spheroidizing, to minimize formation of pearlite on cooling, it is important to ensure that no part of the charge be allowed to approach A_3. Conversely, if temperatures only slightly above A_1 are used and temperature controls are inaccurate because of poor placement of thermocouples, it is probable that the A_1 temperature will not be attained and that no austenitization will occur.

Table 6 gives typical mechanical properties that can be obtained in hypoeutectoid plain carbon steels by spheroidizing. Recommended temperatures and times for lamellar and spheroidize annealing of hypoeutectoid alloy steels are presented in Table 4.

Table 6 Typical mechanical properties of spheroidized plain carbon steels

Steel	Tensile strength			
	Hot rolled		Spheroidized	
	MPa	ksi	MPa	ksi
1010	365	53	295	43
1018	450	65	365	53
1022	470	68	385	56

1030	585	85	415	60
1038	600	87	485	70
1045	675	98	515	75
1060	860	125	550	80
1065	910	132	600	87
1524	510	74	450	65
1541	710	103	540	78

Prior cold working increases the degree of spheroidization and provides even greater ductility. For example, 4037 steel in the as-rolled condition normally can be spheroidized to a tensile strength of about 515 MPa (75 ksi). If, however, the material is drawn 20% and then spheroidized (referred to as spheroidize annealed in-process), the resulting tensile strength will be around 470 MPa (68 ksi).

Although prior cold work can enhance response to annealing, caution must be observed in spheroidizing cold-worked plain carbon steels with 0.20% C or less. Unless a reduction of at least 20% is applied, severe grain coarsening may be observed after spheroidizing. Such grain coarsening is the result of a unique critical combination of strain and annealing temperature for the particular steel and may severely impair subsequent performance.

In the wire industry, a wide variety of in-process annealing operations have been evolved for rendering coiled material suitable for further processing that may require formability, drawability, machinability, or a combination of these characteristics. One large wire mill reports current use of 42 separate and distinct annealing cycles, the majority of which represent compromises between practical considerations and optimum properties. For example, annealing temperatures below those that might yield optimum softness sometimes must be used in order to preclude scaling of wire coils, which often can occur even in controlled-atmosphere furnaces. Even slight scaling may cause the coil wraps to stick together, which can impede coil payoff in subsequent operations.

Some of the terms used to describe various in-process annealing treatments are in common usage throughout the wire industry, whereas others have been developed within specific plants or mills. No attempt will be made here to list or define all the names that refer to specific treatments.

"Patenting" is a special form of annealing that is unique to the rod and wire industry. In this process, which usually is applied to medium- and higher-carbon grades of steel, rod or wire products are uncoiled, and the strands are delivered to an austenitizing station. The strands are then cooled rapidly from above A_3 in a molten medium-- usually lead at about 540 °C (1000 °F)--for a period of time sufficient to allow complete transformation to a fine pearlitic structure. Both salt baths and fluidized beds have also been used for this purpose. This treatment increases substantially the amount of subsequent wiredrawing reduction that the product can withstand and permits production of high-strength wire. Successive drawing and patenting steps may be employed if necessary, in order to obtain the desired size and strength level.

Austenitizing for patenting can be accomplished in oil, gas, or electric furnaces; in high-temperature lead or salt baths; or by induction or direct resistance heating. As an alternative to quenching in molten lead, continuous air cooling often is employed. Such air patenting is less expensive than lead patenting but results in coarser pearlite and often more proeutectoid ferrite, a microstructure that is less desirable from the standpoint of drawing high-strength wire.

Annealing of Plate

Plate products are occasionally annealed to facilitate forming or machining operations. Annealing of plate usually is done at subcritical temperatures, and long annealing times generally are avoided. Maintaining adequate flatness can be a significant problem in annealing of large plates.

Annealing of Tubular Products

Tubular products known as mechanical tubing are used in a variety of applications that can involve machining or forming. For these products, which are made from various grades of steel, annealing is a common treatment. In most annealing cycles, subcritical temperatures and short annealing times are used to reduce hardness to the desired level. High-carbon grades, such as 52100, generally are spheroidized to facilitate machining. Tubular products manufactured in pipe mills are rarely annealed. These products normally are used in the as-rolled, the normalized, or the quenched and tempered condition.

Continuous Annealing of Steel

R. Pradhan, Bethlehem Steel Corporation

Introduction

ANNEALING OF STEEL SHEET products, a process often (but not solely) used to produce a recrystallized ferrite microstructure after cold rolling, is performed on a commercial scale by either batch annealing or continuous annealing. In batch annealing, multiple coils of sheet are placed under a cover with a reducing atmosphere (Fig. 1a) and heated for a time period that may involve days (see Fig. 1b). In contrast, continuous annealing of sheet involves the rapid passage of uncoiled sheet through heating and cooling equipment (Fig. 1a).

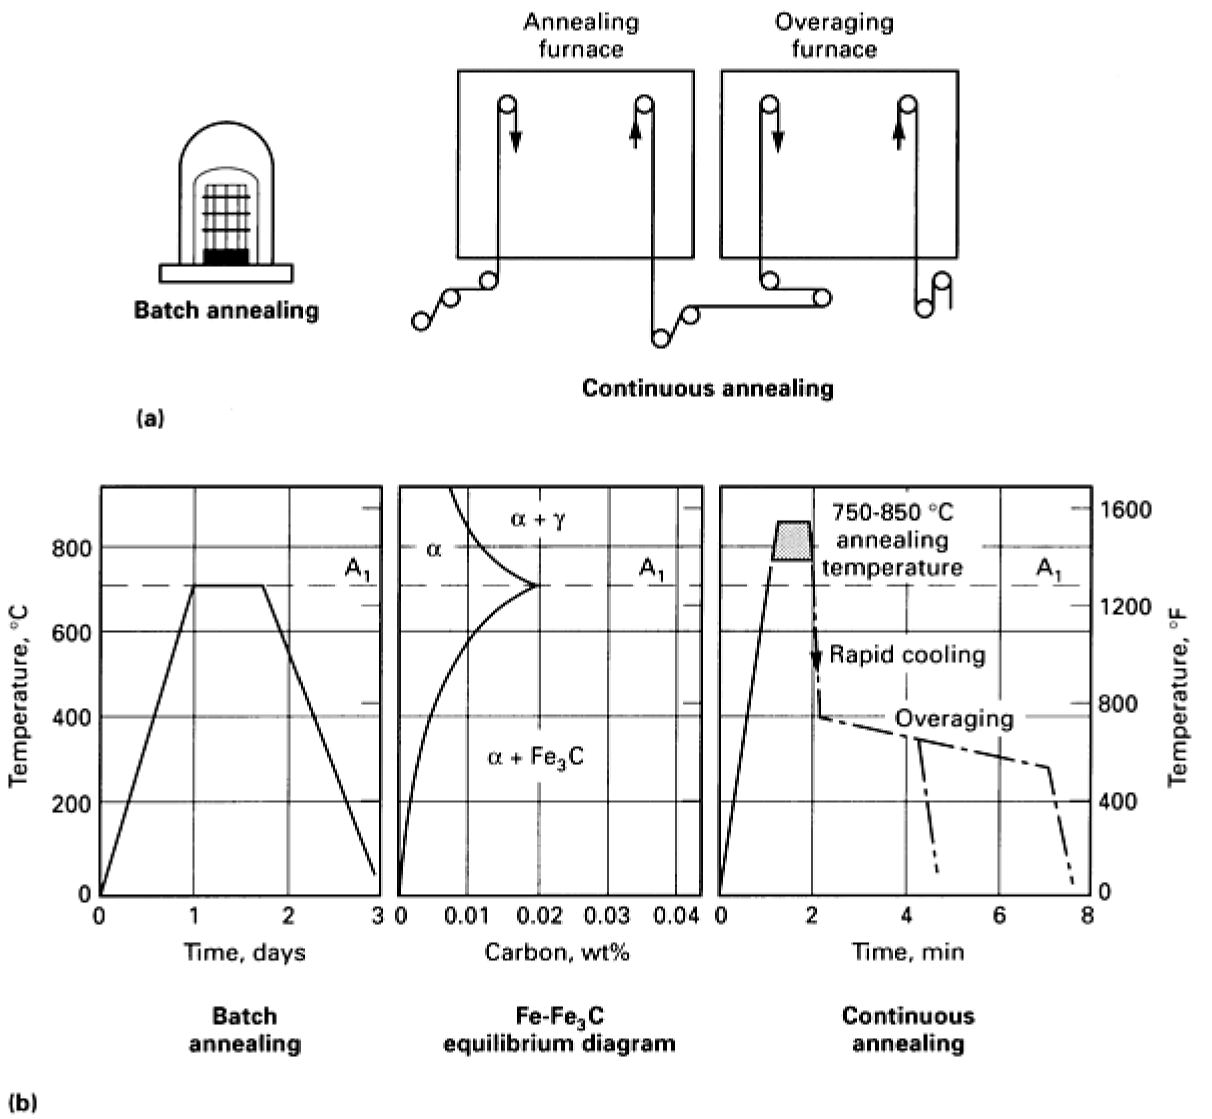

Fig. 1 Comparison of (a) processing methods and (b) thermal treatment profiles for batch annealing and continuous annealing. As in batch annealing, the continuous-anneal temperature can be as low as 675 °C (1250 °F) for the recrystallization of commercial-quality (CQ) sheet, but is generally in the range of 750 to 850 °C (1380 to 1560 °F) for critical formability products.

In addition to the obvious differences in equipment, batch and continuous annealing have important differences in heating and cooling profiles (Fig. 1b). The very large mass of steel heats and cools very slowly during batch annealing, and the process requires several days for completion. Annealed grain sizes are coarse, and the slow cooling rates ensure that all carbon dissolved during annealing precipitates upon cooling. Thus excellent ductility results, although some nonuniformity develops because the inside and outside parts of a coil experience different thermal histories.

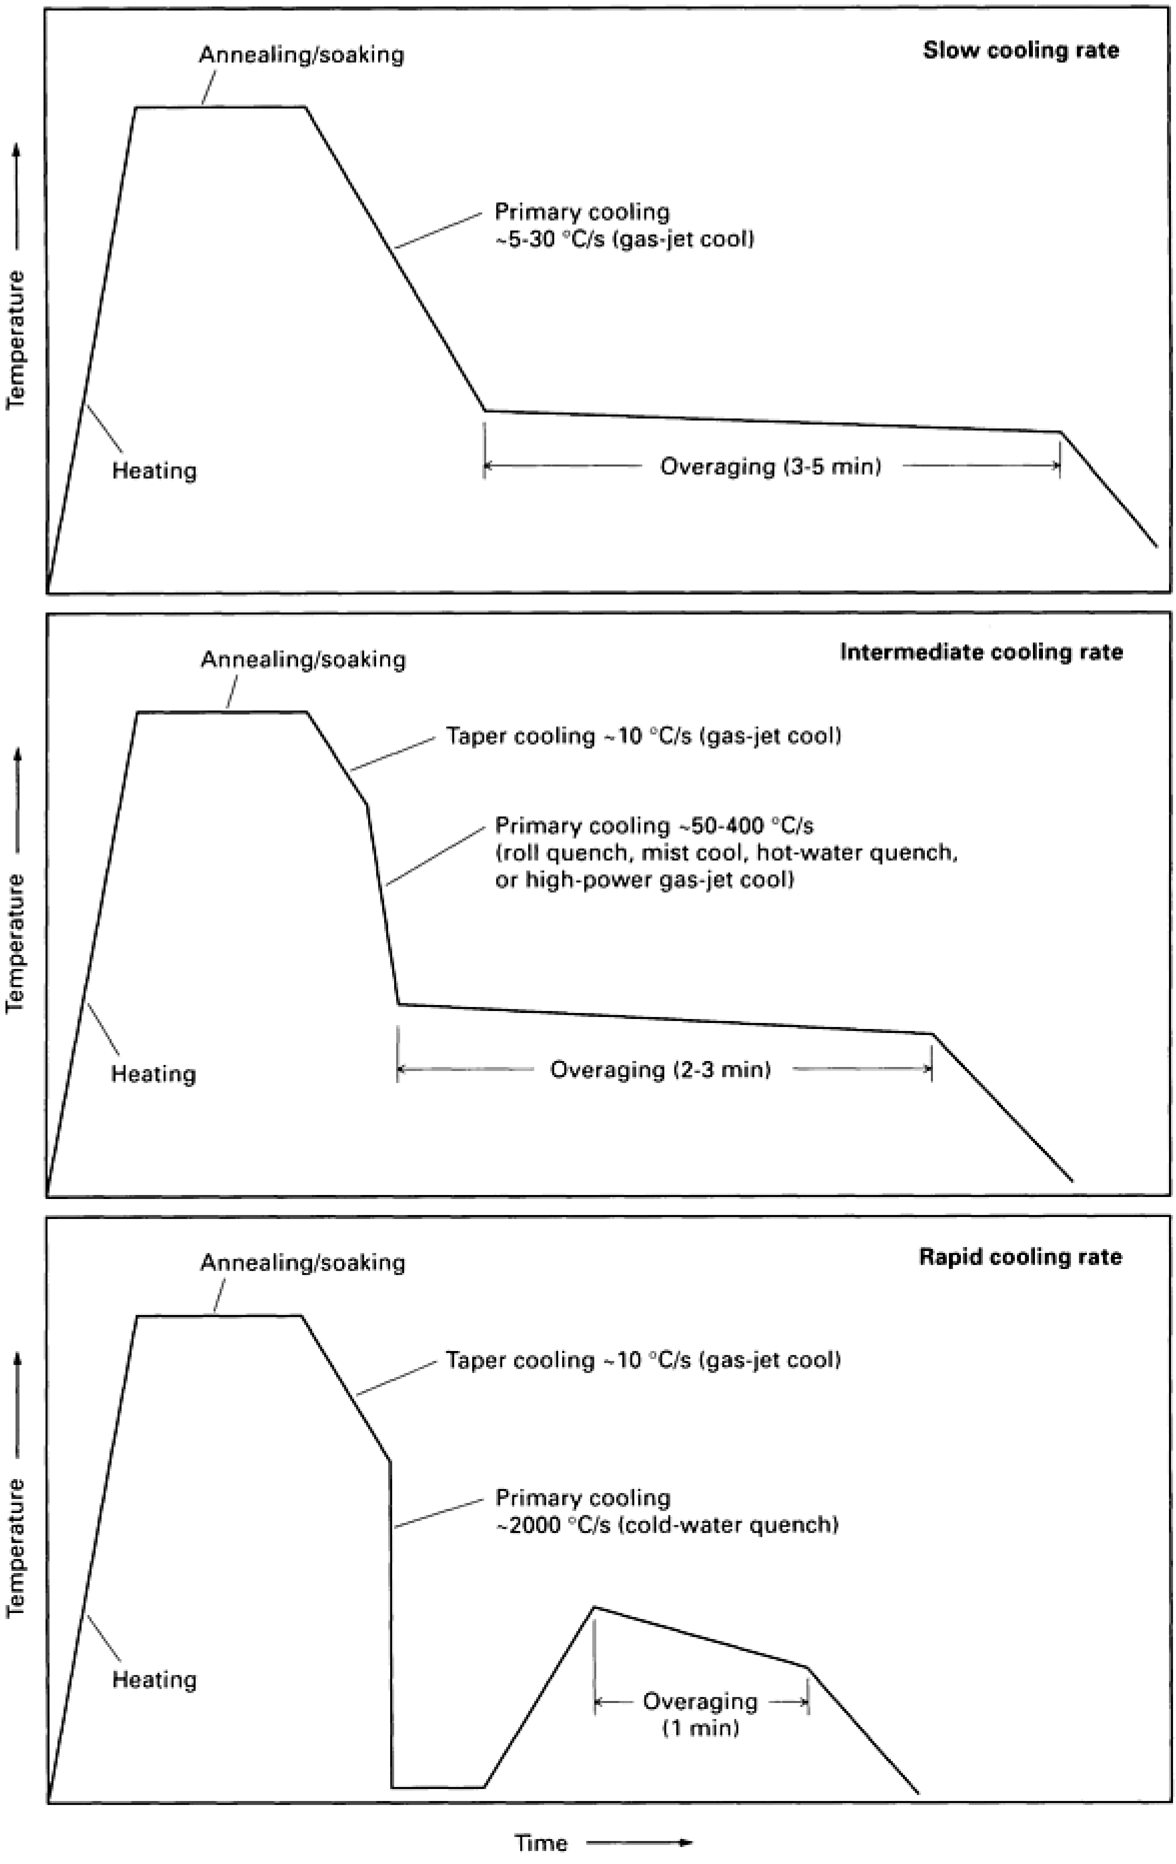
During continuous annealing, uncoiled steel sheet is passed though a two-stage furnace for times on the order of a few minutes. The first stage heats the steel and accomplishes recrystallization, while the second stage heats at a lower temperature to overage the steel and remove carbon from the solution effectively. Without this step, the thin sheet would cool too rapidly and retain carbon in solution. This carbon would eventually cause strain or quench aging and reduce sheet formability. There are several processing approaches to overaging, some of which are discussed in this article.

For several decades, continuous-annealing lines have been widely used for the production of such sheet steel products as hot-dip galvanized steels, tinplate, nonoriented electrical steels, and stainless steels. The thermal profile on these lines generally involves short-time annealing followed by relatively slow cooling (~10 °C/s, or 20 °F/s) to ambient temperature with no inline overaging. Since the late 1970s, however, continuous-annealing technology, in conjunction with modern steelmaking and upstream processing facilities, has used rapid cooling and in-line overaging to enable the production of sheet steels for very demanding automotive and appliance applications. The metallurgical advantages of continuous

annealing over conventional batch annealing include improved product uniformity, surface cleanliness and shape, and the versatility to produce a wide range of steel grades.

Process Description

The modern continuous-annealing lines combine several processes. At the entry end, the uncoiled sheet is chemically and/or electrolytically cleaned and rapidly heated to an annealing temperature between 675 and 850 °C (1250 and 1550 °F). The cold-rolled sheet is "soaked" for an annealing time on the order of about 1 min and is then subjected to cooling and overaging (tempering) schedules such as those shown in Fig. 2. These stages in the heat treatment are discussed below. In most cases, a continuous-annealing line also includes a stage for tension leveling or temper rolling.



Annealing/soaking
Slow cooling rate
Primary cooling
~5-30 °C/s (gas-jet cool)
Temperature
Heating
Overaging (3-5 min)
Annealing/soaking
Intermediate cooling rate
Taper cooling ~10 °C/s (gas-jet cool)
Primary cooling ~50-400 °C/s
(roll quench, mist cool, hot-water quench,
or high-power gas-jet cool)
Temperature
Heating
Overaging (2-3 min)
Annealing/soaking
Rapid cooling rate
Taper cooling ~10 °C/s (gas-jet cool)
Primary cooling
~2000 °C/s (cold-water quench)
Temperature
Heating
Overaging
(1 min)
Time

Fig. 2 Typical continuous-annealing thermal profiles. Anneal/soak temperature, approximately 750 to 850 °C (1380 to 1560 °F); overage temperature, approximately 350 to 400 °C (660 to 750 °F)

The heating and soaking/annealing stage provides recrystallization of the cold-rolled structure and achieves some degree of grain growth. The soaking temperature, which can range from 675 to 850 °C (1250 to 1560 °F), is generally above the A_1 temperature. The low end of the annealing temperature range (675 °C, or 1250 °F) is used for commercial-quality (CQ) products, whereas the high end is used for drawing-quality (DQ) and deep-drawing-quality special-killed (DQSK or DDQ) products. In some dual-phase steels, the soaking temperature is chosen to generate the proper amount of austenite phase, depending on the desired strength of the product.

The slow-cooling (or taper-cooling) stage, immediately following the annealing treatment, involves a gas-jet cooling (~10 °C/s, or 20 °F/s) to below the A_1 temperature. The slow cooling serves to promote partial precipitation of the solute carbon (that is, the dissolved carbon) from the ferrite phase and, in systems having rapid primary cooling, to prevent the formation of martensite in non-dual-phase steels.

The primary cooling stage involves rapid cooling at rates of 10 to 1000 °C/s (20 to 2000 °F/s), depending on the cooling medium used. The primary cooling medium and associated cooling rate used (Fig. 3) have several engineering consequences. For fast cooling rates (gas-water spraying, hot- or cold-water quenching, roll quenching), sophisticated proprietary techniques are employed to provide uniform cooling without which severe buckling and poor flatness/shape would occur. On the other hand, gas-jet cooling lines require very few controls other than steering or tracking over rolls and in-line tension (Ref 1). For those cooling systems involving contact with water, in-line pickling and rinsing are required to remove the thin oxide layer. No such provisions are needed in those lines having nonoxidizing gas-jet cooling.

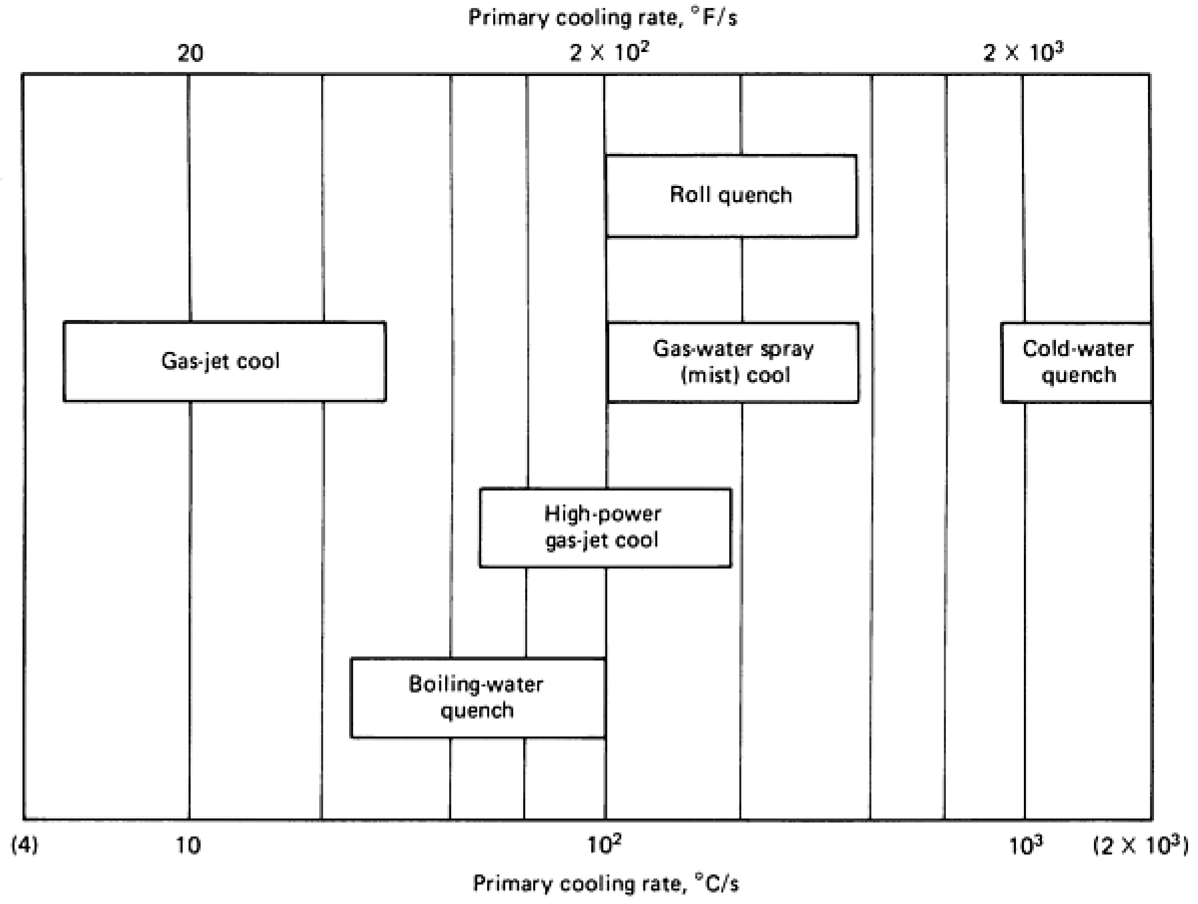


Fig. 3 Primary cooling systems and associated cooling rates

The choice of the primary cooling medium has metallurgical consequences as well (Ref 2, 3, 4). For plain carbon steels, especially where exposed outer-body applications are involved, adequate resistance to ambient strain-aging is a critical requirement in order to prevent stretcher-strain formation in the stamped part. In these cases, a solute-carbon concentration of less than about 10 ppm is needed in the final product. A higher primary cooling rate leads to a larger carbon supersaturation in the ferrite, which increases the driving force for carbon precipitation during subsequent overaging. Accordingly, the overaging time is reduced: 3 to 5 min with the slow gas-jet cooling, compared to 1 min with water quenching. On the other hand, a higher cooling rate increases the density of fine carbides in the ferrite, thereby slightly impairing formability (total elongation and *n*-value), as can be seen in Fig. 4. The optimum balance of properties is realized at a primary cooling rate of about 100 °C/s (180 °F/s) for carbon steel (Fig. 5).

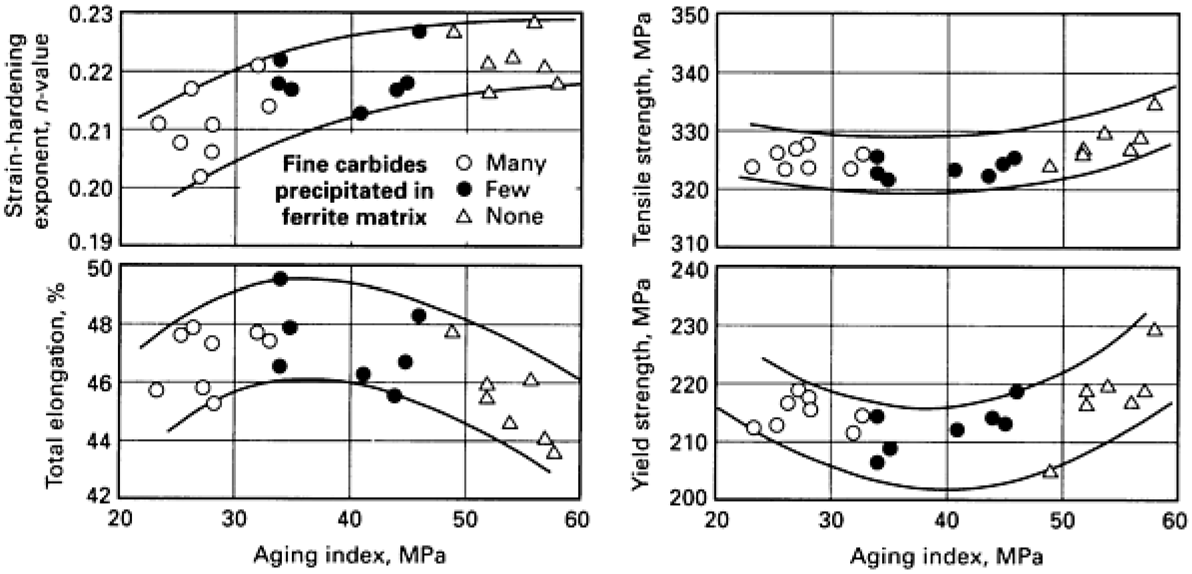

Fig. 4 Relationship between the fine carbide morphology and the aging index and tensile properties of a plain carbon steel. Source: Ref 4

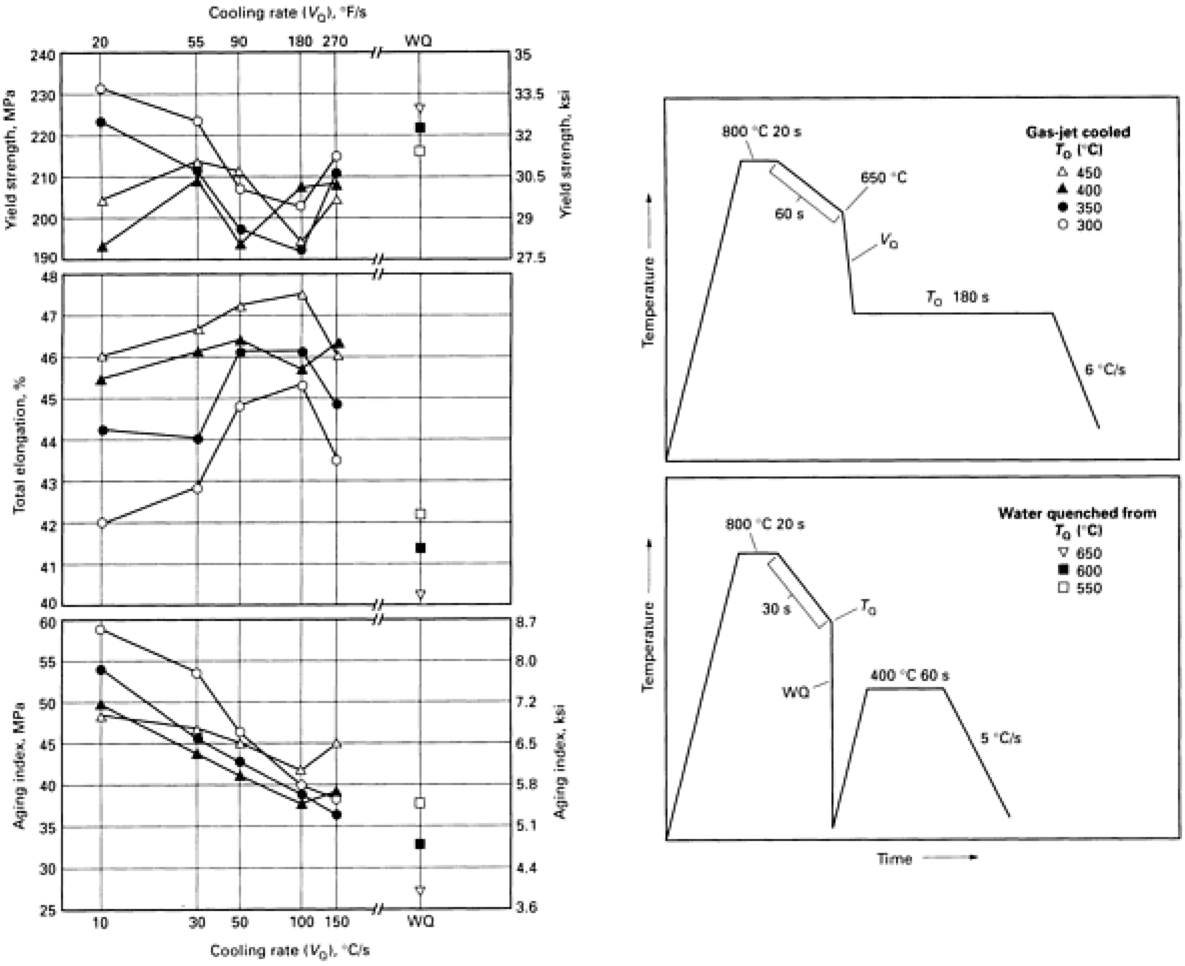

Fig. 5 Effect of the primary cooling rate and overaging temperature on the mechanical properties of a 0.035% C steel. WQ, water quench. Source: Ref 2

In addition to the primary cooling rate, the starting temperature of primary cooling is an important parameter, especially for the higher cooling rates, in optimizing the combination of ductility and aging resistance: A lower starting temperature favors improved ductility at the expense of aging resistance. A lower starting temperature is favorable in the case of faster cooling rates; for example, the optimum starting temperature is 560 °C (1040 °F) for water quenching, compared to 600 °C (1110 °F) for the slower roll quenching (Ref 4).

For the processing of high-strength dual-phase grades, the higher primary cooling rate associated with the water-quenching system has a distinct advantage in that the level of alloying (generally, manganese) needed for hardenability is considerably lower.

Gas-Jet and Water-Spray Cooling. At Nippon Steel Corporation, early continuous-anneal process line (CAPL) technology involved gas-jet cooling (Ref 5) in which a protective nitrogen-hydrogen gas mixture was passed through jets to impinge the steel. Cooling rates of about 5 to 30 °C/s (10 to 55 °F/s) could thus be achieved. A recent development in high-injection-rate technology has enabled higher cooling rates of 100 to 200 °C/s (180 to 360 °F/s) with high gas-jet cool (H-GJC) techniques. Nippon Steel has also designed a cooling system (Acc cooling, or AcC) that involves spraying the steel with a mixed flow of nitrogen and atomized water (Ref 6). Here the cooling rate can be varied between 100 to 400 °C/s (180 to 720 °F/s) by altering the water flow. The gas-water spray system is employed in automotive lines, while the gas-jet cooling system is used in tinplate lines. By using a high-power gas-jet cooling system, Kawasaki Steel Corporation (Ref 7, 8) has been able to attain cooling rates of 50 to 70 °C/s (90 to 125 °F/s) for 0.8 mm (0.315 in.) thick sheet. The multipurpose system (KM-CAL) is employed in the processing of both automotive and tinplate products (Ref 9).

Quenching. The continuous-anneal technology (CAL) developed at NKK Corporation involves a quenching system (Ref 10) consisting of submerged waterjets and is capable of rapid cooling rates of over 1000 °C/s (1800 °F/s). A disadvantage

of the coldwater quenching system, in contrast to the slower cooling systems, is that it is impossible to arrest the primary cooling at the overaging temperature. Reheating to the overaging temperature increases energy costs. Le Centre de Recherches Metallurgiques (Belgium) has developed a process of quenching the moving sheet into boiling water to achieve cooling rates of 25 to 100 °C/s (45 to 180 °F/s) (Ref 11).

Roll-cooling or roll-quenching technology, also developed by NKK (Ref 12) involves cooling the steel by bringing it into direct contact with metallic rolls having a water-cooled interior. The cooling rate ranges between 100 and 400 °C/s (180 to 720 °F/s) depending on sheet thickness. Some continuous-annealing lines have dual-cooling (that is, water- and roll-quenching) capabilities.

The overaging stage reduces the concentration of solute carbon to less than 10 ppm in the ferrite of ferritic-pearlitic steels in order to improve ductility and the resistance to aging. The overaging temperature is typically 400 °C (750 °F) with the time at temperature being governed by the starting temperature of primary cooling and the cooling rate. To further improve the efficiency of the overaging treatment, some lines have a tapered overaging thermal profile. For example, in the water-quenching continuous-anneal line, the steel is first heated to 400 °C (750 °F) and then cooled to a final temperature of 350 °C (660 °F) within 1 to 1.5 min (Ref 3). For the ferrite-plus-martensite (dual-phase) steels, the overaging treatment additionally serves to temper the martensite phase in order to improve ductility. In hot-dip coating lines that incorporate both annealing and coating, the overaging section is generally excluded because coating (at ~480 °C, or 900 °F) after overaging would result in redissolution of the carbides, while overaging after the coating treatment poses the potential problem of zinc pickup on the furnace rolls.

Final cooling from the overaging temperature to the ambient temperature is preferably about 2 °C/s (4 °F/s) for the best properties. In order to restrict the line length (to reduce capital costs), however, a cooling rate up to 10 °C/s (20 °F/s) is tolerated, and in some lines, the steel is quenched from below about 150 °C (300 °F).

Processing of Specific Types of Steels

With the trend toward more and more continuous processing, batch annealing is gradually being replaced by continuous annealing. The prime advantage of continuous annealing is the considerable increase in product uniformity along the length of the given coil. This is of increasing importance as tolerances and allowable property variabilities are reduced as a result of the increasing automation of forming processes.

Steels for Automotive Applications

Continuous annealing provides the capability to produce a wide variety of automotive cold-rolled sheet grades, all with greater property uniformity and surface cleanliness than conventional batch-annealed steels. Most of these steel grades are

variants of existing batch-annealed products, but some (for example, dual-phase grades) can only be produced by continuous annealing. Also, with continuous annealing, high-strength steels can be produced using lower levels of alloying than is possible with batch annealing.

Commercial-Quality (CQ), Drawing-Quality (DQ), and Deep-Drawing-Quality (DDQ/DQSK). The continuous-annealing lines used in the tin-mill and hot-dip galvanizing facilities of the 1960s and 1970s were comprised of short-time soaking and slow cooling to ambient with no in-line overaging. The CQ product processed on such lines was higher in yield strength (about 250 MPa, or 36 ksi) than conventional automotive batch-annealed grades and had low drawability (average $\bar{r}$ = ~1.0) and poor antiaging properties (see Fig. 6 caption for definition of $\bar{r}$).

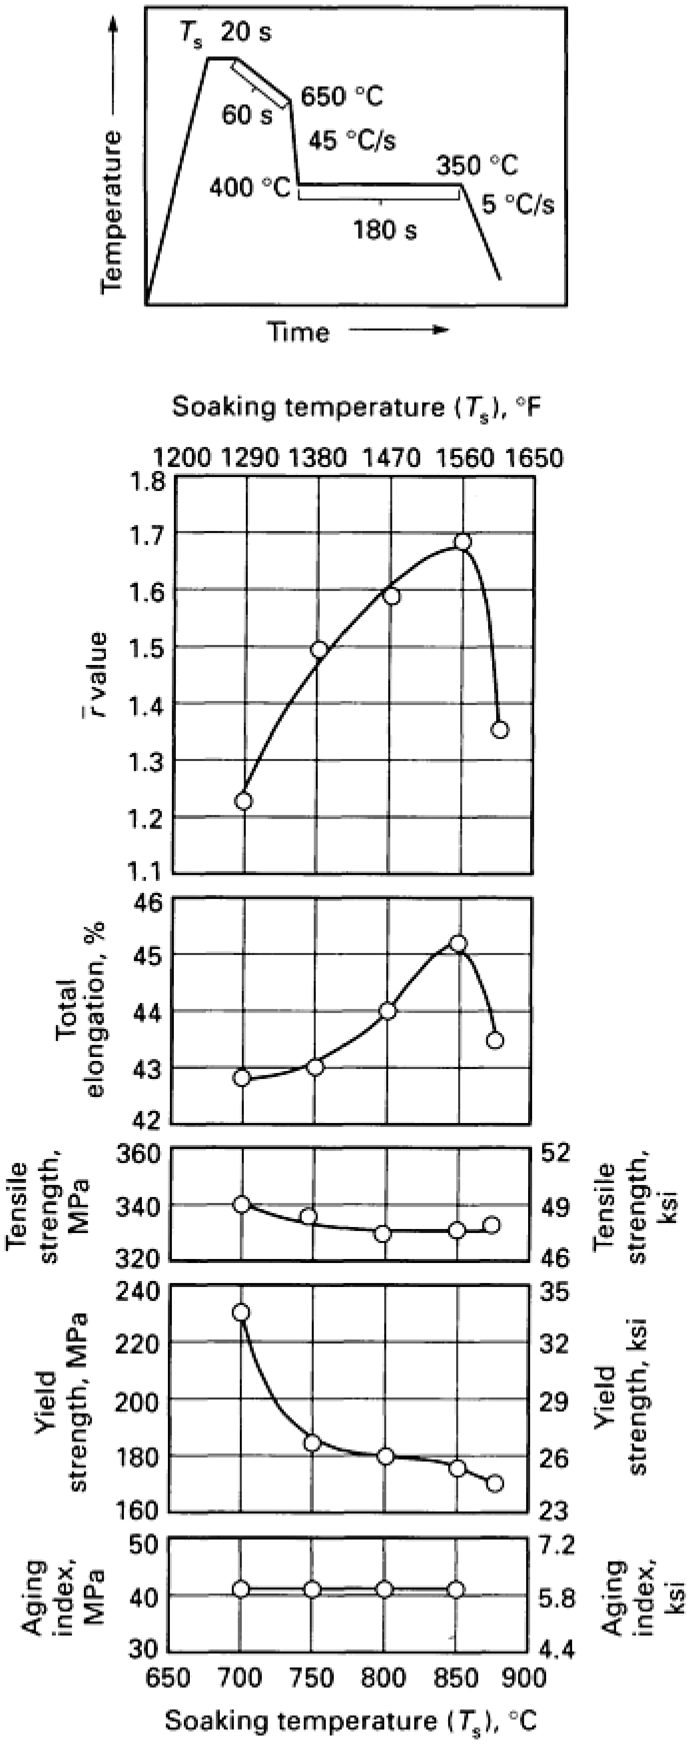

Fig. 6 Effect of soaking temperature on the properties of a 0.035% C steel. The quantity $\bar{r}$ represents the mean of the drawability values taken from measurements in the longitudinal (L), transverse (T), and two 45° (A + B) orientations. $\bar{r} = \frac{1}{4}$ (L + T + 45A° + 45B°). Source:

Ref 2

In a typical modern continuous-annealing line, the antiaging behavior is primarily improved by the adoption of rapid cooling after soaking and overaging, as described earlier. In addition, the heating capacity of the soaking furnace is increased to realize steel temperatures up to about 850 °C (1560 °F). The effect of the soaking temperature on mechanical properties is shown in Fig. 6. Increasing the soak temperature, up to the A_3 temperature, serves to improve formability (total elongation, average $\bar{r}$-value) and lower the yield strength by means of grain growth.

Additional control over steel chemistry and hot-mill processing is required. The influence of carbon content on mechanical properties is shown in Fig. 7. In order to economically achieve the optimum combination of properties, (that is, low strength, high total elongation, *n*- and $\bar{r}$-values, and low strain-aging index), the ideal carbon content is between 0.015 and 0.02%. Reducing the manganese content improves the $\bar{r}$-value. Lowering the nitrogen content to less than about 30 ppm also helps achieve optimum properties by reducing the volume fraction of aluminum nitride (AIN) particles, which inhibit grain growth. A high-temperature hot-mill coiling practice (>700 °C, or 1300 °F) is used (Ref 3) in order to:

- Ensure complete AIN precipitation and hence prevent any nitrogen strain-aging in the product
- Coarsen the AIN particles to promote grain growth during annealing
- Obtain coarse cementite in the hot band with the purpose of realizing strong {111} texture and high $\bar{r}$-value in the final product (Ref 13)

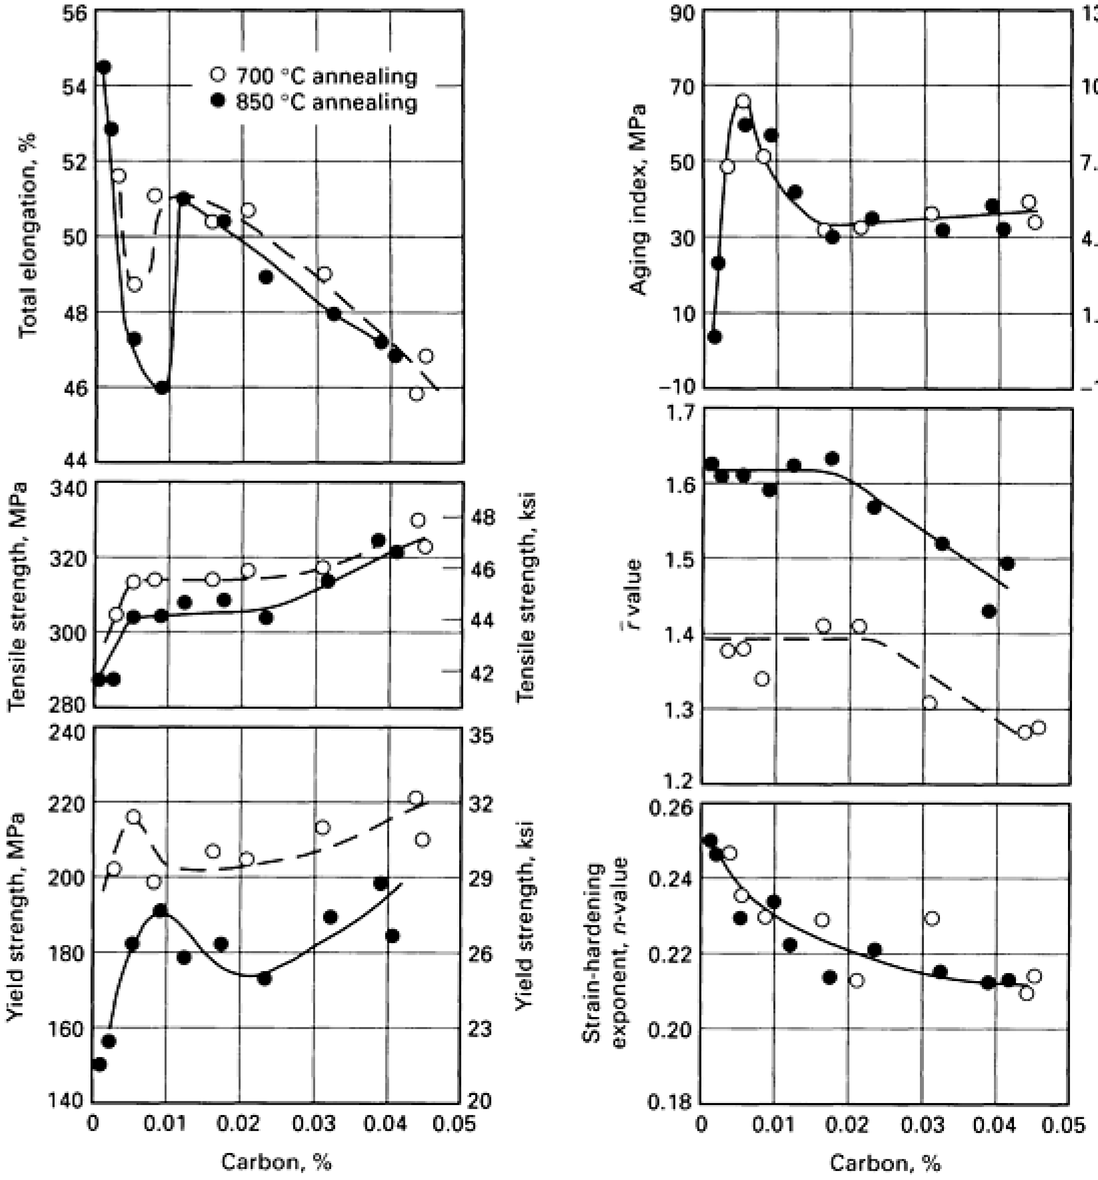

Fig. 7 Influence of carbon content on the mechanical properties of continuously annealed steel sheets. See Fig. 6 for definition of $\bar{r}$ Source: Ref 4

One disadvantage of the high-temperature coiling practice is that faster cooling conditions at the head and tail of the hotrolled coil length lead to insufficient coarsening (compared to the rest of the coil) of the AIN particles and the carbides, resulting in the degradation and nonuniformity of product properties at the coil ends after continuous annealing. This nonuniformity can be rectified by reducing the carbon and nitrogen contents to very low levels, lowering the hot-mill slab soaking temperature to suppress AIN dissolution, or raising the temperature in the head and tail sections by means of differential cooling on the hot-mill runout table (Ref 3).

The deleterious effect of AIN particles in inhibiting grain growth during annealing can be circumvented by the addition of boron (Ref 14). The addition of boron, up to the B:N stoichiometric level, results in a lowering of strength (Fig. 8) without the necessity of resorting to high hot-mill coiling temperatures. However, product with boron added has a low $\bar{r}$-value (Ref 15).

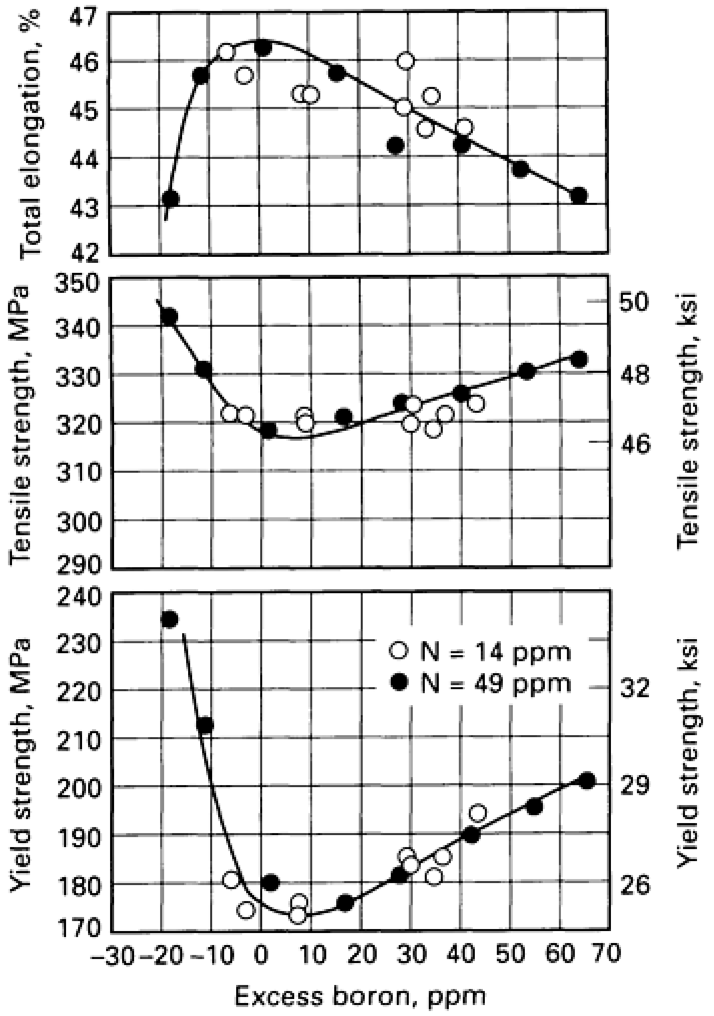

Fig. 8 Effect of boron addition on the tensile properties of a continuously annealed 0.035% C steel. Excess boron = B - 11/14 N. Source: Ref 14

Depending on the chemistry and processing controls used (as described above), the mechanical properties can fall within specific ranges:

- Yield strength, 170 to 250 MPa (25 to 36 ksi)
- Total elongation, 35 to 45%
- $\bar{r}$-value, 1.0 to 1.7

These ranges encompass both DQ and DDQ/DQSK requirements. One exception, however, is that the continuously annealed steels are not totally resistant to carbon strainaging. This is of concern when the temper-rolled product must undergo coil-coating surface treatments that involve curing at elevated temperatures (200 to 300 °C, or 400 to 600 °F), prior to forming. A return of the yield-point elongation can result in stretcher-strain defects during forming. A similar problem is encountered with hot-dip coated steel processed on an annealing and coating line that generally does not have in-line overaging (necessitating postannealing in a batch furnace). In these cases, interstitial-free steels can be used to advantage.

Interstitial-Free Steels. In IF steels, the elimination of interstitials (carbon and nitrogen) is accomplished by adding sufficient amounts of carbide/nitride-forming elements (generally titanium and/or niobium) to tie up carbon and nitrogen completely, the levels of which can be reduced to less than 50 ppm by modern steelmaking/casting practices, including vacuum degassing.

The choice of the microalloying additions (titanium, niobium, or titanium plus niobium) and the hot-mill coiling practice influence the recrystallization temperature (that is, the minimum temperature required on the annealing line to ensure 100% recrystallization) and product properties (Fig. 9). A higher coiling temperature lowers the recrystallization temperature and, in conjunction with heavy cold reduction (~80%), results in superior forming properties. A high annealing temperature is preferred for increased grain growth and high $\bar{r}$-values (Fig. 10). The cooling rate after annealing is not critical, and no overaging treatment is required. Because of this, the IF steels are ideally suited for the production of highly formable, continuously annealed, cold-rolled, hot-dip coated steels.

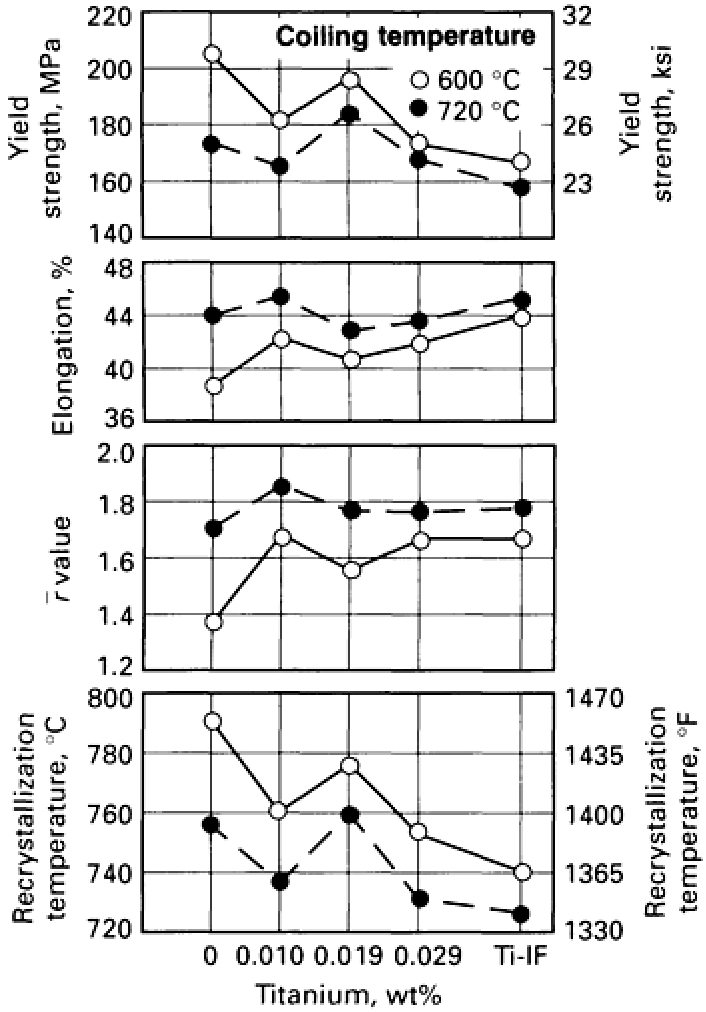

Fig. 9 Dependence of recrystallization temperature and mechanical properties on titanium content and hot-mill coiling temperature for interstitial-free steel (36 ppm C, 35 ppm N, 0.023% Nb, 0.05% Al). Source: Ref 16

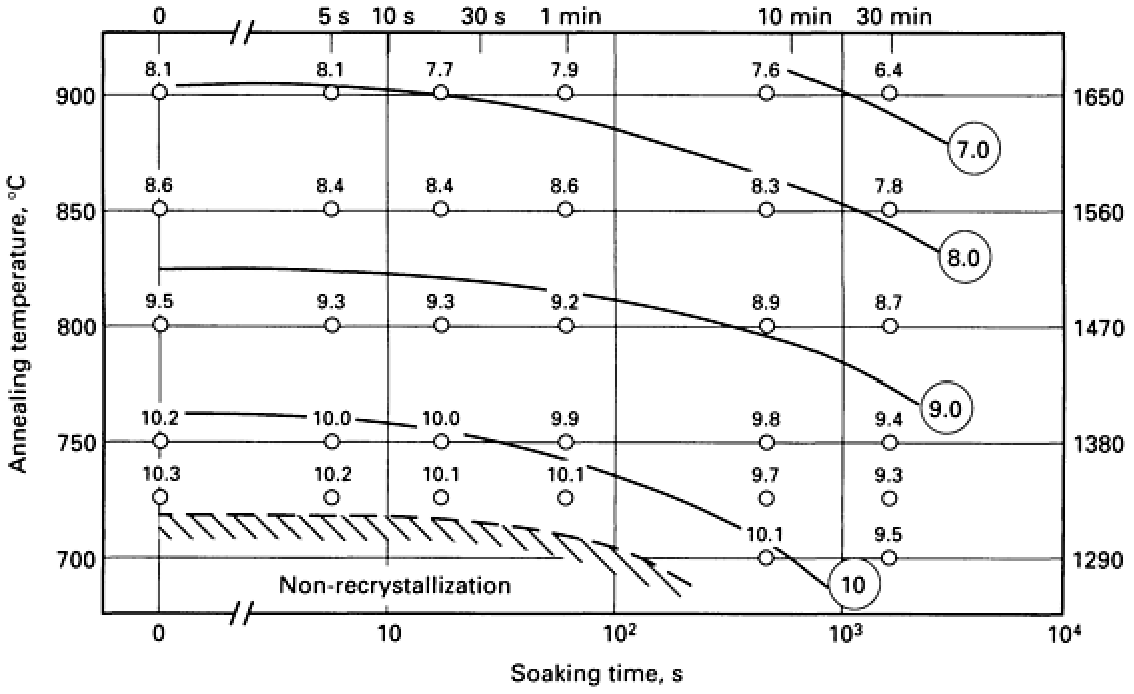
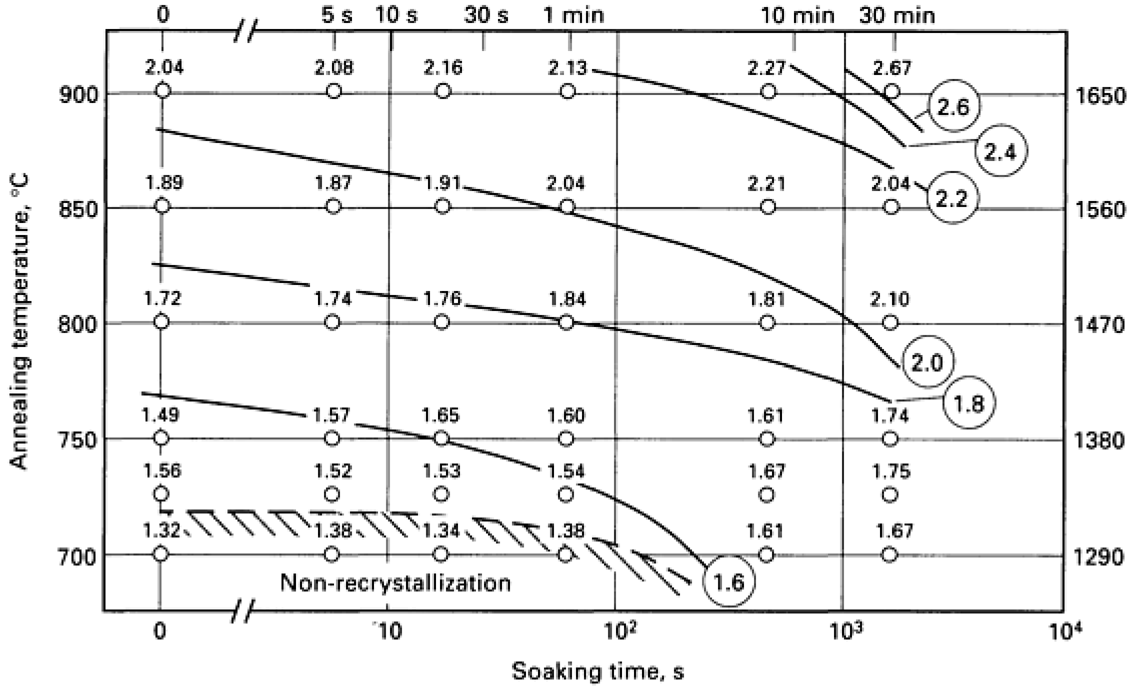


(a)



(b)

Fig. 10 Dependence of (a) grain size and (b) $\bar{r}$-value on annealing temperature/time for titanium-stabilized IF steel. In (a), numbers are ASTM grain sizes. In (b), numbers are $\bar{r}$-values. Source: Ref 17

Depending on the processing conditions, the mechanical properties of IF steels fall in the ranges:

- Yield strength, 130 to 170 MPa (19 to 25 ksi)
- Total elongation, 40 to 47%
- $\bar{r}$-value, 1.6 to 2.2

- *n*-value, 0.25 to 0.28

Higher yield strengths up to 300 MPa (34 ksi) are achieved by solid-solution strengthening with phosphorus, manganese, or silicon (Ref 16).

Bake-hardening steels are characterized by their ability to exhibit an increase in yield strength due to carbon strain aging during paint-baking operations at moderate temperatures (125 to 180 °C, or 260 to 355 °F). Bake hardening has little effect on tensile strength.

Plain Carbon Steels. In the continuous annealing of plain carbon steels, the final solute carbon is restricted to less than about 10 ppm by the fine-tuning of the primary cooling rate and the overaging temperature/time (Ref 2, 4) to ensure adequate freedom from ambient strain-aging. This level of solute carbon, however, is sufficient to realize a bake-hardening (175 °C, or 350 °F, for 20 min) yield strength increment of up to 50 MPa (7 ksi) (Ref 18).

In dual-phase steels, the martensite phase ($\leq$20 to 30 vol%) suppresses ambient strain-aging (Ref 19). Accordingly, a higher solute carbon concentration and a consequent larger bake-hardening yield strength increment ($\leq$90 MPa, or 13 ksi) are feasible.

In IF steels, a bake-hardening strength increment can be generated if several conditions are satisfied (Ref 20):

- Nb or Nb-plus-Ti chemistry with a niobium-to-carbon atomic ratio less than or equal to 1
- High annealing temperatures (~850 °C, or 1560 °F) in the continuous-annealing line to permit partial dissolution of the NbC precipitates
- Rapid cooling of $\leq$20 °C/s (35 °F/s) after annealing
- No overaging, in order to prevent the reprecipitation of carbon

In addition, if processed on a hot-dip galvanizing line, rapid cooling between the coating pot temperature and about 200 °C (400 °F) is necessary to circumvent precipitation of the solute carbon as Fe_3C. A bake-hardening yield strength increment of 20 to 40 MPa (3 to 6 ksi) has been reported (Ref 16).

Solution-Strengthened and Microalloyed HSLA Steels (Ref 21, 22, 23, 24). In solution-strengthened steels, alloying additions of manganese, phosphorus, and/or silicon are made to increase strength by substitutional solid-solution strengthening: approximately 3 MPa (0.4 ksi) per 0.1% Mn, 7 MPa (1 ksi) per 0.01% P, and 8.5 MPa (1.2 ksi) per 0.1% Si. These elements are equally effective whether the steel is batch or continuously annealed. With continuous annealing, lower alloying additions are needed to achieve a desired strength level, however, because of the finer ferrite grain size. The finer grain size is a result of, first, the very fast heating rate (compared to batch annealing), which leads to more nucleation, and, in turn, a fine grain size, and second, the short soak time (<1 min), which prevents the growth of the fine recrystallized-ferrite grains. The continuous-annealing thermal profile used to produce solid-solution-strengthened steels consists primarily of a recrystallization annealing followed by overaging, as in the case of DQ and/or DDQ steels.

In microalloyed high-strength low-alloy (HSLA) steels, which contain microadditions of niobium, titanium, or vanadium (niobium is generally preferred), higher strength levels are achieved by precipitation strengthening and grain refinement. In a continuous-annealing process, the microalloy carbonitride particles can provide effective precipitation strengthening because the short annealing time prevents the occurrence of any appreciable particle coarsening. In contrast, the coarsening of the precipitate particles that occurs during batch annealing results in a considerable decrease in the precipitation strengthening, although the particles do retard grain growth to some extent. As a consequence, for the same composition, a higher yield strength is achievable with continuous annealing (Fig. 11).

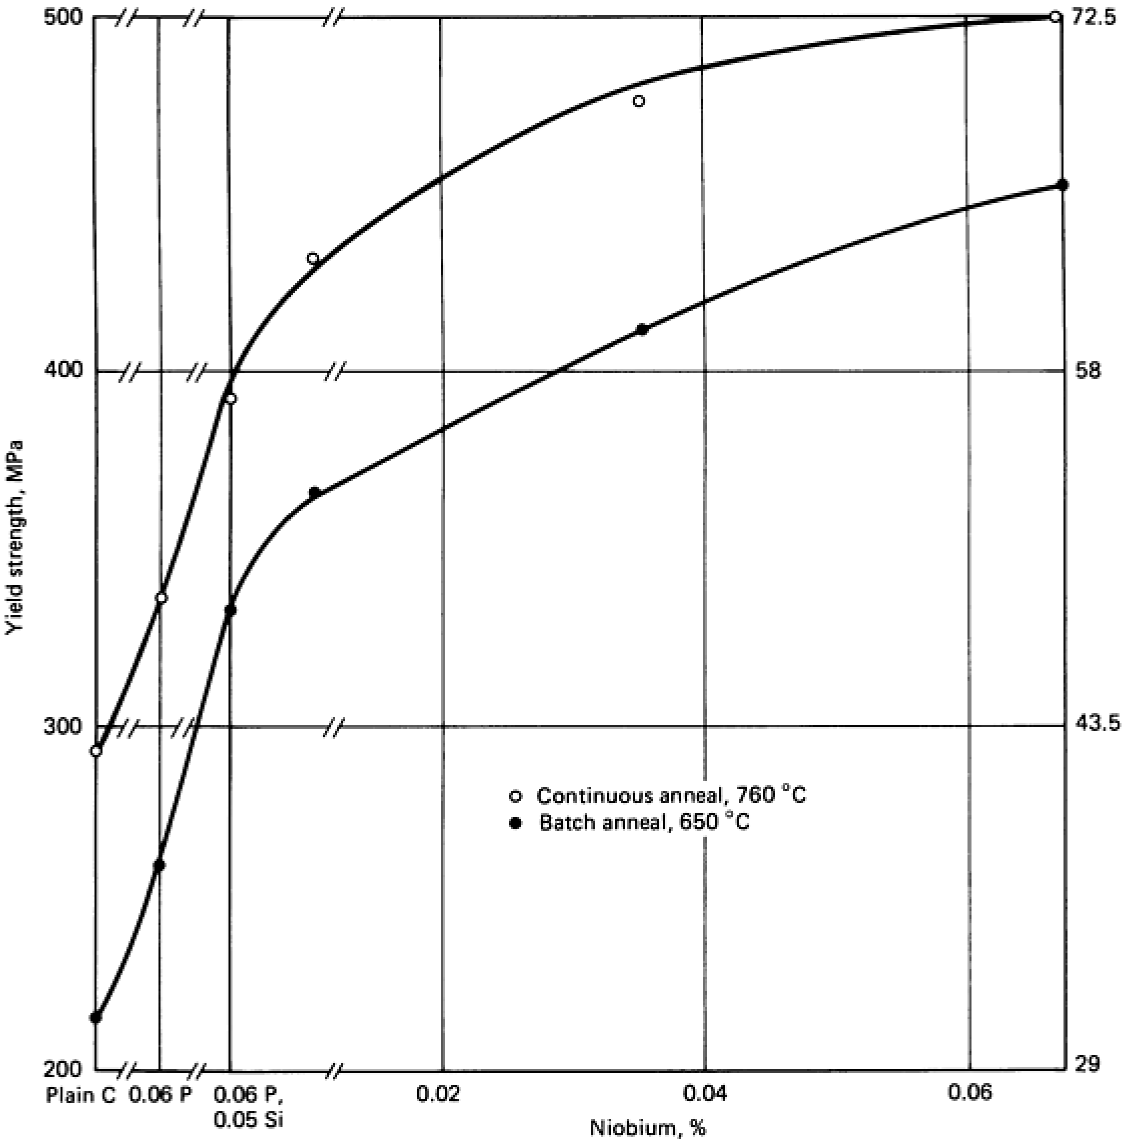


Fig. 11 Comparison of strength levels achievable by means of continuous and batch annealing of solution-strengthened and HSLA steels. Source: Ref 21

The HSLA steels are sensitive to the hot-mill coiling temperature, and a low-temperature coiling practice is preferred to maximize precipitation strengthening. The thermal profile on a continuous-annealing line for microalloyed HSLA steels is similar to that for the solution-strengthened steels. However, the HSLA steels require higher annealing temperatures in order to ensure complete recrystallization because the carbonitride particles of niobium, titanium, and vanadium retard recrystallization (Fig. 12).

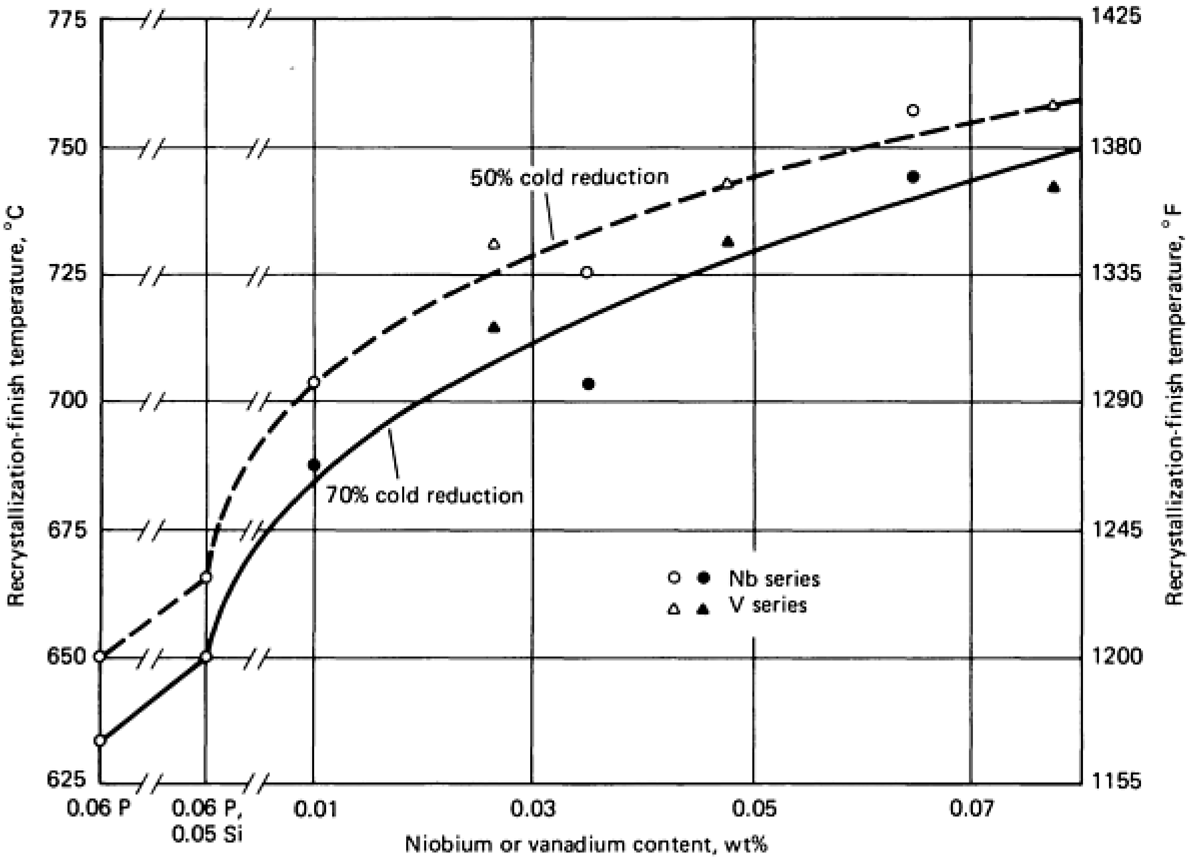

Fig. 12 Variation of recrystallization-finish temperature with alloy content in solution-strengthened and HSLA steels. Source: Ref 22

Yield strength levels ranging from about 280 to 550 MPa (40 to 80 ksi) are possible and practical with solution-strengthened and microalloyed HSLA steels. Yield ratio, that is, the ratio of yield strength to tensile strength, is about 0.8. Like the plain carbon steels, these steels exhibit bake-hardening characteristics.

Recovery-annealed steels, also known as stress-relief annealed steels, can be produced by a low-temperature annealing treatment (Fig. 13) of about 565 °C (1050 °F). High strength levels are achievable by preventing recrystallization (substructure strengthening), while some improvement in ductility can be realized because of the recovery of the cold-worked structure. The substructure strengthening is of the order of 340 MPa (50 ksi), and further increases in strength can be achieved with additions of phosphorus or silicon and also niobium, in a manner similar to that used with the fully recrystallized steels (Ref 24). Yield strengths of commercially available steels range from 600 to 800 MPa (90 to 120 ksi), with a yield ratio of about 0.95.

Dual-Phase Steels. Annealing of dual-phase steels involves soaking in the intercritical or two-phase (ferrite-plus-austenite) region, followed by the transformation of some of the austenite into martensite. The martensite is responsible for the higher strength levels, especially tensile strength, of these steels (Ref 25, 26). To promote the austenite-to-martensite transformation, a critical level of hardenability is needed, depending on the cooling rate. Lower hardenability, from a reduced amount of manganese (and/or molybdenum, chromium) in the steel, can be tolerated with a higher cooling rate (Fig. 14). As described below, there are several types of dual-phase steels, determined by the thermal profile on the annealing line following the intercritical anneal.

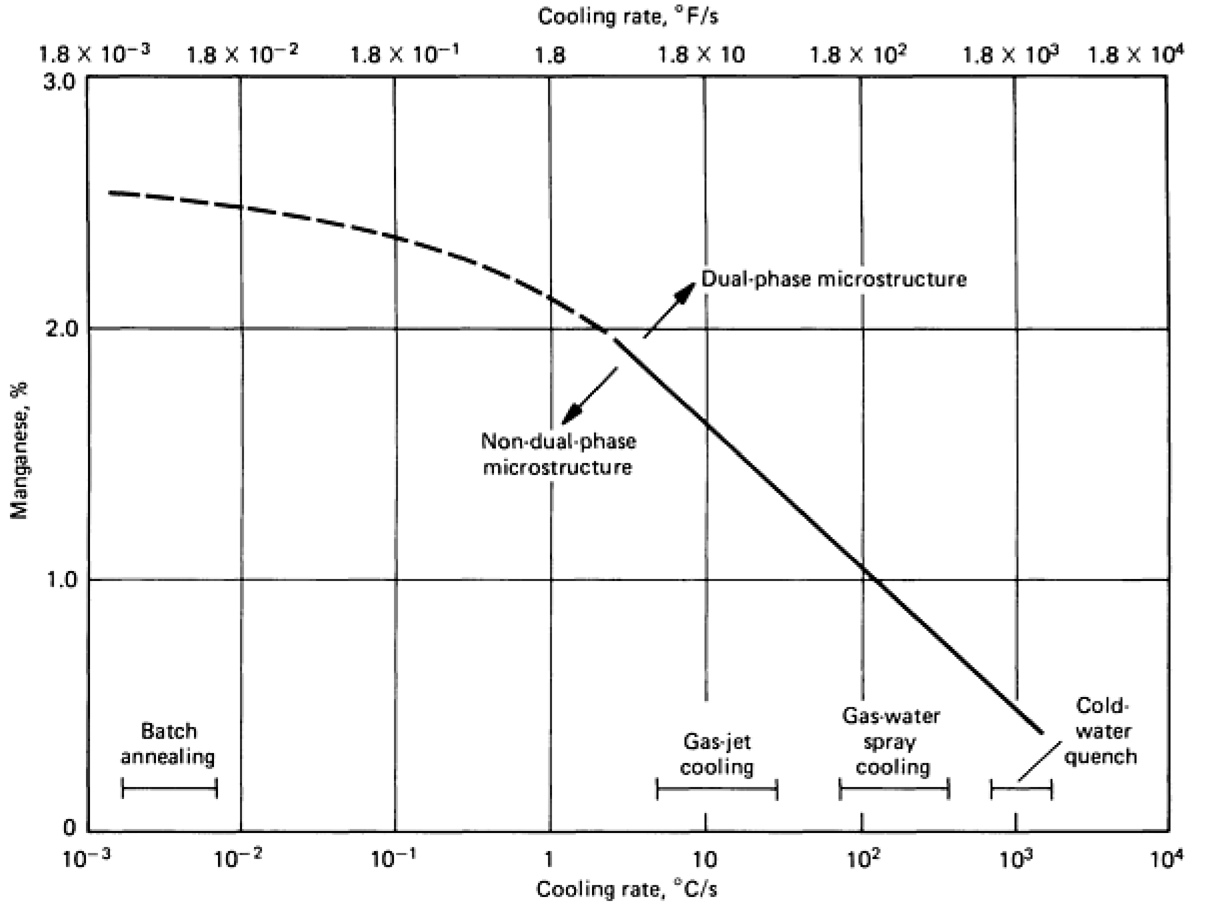

Fig. 14 Effect of cooling rate from the intercritical temperature on the manganese required to form dual-phase microstructures. Source: Ref 1

Quenching from the Intercritical Temperature. The most economical dual-phase steels can be produced by water quenching low-hardenability (0.3 to <1% Mn) steels directly from the intercritical-annealing temperature (>740 °C, or 1365 °F). The overaging treatment tempers the martensite phase and lowers the solute carbon content in the ferrite. Overaging is conducted at 400 °C (750 °F) if ductility is to be maximized or at 260 °C (500 °F) if bake hardenability is to be maximized (Ref 25, 26, 27). The overaging treatment can result in the return of the yield-point elongation, necessitating subsequent temper rolling. Different tensile strength levels (400 to 1200 MPa, or 60 to 170 ksi) are realized by altering the volume fraction of the martensite phase through changes in the carbon content, manganese content, and quenching temperature (Ref 25, 26). Dual-phase steels of this type are characterized by a yield ratio of about 0.7 and, while the $\bar{r}$-value is generally low, it can be improved somewhat by resorting to high hot-mill coiling temperatures, in conjunction with high soak temperatures on the annealing line (Ref 3).

Dual-Phase Steels with Increased Hardenability. Dual-phase steels (tensile strengths of 400 to 1000 MPa, or 60 to 140 ksi) having a low yield ratio (about 0.5), along with a superior tensile strength-ductility combination and strain-hardening behavior (high *n*-value) can be produced by lowering the quenching temperature to about 450 °C (840 °F) (Fig. 15). Because lowering the quench temperature requires gas-jet cooling (~20 °C/s, or 35 °F/s) between the soak and quench stages, the hardenability must be increased by the addition of manganese (Fig. 16). Although the manganese level is generally about 1.6%, partial substitution with molybdenum (for example, 1.3% Mn plus 0.3% Mo) offers some advantages (Ref 29). These types of dual-phase steels can be processed even on a gas-jet cooling line, with similar alloying levels. Overaging is generally restricted to less than about 150 °C (300 °F) and, because the steels are continuous yielding in the as-annealed condition, no temper rolling is required.

Fully Martensitic Steel. A related category of steels comprises the fully martensitic steels produced by annealing and water quenching from above the A_3 critical temperature. Ultrahigh tensile strength levels, ranging from 900 to 1500 MPa (130 to 210 ksi), are realized using relatively lean compositions (0.08 to 0.25% C, 0.45% Mn). To ensure a martensitic structure, some boron (10 ppm) is generally added. These steels have very limited ductility. Bendability can be improved by low-temperature (<260 °C, or 500 °F) overaging.

Both the yield and tensile strengths of martensitic steels are primarily determined by the carbon content. The 0.2% yield strength of low-carbon martensite increases with increasing carbon, as shown by (Ref 30):

$$\sigma_{0.2}(\text{MPa}) = 413 + 17.2 \times 10^5 \sqrt{wt\%C} \qquad \textbf{(Eq 1)}$$

Advantages of Continuous Annealing. Paint performance, particularly as it relates to adhesion and corrosion resistance, is dependent on sheet surface cleanliness. The presence of in-line electrolytic cleaning/scrubbing in modern annealing lines, followed by annealing at high temperatures, provides a cleaner surface than is attained for batch-annealed sheet, which is not usually cleaned electrolytically. Continuous-annealed and batch-annealed sheets are compared with regard to surface carbon contamination in Fig. 17.

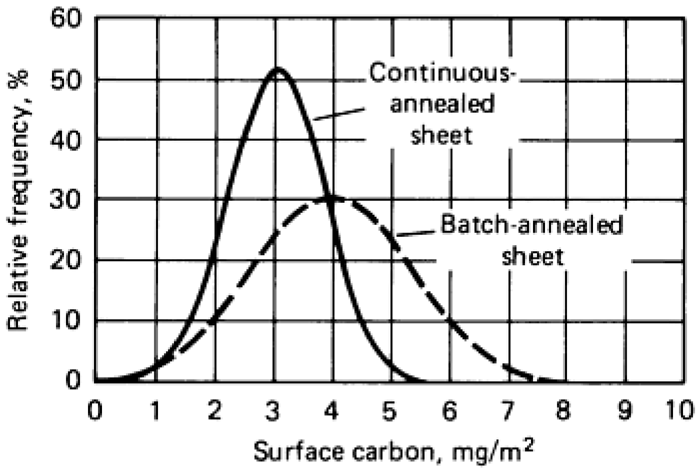

Fig. 17 Comparison of surface carbon contamination on batch- and continuous-annealed sheets. Source: Ref 31

Because a single strand of sheet is annealed on the continuous lines, the control of temperature is better than for batch annealing, and more uniform properties are obtained along the coil length. This is especially true of high-strength steel grades in which the strengthening components--precipitation (HSLA steels), substructure (recovery-annealed steels), and martensite (dual-phase steels)--are dependent on the annealing temperature. For example, in the case of a 420 MPa (60 ksi) yield strength HSLA grade, standard deviations of yield strength are reported to be 10 MPa (1.5 ksi) with continuous annealing, compared to 22 MPa (3 ksi) with batch annealing (Ref 23). For a 700 MPa (100 ksi) yield strength recovery-annealed grade, the standard deviations are 12 MPa (1.7 ksi) with continuous annealing and 31 MPa (4.5 ksi) with batch annealing.

Steels for Tinplate Applications

The conventional tinplate continuous-annealing lines involve soaking at 650 to 700 °C (1200 to 1300 °F), followed by slow gas-jet cooling (~10 °C/s, or 20 °F/s) to the ambient. The T4 (Rockwell Hardness, HR 30T = 61 ± 3) and T5 (HR 30T = 65 ± 3) tempers are being produced on these lines using plain carbon aluminum-killed chemistries.

The production of T2 (HR 30T = 53 ± 3) and T3 (HR 30T = 57 ± 3) tempers by continuous annealing have necessitated several chemistry restrictions and process modifications (Ref 32, 33, 34, 35). The optimum carbon level is 0.02 to 0.07%, with total nitrogen restricted to less than 0.003%. Hotmill coiling is restricted to below 630 °C (1165 °F) to prevent deterioration of corrosion resistance due to the presence of coarse carbides (Ref 32). The effects of pertinent continuous-annealing parameters on black-plate hardness (0.035% C, 0.003% N steel) are shown in Fig. 18. Rapid cooling (40 to 70 °C/s, or 70 to 125 °F/s) from 700 °C (1300 °F), followed by overaging at 400 to 450 °C (750 to 840 °F) for 60 s, is necessary to reduce the carbon concentration solute and, consequently, the hardness. The rapid cooling is achieved by means of high-speed gas-jet cooling systems (Ref 9, 34).

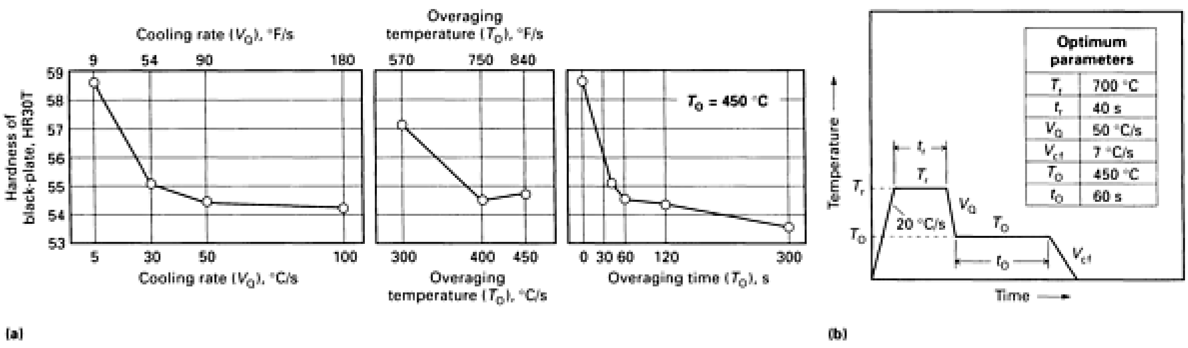

Fig. 18 (a) Effect of annealing-cycle parameters on black-plate hardness of a 0.035% C steel. (b) Heat cycle parameters and optimum

conditions determined from plots shown in (a). Source: Ref 33

Improved hardness distribution in the continuous-annealed T3 product is shown in Fig. 19 (Ref 33). Other advantages over batch-annealed product include improved corrosion resistance as a result of enhanced surface cleanliness and the prevention of surface defects caused by the surface enrichment of carbon and manganese.

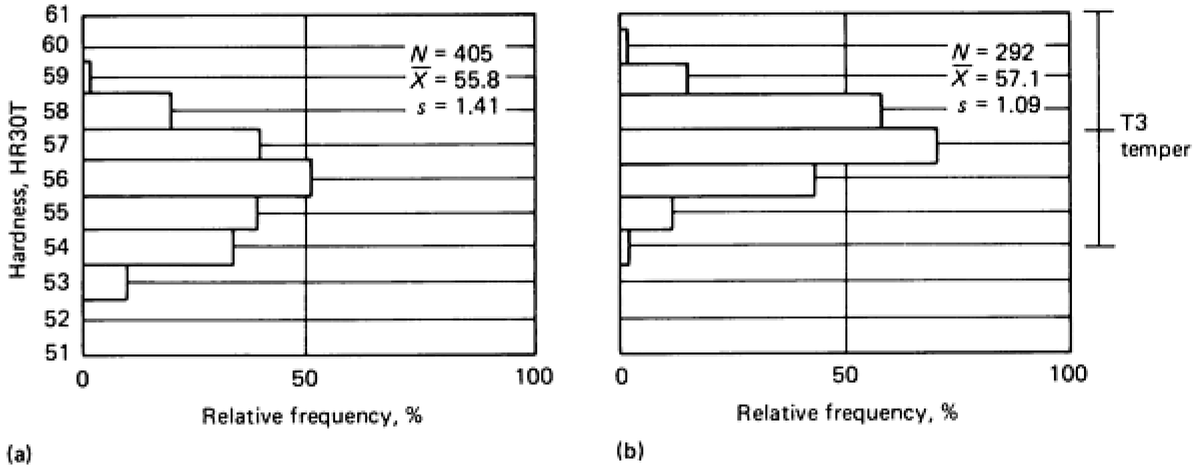

Fig. 19 Comparison of the hardness distribution of T3 tinplate produced by (a) batch annealing and (b) continuous annealing. *N*, number of specimens; *X*, mean; *S*, standard deviation. Source: Ref 33

Steels for Enameling Applications

Specific requirements for steels to be used in porcelain-enameled appliance parts, other than good formability, surface cleanliness, and flatness; include freedom from carbon boil and absence of fish scaling (Ref 1, 36, 37). Carbon boiling is associated with the presence of coarse carbides near the sheet surface that react with the enamel frit and produce carbon monoxide/dioxide bubbles and pits in the enamel surface. The formation of such carbides is unlikely with continuous annealing.

While a low carbon level of 0.015 to 0.02% is desirable from a formability stand-point (Fig. 7), a higher carbon level is preferred in enameling steels to provide resistance to fish scaling, which is the expulsion of enamel fragments caused by the diffusion of hydrogen from the steel. Alternate means of improving the fish scaling resistance include the introduction of BN particles by the addition of boron (30 to 60 ppm) or of TiN/TiS particles by the use of an IF-type chemistry. The second alternative also provides excellent formability.

Quenching of Steel

Charles E. Bates, Southern Research Institute; George E. Totten, Union Carbide Chemicals and Plastics Company Inc.; Robert L. Brennan, E.F. Houghton & Company

Introduction

QUENCHING refers to the process of rapidly cooling metal parts from the austenitizing or solution treating temperature, typically from within the range of 815 to 870 °C (1500 to 1600 °F) for steel. Stainless and high-alloy steels may be quenched to minimize the presence of grain boundary carbides or to improve the ferrite distribution but most steels including carbon, low-alloy, and tool steels, are quenched to produce controlled amounts of martensite in the microstructure. Successful hardening usually means achieving the required microstructure, hardness, strength, or toughness while minimizing residual stress, distortion, and the possibility of cracking.

The selection of a quenchant medium depends on the hardenability of the particular alloy, the section thickness and shape involved, and the cooling rates needed to achieve the desired microstructure. The most common quenchant media are either liquids or gases. The liquid quenchants commonly used include:

- Oil that may contain a variety of additives
- Water
- Aqueous polymer solutions
- Water that may contain salt or caustic additives

The most common gaseous quenchants are inert gases including helium, argon, and nitrogen. These quenchants are sometimes used after austenitizing in a vacuum.

The ability of a quenchant to harden steel depends on the cooling characteristics of the quenching medium. Quenching effectiveness is dependent on the steel composition, type of quenchant, or the quenchant use conditions. The design of the quenching system and the thoroughness with which the system is maintained also contribute to the success of the process.

Fundamentals of Quenching and Quenchant Evaluation

Fundamentally, the objective of the quenching process is to cool steel from the austenitizing temperature sufficiently quickly to form the desired microstructural phases, sometimes bainite but more often martensite. The basic quenchant function is to control the rate of heat transfer from the surface of the part being quenched.

Quenching Process

The rate of heat extraction by a quenching medium and the way it is used substantially affects quenchant performance. Variations in quenching practices have resulted in the assignment of specific names to some quenching techniques:

- Direct quenching
- Time quenching
- Selective quenching
- Spray quenching
- Fog quenching
- Interrupted quenching

Direct quenching refers to quenching directly from the austenitizing temperature and is by far the most widely used practice. The term direct quenching is used to differentiate this type of cycle from more indirect practices which might involve carburizing, slow cooling, reheating, followed by quenching.

Time quenching is used when the cooling rate of the part being quenched needs to be abruptly changed during the cooling cycle. The change in cooling rate may consist of either an increase or a decrease in the cooling rate depending on which is needed to attain desired results. The usual practice is to lower the temperature of the part by quenching in a medium with high heat removal characteristics (for example, water) until the part has cooled below the nose of the time-temperature-transformation (TTT) curve, and then to transfer the part to a second medium (for example, oil), so that it cools more slowly through the martensite formation range. In some applications, the second medium may be air or an inert gas. Time quenching is most often used to minimize distortion, cracking, and dimensional changes.

Selective quenching is used when it is desirable for certain areas of a part to be relatively unaffected by the quenching medium. This can be accomplished by insulating an area to be more slowly cooled so the quenchant contacts only those areas of the part that are to be rapidly cooled.

Spray quenching involves directing high-pressure streams of quenching liquid onto areas of the workpiece where higher cooling rates are desired. The cooling rate is faster because the quenchant droplets formed by the high-intensity spray impact the part surface and remove heat very effectively. However, low-pressure spraying, in effect a flood-type flow, is preferred with certain polymer quenchants.

Fog quenching utilizes a fine fog or mist of liquid droplets in a gas carrier as the cooling agent. Although similar to spray quenching, fog quenching produces lower cooling rates because of the relatively low liquid content of the stream.

Interrupted quenching refers to the rapid cooling of the metal from the austenitizing temperature to a point above the M_s where it is held for a specified period of time, followed by cooling in air. There are three types of interrupted quenching: austempering, marquenching (martempering), and isothermal quenching. The temperature at which the quenching is interrupted, the length of time the steel is held at temperature, and the rate of cooling can vary depending on the type of steel and workpiece thickness. Comparisons of direct and interrupted quench cycles are shown in Fig. 1.

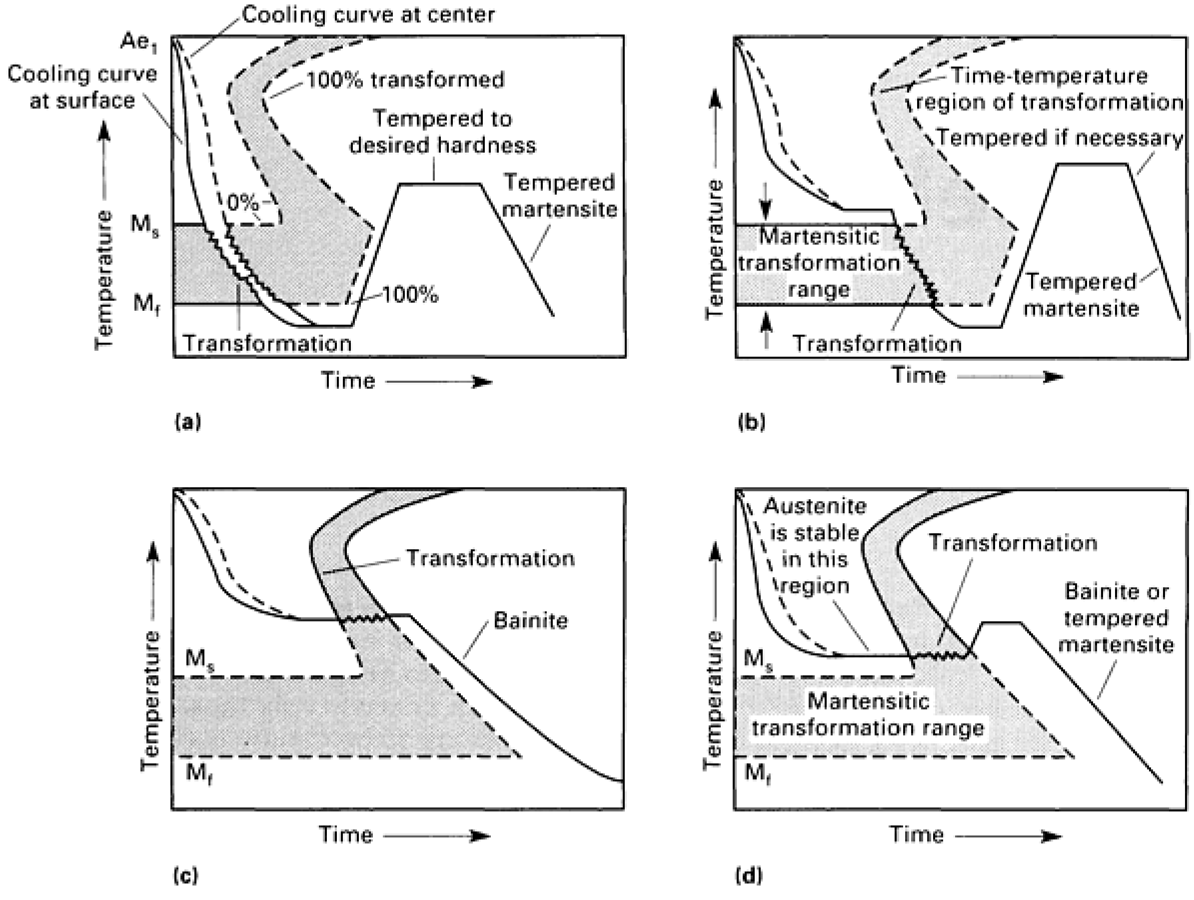

Fig. 1 Comparison of cooling rates and temperature gradients as workpieces pass into and through martensite transformation range for a conventional quenching and tempering process and for interrupted quenching processes. (a) Conventional quenching and tempering processes that use oil, water, or polymer quenchants. (b)

Marquenching, which uses either salt or hot oil as a quenchant. (c) Austempering, which uses a salt as a quenchant. (d) Isothermal quenching, which uses either salt or hot oil as a quenchant. Source: Ref 1

Austempering consists of rapidly cooling the metal part from the austenitizing temperature to about 230 to 400 °C (450 to 750 °F) (depending on the transformation characteristics of the particular steel involved), holding at a constant temperature to allow isothermal transformation, followed by air cooling.

Austempering is applicable to most medium-carbon steels and alloy steels. Low-alloy steels are usually restricted to 9.5 mm ($\frac{3}{8}$ in.) or thinner sections, while more hardenable steels can be austempered in sections up to 50 mm (2 in.) thick.

Molten salt baths are usually the most practical for austempering applications. Oils have been developed that suffice in some cases, but molten salts possess better heat-transfer properties and eliminate the fire hazard.

Marquenching. The marquenching (martempering) process is similar to austempering in that the workpiece is quenched rapidly from the austenitizing range into an agitated bath held near the M_s temperature. It differs from austempering in that the workpiece remains at temperature only long enough for the temperature to be equalized throughout the workpiece. When the temperature has attained equilibrium but before transformation begins, the workpiece is removed from the salt bath and air cooled to room temperature. Oils are used successfully for marquenching, but molten salt is usually preferred because of its better heat-transfer properties.

Cooling from the marquenching bath to room temperature is usually conducted in still air. Deeper hardening steels are susceptible to cracking while martensite forms if the cooling rate is too rapid. Alloy carburizing steels, which have a soft core, are insensitive to cracking during martensite formation, and the rate of cooling from the M_s temperature is not critical.

Marquenching does not remove the necessity for subsequent tempering. The structure of the metal is essentially the same as that formed during direct quenching.

Isothermal quenching is also similar to austempering in that the steel is rapidly quenched through the ferrite and pearlite formation range to a temperature just above M_s. However, isothermal quenching differs from austempering in that two quench baths are employed. After the first quench, and before transformation has time to begin, the workpiece is transferred to a second bath at a somewhat higher temperature where it is isothermally transferred, followed by cooling in air.

Cooling Curves and Processing Effects on Curve Shape

The examination of quenching performance by cooling curve analysis is becoming increasingly popular and perhaps the most informative method of characterizing a quenchant medium. Cooling curves are obtained by quenching a test piece containing one or more thermocouples into a test sample of the quenching fluid, in a laboratory quenching bath, or in the production bath itself. The test piece (probe) may be constructed from the alloy of interest, from an austenitic stainless steel, or a nickel-base alloy such as Inconel. The use of austenitic steel and nickel alloy specimens reduces or eliminates the need for a protective atmosphere while the test pieces are being solution treated. Silver has also been used as the probe material.

The test probes are heated to an elevated temperature and then quenched into the medium of interest. A high-speed recorder is used to record temperature changes with respect to time. The resulting time-temperature curves reflect the heat removal characteristics of the quenching fluid and the mass and surface area of the test probe.

The resulting cooling curves provide information about the cooling rates achieved in the part. Most metallurgical transformation data is presented in terms of the cooling rate needed to achieve a specific microstructure and these rates

can often be related to the cooling rates obtained from quenchant cooling curve analysis. In a given grade of steel, low cooling rates usually produce ferritic microstructures while progressively higher rates produce pearlite, bainite, and finally, martensite. Cooling rates produced by quenchants may be related to specific microstructures, as will be subsequently discussed.

There are generally considered to be three stages of heat removal, referred to as A, B, and C stages, associated with quenching in liquids. A temperature-time cooling curve illustrating the three stages is shown in Fig. 2. This curve was obtained with a 38 mm (1.5 in.) stainless steel probe solution treated at 845 °C (1550 °F) and quenched in unagitated water. The probe had a thermocouple located at the geometric center. A cooling rate curve, which is obtained by taking the first derivative of the time-temperature curve, is also shown.

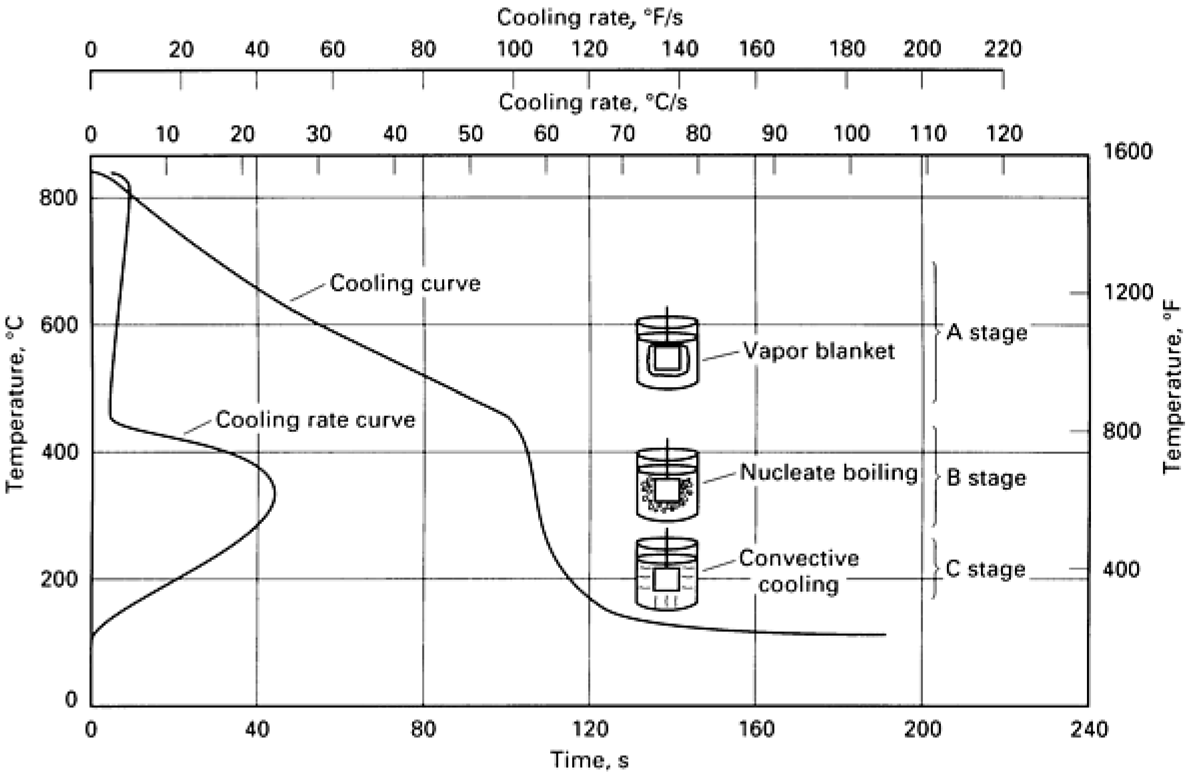

Fig. 2 Cooling curve and cooling rate curve at the center of a 25 mm (1.0 in.) diameter probe quenched with 95 °C (200 °F) water flowing at 15 m/min (50 ft/min)

Stage-A Heat Removal. The first stage of cooling, referred to as the A-stage, is characterized by a quenchant vapor blanket around the part. Stage A, also called the vapor blanket cooling stage, is characterized by the Leidenfrost phenomenon, namely, the formation of a uniform vapor blanket around the test piece. The vapor blanket develops and is maintained while the supply of heat from the interior of the part to the surface exceeds the amount of heat needed to evaporate the quenchant and maintain the vapor phase.

Relatively slow cooling occurs during this period because the vapor envelope acts as an insulator, and cooling occurs principally by radiation through the vapor film. The temperature above which a total vapor blanket is maintained is called the characteristic temperature of the liquid. The characteristic temperature is also known as the Leidenfrost temperature. Beck has shown that the Leidenfrost temperature of a quenchant medium is independent of the initial temperature of the metal being quenched, as illustrated in Fig. 3.

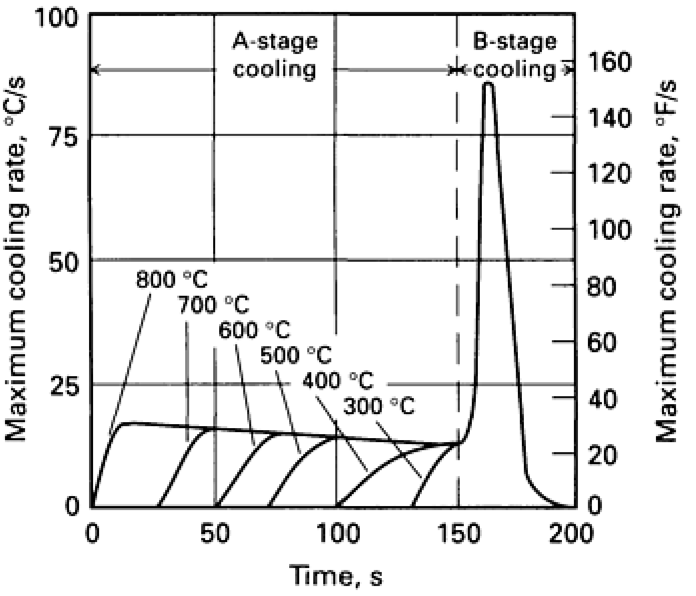

Fig. 3 Cooling rate in a 24 mm ($\frac{15}{16}$ in.) diam by 72 mm ($\frac{27}{32}$ in.) long Inconel 600 probe quenched from temperatures between 300 and 800 °C (570 to 1470 °F) into 100 °C (212 °F) water. Source: Ref 2)

The A-stage of cooling is not usually present in parts quenched in aqueous solutions containing more than about 5 wt% of an ionic material such as potassium chloride, lithium chloride, sodium hydroxide, or sulfuric acid. Cooling curves for these solutions start immediately with stage B. The presence of the salts at the hot metal quenchant interface initiates nucleate boiling almost immediately.

A-stage cooling is not observed when quenching in nonvolatile quenchant media such as molten salt baths. Conversely, heat transfer in gas quenchants such as air and inert gases occurs exclusively by a vapor blanket mechanism.

Stage-B Heat Removal. The highest cooling rates occur in stage B or the nucleate boiling stage. During this period, the vapor envelope collapses, and high heat extraction rates are achieved that are associated with nucleate boiling of the quenchant on the metal surface. Heat is rapidly removed from the surface as liquid quenchant contacts the metal surface and is vaporized.

Stage-C Heat Removal. Stage C is called the liquid cooling stage. Stage C begins when the temperature of the metal surface is reduced below the boiling point of the quenching liquid. Below this temperature, boiling stops and cooling takes place by conduction and convection into the quenchant. C-stage cooling rates are dependent on the viscosity of the quenchant. All other factors being equal, cooling rates decrease with increasing viscosity.

Figure 4 illustrates the three stages of cooling: vapor blanket (A-stage), nucleate boiling (B-stage), and convective (C-stage). These cooling stages are typically obtained when an austenitized steel rod is quenched into an aqueous polyalkylene glycol (PAG) polymer solution. Similar studies have also been performed with other quenchants including water, oil, and other aqueous polymer quenchants (Ref 3, 4, 5).

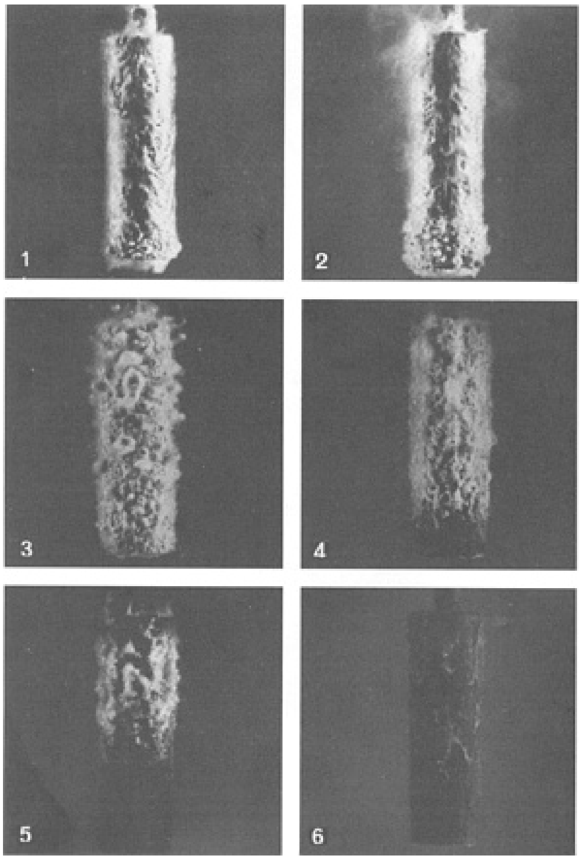

Fig. 4 Photo sequence of a hot steel rod being quenched in a 25% polyalkylene glycol (PAG) polymer in water solution. (1) When the rod is immersed, a polymer film forms on its surface. (2) After 15 s, polymer activates and begins to boil. (3) After 25 s, boiling occurs over the entire rod as the cooling rate increases. (4) After 35 s, boiling collapses and the convection stage begins. (5) After 60 s, the polymer starts to redissolve. (6) After 75 s, polymer film has completely redissolved and the heat removal is achieved entirely by convection.

Agitation refers to liquid quenchant movement relative to the part. Agitation is usually obtained by stirring the liquid, but in some cases it is obtained by moving the part in the liquid. Agitation has an extremely important influence on the heat transfer. Agitation causes mechanical disruption of the vapor blanket in Stage A and a faster transition to B-stage cooling. Increasing agitation usually produces a shorter A-stage cooling time and faster cooling rates in all three regions.

Conversely, higher quench bath temperatures typically produce longer A-stage cooling times and slower cooling rates in the B- and C-stage regions. However, modestly higher temperatures in oil quench baths can improve the heat removal characteristics by reducing oil viscosity. An improvement in quench oil wetting characteristics may be obtained with increasing bath temperature, which results in higher cooling rates. Therefore, the cooling performance of many quench oils is often independent of modest variations in bath temperature.

Nonuniform quenching may result if agitation is not used because of localized hot spots resulting from uneven heat removal from the metal surface. This may lead to spotty hardness, increased surface cracking, distortion, and higher residual stresses.

Factors Affecting Heat Transfer Rate. The rate of heat transfer from a part being quenched may be affected by oxidation of the surface. This can either increase or decrease the heat transfer rate, depending on the thickness of the oxide developed.

The effect of irregular configuration on heat flow from a gear to the quenching area is illustrated in Fig. 5. High temperatures persist near the surface at the roots of the teeth where large vapor bubbles are trapped. If the gear were induction or flame heated, and thus had a uniformly thin heated layer conforming to the contour, quenching would progress more rapidly and uniformly because heat also would flow simultaneously to the cold metal underlying the heated exterior and the quenchant.

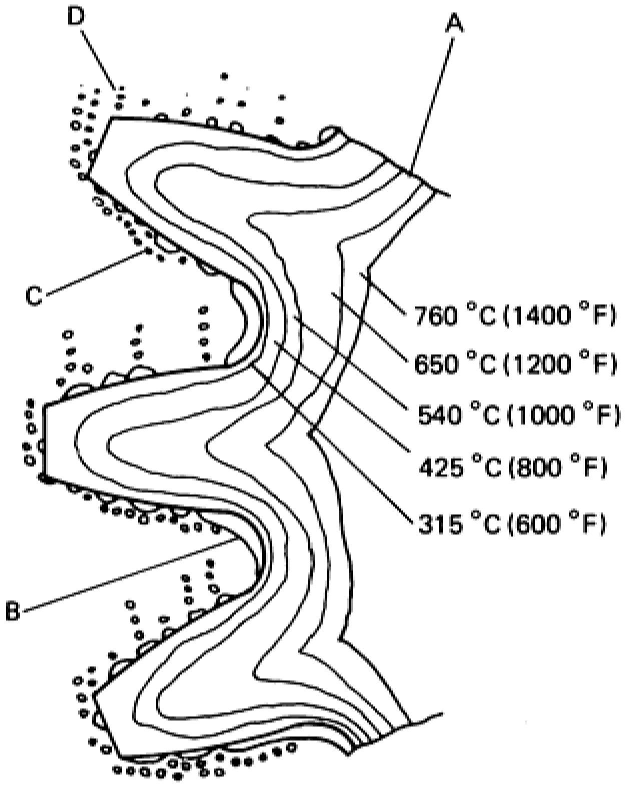

Fig. 5 Temperature gradients and other factors affecting the edgewise quenching of a gear in a quiescent volatile liquid. A, flow of heat from hot core of gear. Temperature and flow rate vary with time; B, vapor blanket stage still exists due to large source of heat and poor agitation; C, trapped vapor bubbles condensing slowly; D, vapor bubbles escaping and condensing

The actual cooling rates and temperature ranges associated with the three stages of cooling vary with the type of quenchant and the mass and surface area of the part being quenched. The highest cooling rates are generally obtained with brine solutions, followed by water, synthetic polymer quenchants, oils, salt baths, fluidized beds, and gases. There are, of course, substantial variations in the attainable cooling rates within particular classes of quenchants depending on the temperature, extent of agitation, viscosity, molecular weight, wetting characteristics, polymer or oil additive concentration, gas pressure, and gas velocity.

The cooling rates are also functions of the thickness and geometry of the part, and characteristics of the quenching facility including the extent of agitation, racking procedure, extent of surface oxidation, and the effective heat transfer coefficient between the part and the quenchant.

The same heat transfer mechanisms involved in cooling test pieces and instrumented probes are involved in quenching parts during a heat-treating operation. Although a particular cooling curve is strictly related only to the size and material of the test piece, thermocouple location in the test piece, and conditions of the quenching liquid under which a test was performed, cooling curves developed under one set of conditions may be translated to other conditions by applying appropriate heat transfer formulas.

Cooling Curve Analysis

An analysis of cooling curves is particularly useful when studying quenchants because they illustrate the mechanisms involved in the quenching process over a wide temperature range. Cooling curves can also be analyzed to provide quantitative heat transfer data as a function of temperature.

Today, it is generally recognized that the cooling rate curve, which is the first derivative of the temperature-time data with respect to time, is probably more informative than the time-temperature curve. Cooling rate curves can be readily

calculated when data are collected using digital recorders or personal computers equipped with an analog-to-digital (A/D) converter.

The heat removal characteristics of a quenchant medium are commonly studied using a standard test piece (probe) which may be a bar, a plate, or a sphere. The most common probe configuration is a cylindrical bar with a length of at least four times the diameter to minimize end cooling effects. A thermocouple is usually located at the geometric center of the probe. For some studies, it may be informative to construct a probe with a second thermocouple located at, or near, the probe surface. This will allow quantification of the temperature change across the test piece during the quenching process.

Two of the more common parameters obtained from cooling curves are the maximum cooling rate ($\dot{T}_{max}$ or CR_{max}) and the cooling rate at about 300 °C (CR_{300}). Usually it is desirable for the CR_{max} to occur at higher temperatures, in the region of the ferrite and pearlite transformation region if maximum hardness is desired, because this minimizes ferrite and pearlite formation. Cooling rates in the region where martensite starts to form from austenite, M_s, should be minimized to reduce the potential for cracking and distortion. The cooling rate at 300 °C (CR_{300}) is often used since this is near the M_s temperature for many carbon and low-alloy steels. Although CR_{max} and CR_{300} temperatures (and other representative values) provide useful descriptions of the quenching process, more comprehensive quantification is often desirable.

Tensi has suggested a set of cooling rate criteria which provides a reasonably complete quantification of the quenching process (see Fig. 6). The values suggested by Tensi include:

- Time (t_u), temperature (T_u), and cooling rate ($\dot{T}_{DHmin}$) where the transition from A-stage to B-stage cooling occurs
- Maximum cooling rate (CR_{max}) and the temperature (T_{max}) where this occurs
- Rate of cooling at defined temperatures where C-stage cooling occurs such as 300 °C (CR_{300}) or 200 °C (CR_{200})

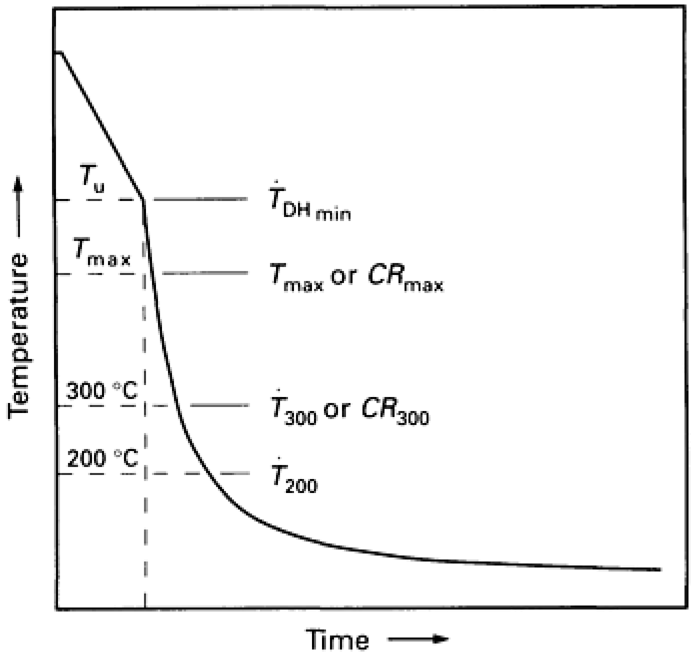

Fig. 6 Critical cooling curve parameters. Source. Ref 6

One of the limitations in the various methods of cooling curve analysis procedures published to date is that very little metallurgical property correlations have been performed. Tensi has addressed this issue by demonstrating that the wettability of a quenchant on a metal workpiece (rewetting time) may be correlated with hardness. A procedure has been developed for obtaining rewetting times by recording cooling curves obtained simultaneously from a probe with multiple

thermocouples (see Fig. 7). These values have been used to develop correlation plots between hardness (HRC) and rewetting time with various steels including an AISI 1045 steel, as illustrated in Fig. 8.

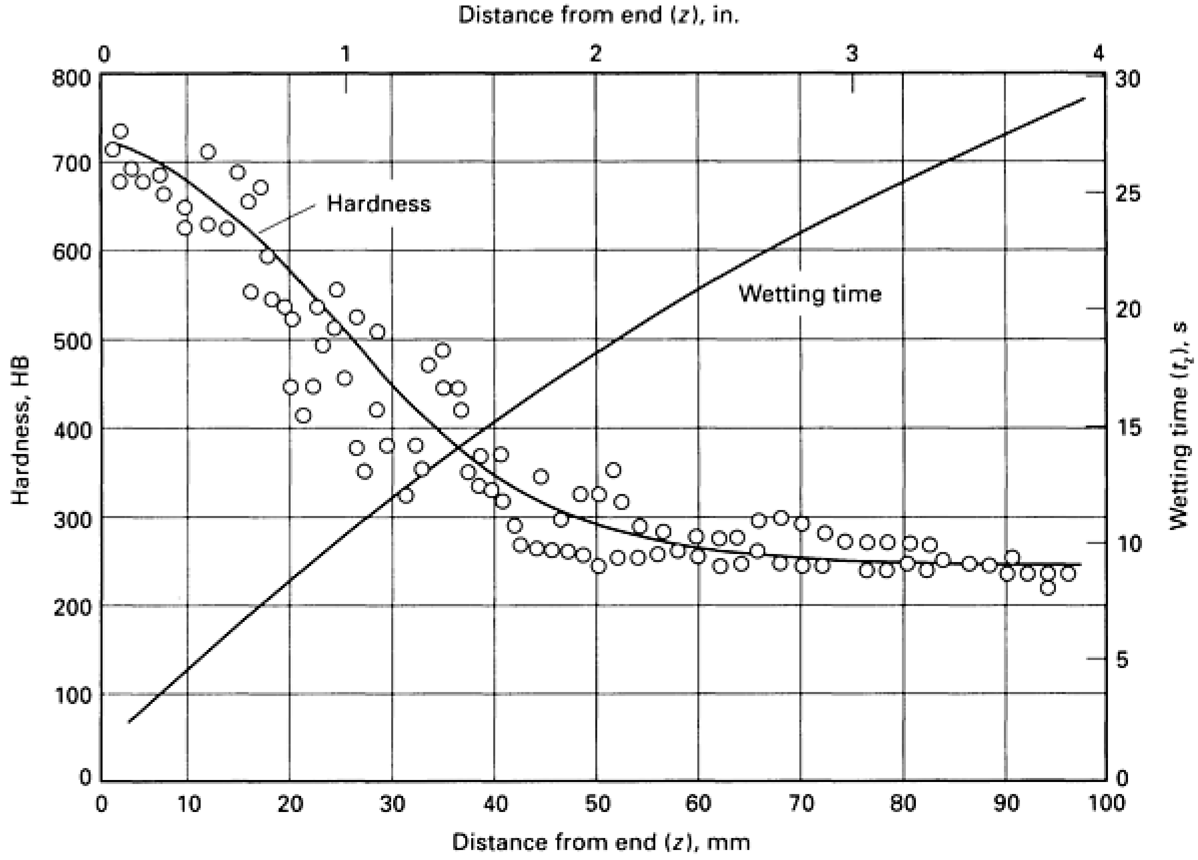

Fig. 8 Wetting time and surface hardness of quenched 1045 steel as a function of the distance from the end of

the specimen. Source: Ref 11

Another method of estimating asquenched hardness of steel from cooling curves is by quench factor analysis (Ref 12). Quench factor analysis permits the direct correlation of the shape of a cooling curve with the appropriate property curve that is developed for the steel of interest. This approach will be described in more detail in the section "Quench Factor Analysis."

Heat Transfer during Quenching. Heat removal from parts during quenching can be mathematically described in terms of the effective interface heat transfer coefficient. A quenchant must impart a sufficiently high interface heat transfer coefficient to produce a cooling rate that will minimize transformation of austenite to ferrite or pearlite and yield the desired amount of martensite or bainite.

The interface heat transfer coefficient is defined as:

$$h = \frac{q}{A\ (T_1 - T_2)} \qquad \textbf{(Eq 1)}$$

where h is the interface heat transfer coefficient; q is the heat flow from the part to the quenchant; A is the part area; T_1 is the part surface temperature; and T_2 is the bath temperature.

A similar ratio, more widely used in steel quenching, is the Grossmann number (H) defined by the following equation:

$$H = \frac{h}{2k} \qquad \textbf{(Eq 2)}$$

where k is the conductivity of the metal.

Thus, the interface heat transfer coefficient is equal to the Grossmann number multiplied by twice the thermal conductivity of the metal.

The interface heat transfer coefficient under conditions of interest can be determined by recording a cooling curve using a thermocouple located in the center of cylindrical test probes, determining the cooling rate over a particular temperature interval (such as 595 to 705 °C, or 1100 to 1300 °F) from the cooling curve, and using this value in a polynomial expression that relates the cooling rate to the interface heat transfer coefficient. This approach provides an effective interface heat transfer coefficient over a temperature range that brackets the nose of most TTT curves. If the effective heat transfer coefficient is divided by twice the thermal conductivity, the Grossmann *H*-factor can be obtained.

Table 1, published in 1947, provides Grossmann numbers for selected quenchants. This table has provided valuable guidance to heat treaters since its publication in spite of the fact that quenchant velocities were not well defined.

Table 1 Approximate Grossmann quenching severity factor of various media in the pearlite temperature range

Circulation or agitation	Grossmann quench severity factor, *H*			
	Brine[a]	Water[a]	Oil[a] and salt	Air[b]
None	2	0.9-1.0	0.25-0.30	0.02
Mild	2-2.2	1.0-1.1	0.30-0.35	. . .

Moderate	. . .	1.2-1.3	0.35-0.40	. . .
Good	. . .	1.4-1.5	0.4-0.5	. . .
Strong	. . .	1.6-2.0	0.5-0.8	. . .
Violent	5	4	0.8-1.1	. . .

(a) Ref 3.

(b) Ref 14.

Often a heat treater requires a more precise estimate of the Grossmann quench severity factor (*H*-factor) of the quench bath than attainable from Table 1. For example, many of the recently introduced software packages for predicting as-quenched hardness require an input of an *H*-factor in order to predict as-quenched hardness, and so on. Therefore, a relatively simple method of estimating the *H*-factor would be particularly valuable.

An algorithm was recently published which permits the estimation of the *H*-factor directly from cooling curve data (Ref 16). The algorithm has the general form:

$$H = A(CR_{1300})^{C} \exp(BX^{D}) \qquad \textbf{(Eq 3)}$$

where CR_{1300} is the cooling rate at 705 °C (1300 °F) obtained with a type 304 stainless steel probe and *A*, *B*, *C*, and *D* are statistical curve fitting parameters given in Table 2. Models have been developed that permit the estimated *H*-factors obtained from 13, 25, 38, and 50 mm (0.5, 1.0, 1.5, and 2.0 in.) diameter cylindrical AISI type 304 stainless steel probes from the cooling rate, as illustrated in Fig. 9.

Table 2 Model parameters used to calculate the *H*-factor

Probe diameter		**Model parameters**			
mm	**in.**	***A***	***B***	***C***	***D***
12.7	0.5	0.002802	0.1857×10^{-7}	1.201	2.846
25.4	1.0	0.002348	0.2564×10^{-9}	1.508	4.448
38.1	1.5	0.002309	0.5742×10^{-9}	1.749	5.076
50.8	2.0	0.003706	0.3546×10^{-10}	1.847	6.631

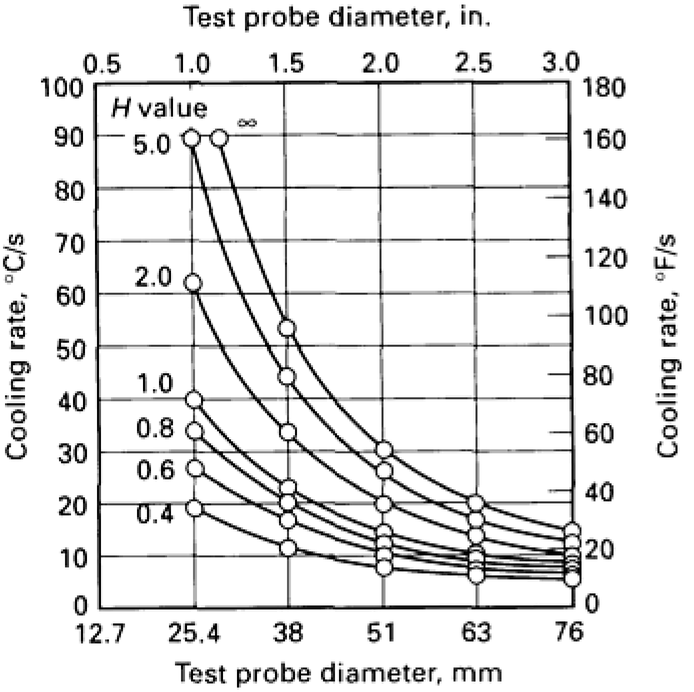

Fig. 9 Calculation of the Grossmann constant, *H,* from cooling rate data at a temperature of 705 °C (1300 °F)

The severity of a quenchant medium is dependent on its ability to mediate heat transfer at the hot metal interface during quenching. Quenchant data obtained by cooling curve analysis is presented in Table 3 for water, fast oil, conventional oil, martemper oil, a 25% solution of an aqueous polyvinyl pyrrolidone polymer quenchant, and air at selected temperatures and velocities . As previously discussed, substantial variations in cooling characteristics may occur depending on the exact formulation of the quenchant and quenchant use conditions. One of the most valuable features of this data is that it illustrates how the heat transfer coefficients vary depending on use conditions. The primary function of a quenchant after all, is to mediate heat transfer from the metal to the quenchant during the quenching process.

Table 3 Grossmann numbers and film coefficients for selected quenchants

Quenchant	Quenchant temperature		Quenchant velocity		Grossmann number, ($H = h/2k$)	Effective film coefficient	
	°C	°F	m/s	ft/min		$W/m^2 \cdot K$	$Btu/ft^2 \cdot h \cdot °F$

Source: Ref 12

The data in Table 3 show that unagitated water at 32 °C (90 °F) has a Grossmann number of about 1 and an interface heat transfer coefficient of about 5000 W/m^2 · K. The effective interface heat transfer coefficient produced by 32 °C (90 °F) water increased to 9000 and 12,000 W/m^2 · K (1600 and 2100 Btu/ft^2 · °F) at velocities of 0.25 and 0.50 m/s (50 and 100 ft/min), respectively. High heat transfer coefficients produce more rapid cooling. Cold water, a relatively severe quenchant, may produce high thermal gradients from the surface to the center of parts and large temperature differences between thick and thin sections that can lead to an increase in distortion or cracking.

The effective interface heat transfer coefficient produced by water generally decreases with increasing water temperature. Unagitated water at 55 °C (130 °F) had an interface heat transfer coefficient of about 1000 W/m^2 · K (180 Btu/ft^2 · h · °F) A water velocity of 0.76 m/s (2.5 ft/s) increased the interface heat transfer coefficient of the 55 °C (130 °F) water to 10,500 W/m^2 · K (1850 Btu/ft^2 · h · °F)

The benefit of knowing or experimentally determining interface heat transfer coefficients produced by specific quenchants under known conditions is that these values can be used in finite element or finite difference heat transfer programs to calculate cooling curves in parts or sections of a part that have not actually been instrumented. These calculated cooling curves can then be used to estimate the as-quenched hardness in these locations.

Quench Intensity. Liščić and Filetin (Ref 17), Wünning (Ref 18), Tensi (Ref 19), and others have developed processes for evaluating quenchant severity (intensity) that is applicable for both the heat-treating plant and for laboratory quenching studies. Liščić's approach is based on a technique for determining the heat flux at the surface of a part during quenching by measuring the temperature gradient from the surface to the center of a 50 mm (2 in.) diameter by 200 mm (8 in.) long test probe. The best probe is illustrated in Fig. 10.

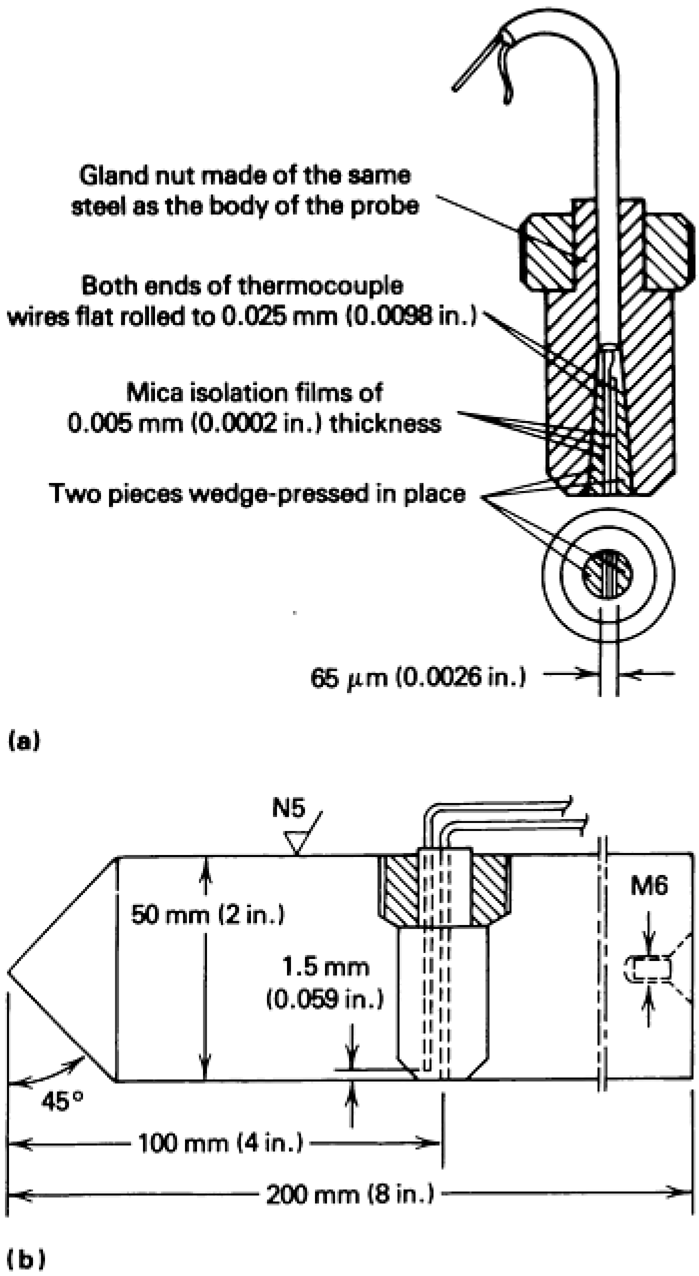

Fig. 10 Schematic of a Liščić-NANMAC probe that incorporates fast-response thermocouples to provide transient thermal measurements of metal surface temperatures. (a) Probe construction. (b) Probe installed in a test specimen

Calculation of cooling curves obtained using this probe is based upon the algorithm:

$$\phi = \lambda\left(\frac{\partial T}{\partial n}\right) \quad \textbf{(Eq 4)}$$

where *f* is the heat flux (W/m^2); λis the thermal conductivity of the probe material (W/m · K); and ∂ *T* is the temperature gradient across the probe perpendicular to the surface ∂ *n* (K/m). Typical cooling curve and heat flux output for water and mineral oil at 20 °C (70 °F) are shown in Fig. 11(a) and 11(b), respectively.

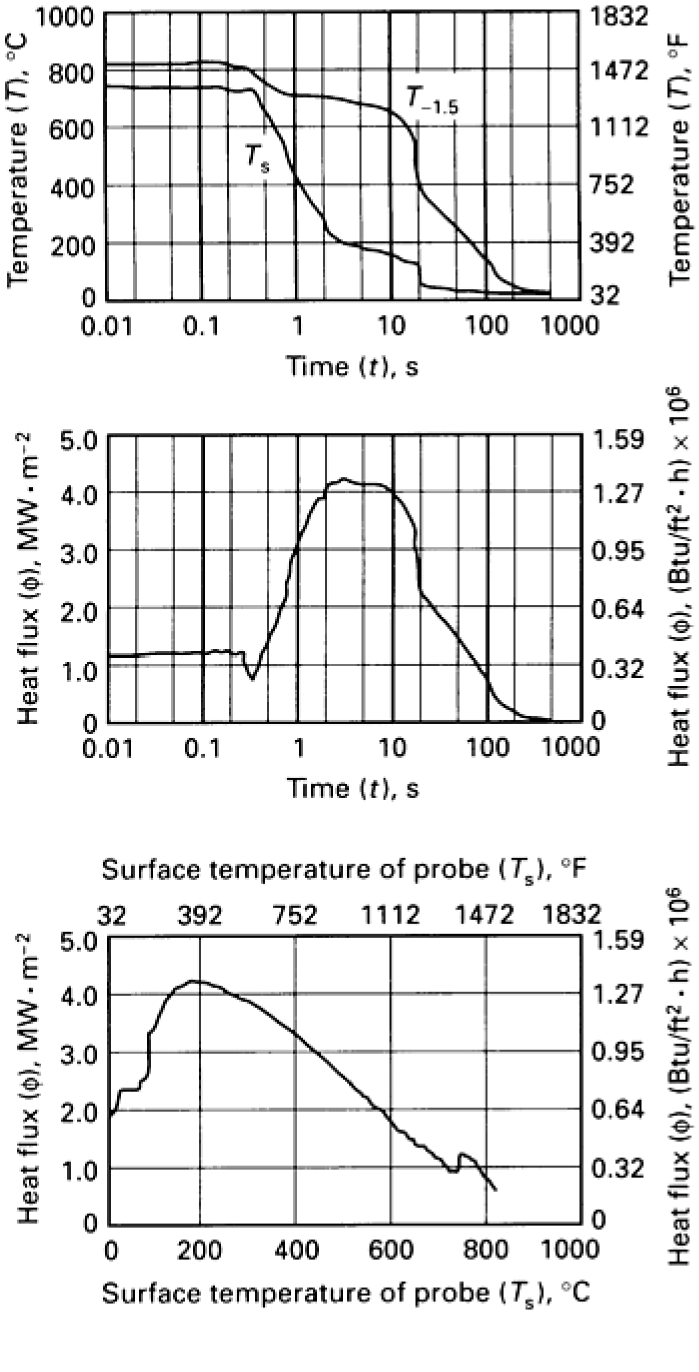

Fig. 11(a) Heat transfer characteristics of unagitated tap water at 20 °C (70 °F). Top: Recorded cooling curves for the very surface of the probe, T_s, and for the point 1.5 mm (0.059 in.) below the surface $T_{-1.5}$, during quenching in plain water at 20 °C (70 °F) without agitation. Middle: Relevant heat flux versus surface temperature curve. Bottom: Heat flux versus surface temperature curve

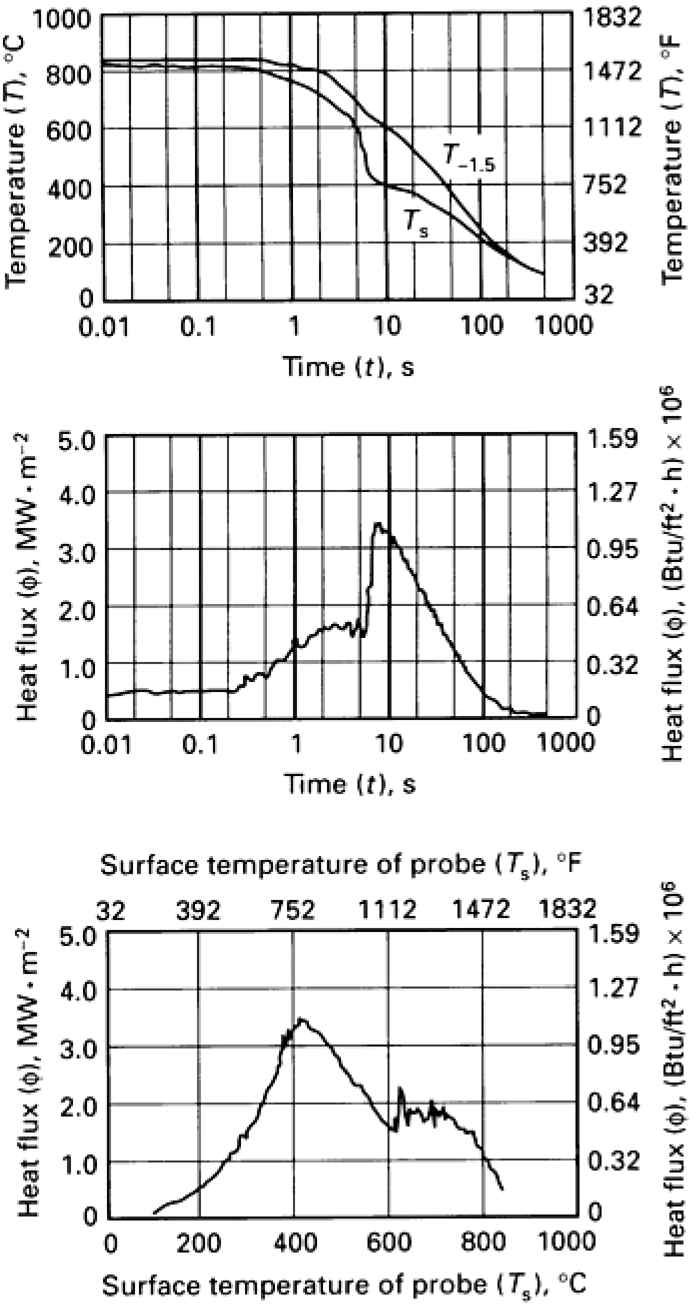

Fig. 11(b) Heat transfer characteristics of unagitated mineral oil at 20 °C (70 °F) Top: Recorded cooling curves for the very surface of the probe, T_s, and for the point 1.5 mm (0.059 in.) below the surface $T_{-1.5}$, during quenching in mineral oil at 20 °C (70 °F) without agitation. Middle: Relevant heat flux versus surface temperature curve. Bottom: Heat flux versus surface temperature curve

In addition to heat flux data obtained from the instrumented probe, a second specimen with the same dimensions as the probe (50 mm, or 2 in., diameter by 200 mm, or 8 in., long) and a Jominy specimen of the same steel is quenched in the same quenchant media using the same quenching conditions. This test specimen is sectioned to determine the cross-sectional hardness by making measurements at the surface, center, $\frac{1}{4}R$, $\frac{1}{2}R$, and $\frac{3}{4}R$ positions (where R is the radius). These data are used for building a database for various quenching conditions and for determining equivalent Jominy distances. The step-by-step process of data analysis proposed by LiŠČiĆ is:

- *Step 1:* Record the quenching intensity measurement of each of the quenching conditions selected as a function of T_s; the surface temperature of the probe (°C); *t,* the time (s); and f, the heat flux of the

probe (MW/m^2)

- *Step 2:* Specify the steel grade and quenching conditions
- *Step 3:* Harden a test specimen by quenching it under the conditions identified in Step 2
- *Step 4:* Make the cross-sectional hardness survey as described above and illustrated in Fig. 12
- *Step 5:* From the Jominy curve for the steel alloy of interest, measure the equivalent Jominy distances; E_s, $E_{3/4R}$, $E_{1/2R}$, $E_{1/4R}$, and E_C that yield the same hardness as determined at the positions specified for cross-sectional hardness survey
- *Step 6:* Calculate the quenching intensity (I) at each of the above characteristic points from the relationship:

$$E_i = A \cdot (D \cdot \exp B_1)/(H \cdot \exp B_2) \quad \textbf{(Eq 5)}$$

where E_i is the corresponding equidistant point on the Jominy curve; A, B_1, and B_2 are regression coefficients; D is the bar diameter; and H is the Grossmann quench intensity factor.

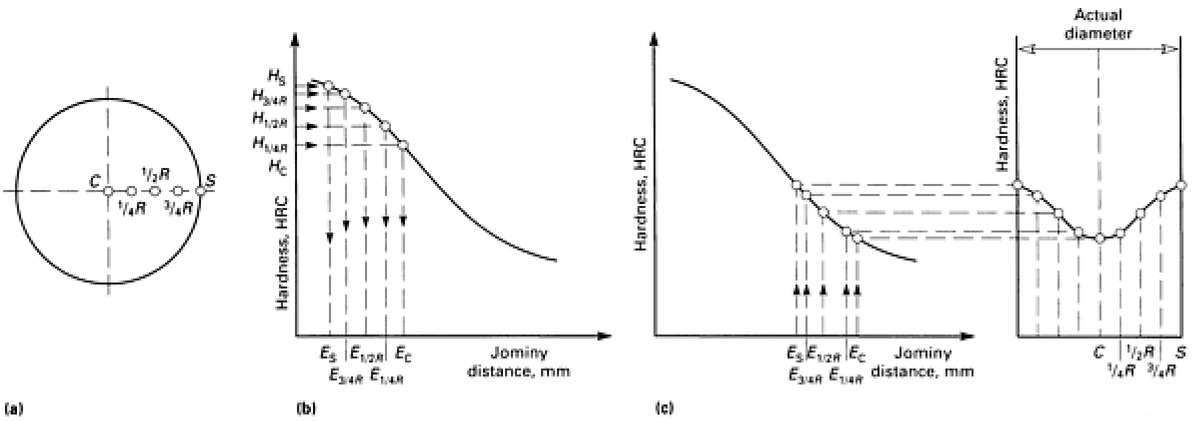

Fig. 12 Procedure for predicting hardness distribution in a steel bar using a Jominy hardenability curve. (a) Cross section of a 50 mm (2 in.) diameter end quench test specimen. (b) Determination of Grossmann quench intensity factor. (c) Determination of equivalent Jominy distance and actual bar diameter

The following relationships have been developed by regression analysis:

$$E_S = D \exp 0.718/(5.11 \cdot H \exp 1.28) \quad \textbf{(Eq 6)}$$

$$E_{3/4R} = D \exp 1.05/(8.62 \cdot H \exp 0.668) \quad \textbf{(Eq 7)}$$

$$E_{1/2R} = D \exp 1.16/(9.45 \cdot H \exp 0.51) \quad \textbf{(Eq 8)}$$

$$E_{1/4R} = D \exp 1.14/(7.7 \cdot H \exp 0.44) \quad \textbf{(Eq 9)}$$

$$E_C = D \exp 1.18/(8.29 \cdot H \exp 0.44) \quad \textbf{(Eq 10)}$$

These equations are valid for: 20 mm $< D < 90$ mm, $0.2 < I < 2.0$, and 1 mm $< E < 40$ mm. From these calculations and the corresponding Jominy curve, hardness distributions in other parts can be calculated (Ref 17).

While this procedure is quite involved, it does integrate all of the classical techniques for quenchant characterization and also permits the surface and the bulk temperature of the part to be measured.

Cooling Curve Applications

Water is an excellent and inexpensive quenchant, but its heat removal characteristics are variable depending on the bath temperature and the relative velocity between the water and the parts being quenched. Water also can be a rather severe quenchant, so oils or aqueous polymer solutions often are used to moderate the heat removal rates.

Bath Temperature Effects. The effect of water bath temperature on cooling curves and cooling rate curves produced when 38 mm (1.5 in.) diameter bars were quenched in water at 27, 32, 60, and 71 °C (80, 90, 140, and 160 °C) flowing at a velocity of 0.25 m/s (50 ft/min) are shown in Fig. 13. All instrumented probes were austenitized at 845 °C (1550 °F) and quenched into water flowing at a velocity of 0.25 m/s (50 ft/min). Some characteristics of these conditions are presented in Table 4. Water at 60 °C (140 °F) produced a cooling rate at 705 °C (1300 °F) of 9.4 °C/s (16.8 °F/s) With a lower water bath temperature of 27 °C (80 °F), the cooling rate at 705 °C (1300 °F) (which is commonly used as an indicator of the ability of quenchants to extract heat) was 32.8 °C/s (58.6 °F/s), about 3.5 times higher than water at 60 °C (140 °F).

Table 4 Effects of quenchant temperature on cooling rates and predicted hardness in 38.1 mm (1.5 in.) diameter 4130 low-alloy steel bars quenched in water (velocity at 0.25 m/s, or 50 ft/min) from 845 °C (1550 °F)

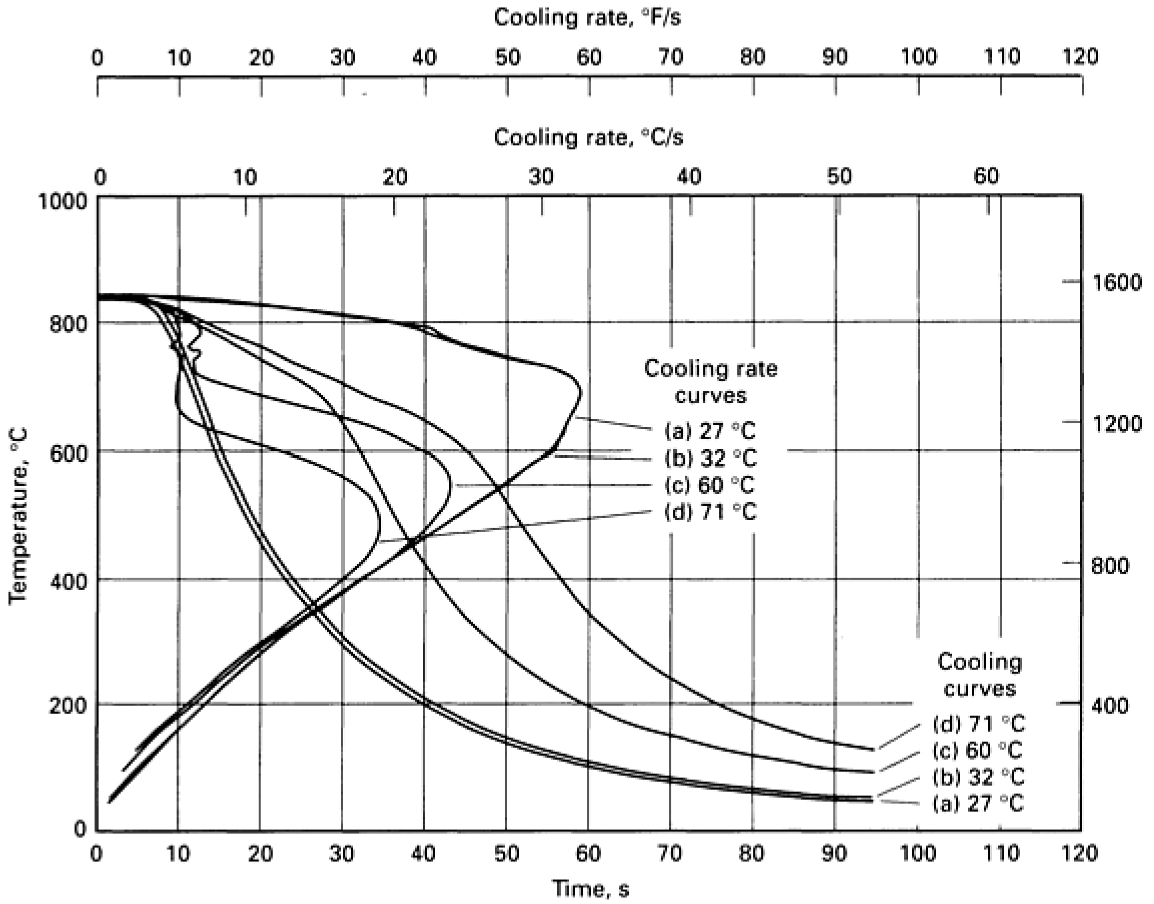

Fig. 13 Cooling curves and cooling rate curves produced by 27, 32, 60, and 71 °C (80, 90, 140, and 160 °F) water that is flowing at 15 m/min (50 ft/min) past a 38 mm (1.5 in.) diameter bar

Quenchant Effects. The type of quenchant used also has a dramatic effect on cooling rates (see Fig. 14). These curves were obtained with a 25.4 mm (1.00 in.) diameter probe quenched into water, a 20% aqueous polyalkylene glycol solution, fast oil, conventional oil, and a martemper oil at temperatures of 32, 49, 65, 65, and 150 °C (90, 120, 150, 150, and 300 °F), respectively. Cooling curves with different shapes were obtained in each solution using the same probe size and quenchant velocity.

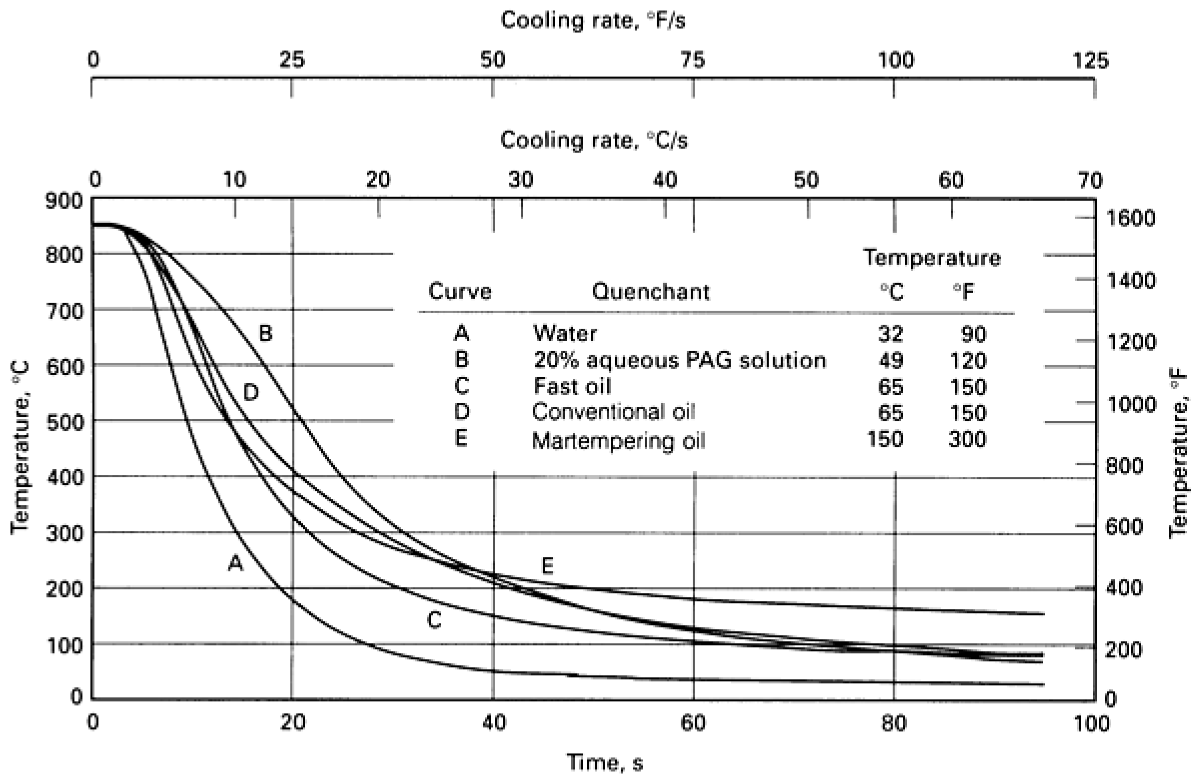

Fig. 14 Effect of selected quenchants on the cooling curve of a 25.4 mm (1.0 in.) diameter steel bar. All quenchants flowing at 0.50 m/s (100 ft/min)

Additional data on the effect of quenchant type, temperature, and quenchant velocity on the Grossmann number and film coefficient produced by water, a fast oil, a conventional oil, a martemper oil, a 25% aqueous polymer solution, and air are presented in Table 3. Water at 27 to 32 °C (80 to 90 °F) can produce film coefficients of over 2800 W/m^2 · K (500 Btu/ft^2 · h · °F) depending on the extent of agitation. The film coefficient decreases rather rapidly however, as the water temperature rises or as the water velocity past the part decreases.

The heat removal characteristics of water at 55 °C (130 °F) are substantially reduced, especially at lower velocities, compared to 27 °C (80 °F) water. The film coefficient of 55 °C (130 °F) water without agitation was only 340 W/m^2 · K (60 Btu/ft^2 · h · °F, but increased to approximately 4100 W/m^2 · K (730 Btu/ft^2 · h · °F with a velocity of 0.75 m/s (150 ft/min).

Thus, without agitation, water at 32 °C (90 °F) can remove heat approximately 5 times faster than water at 55 °C (130 °F) without agitation. At 0.25 m/s (50 ft/min), 55 °C (130 °F) water has less than $\frac{1}{3}$ the heat removal capacity of 32 °C (90 °F) water at the same velocity. At a velocity of 0.50 m/s (100 ft/min), the heat removal capacity of 55 °C (130 °F) water is approximately one-half that of 32 °C (90 °F) water.

The practical implication of this fact is that the temperature of water (and aqueous polymer) quenchants must be carefully controlled to obtain process consistency. Occasionally, some aqueous polymer waterbased quenchants must be agitated more vigorously than oil quenchants to minimize localized bath overheating that could cause a decrease in the cooling rate and produce soft spots on parts.

The temperature of the liquid has a marked effect on its ability to extract heat. Water loses its cooling power as it approaches its boiling point. In oil, this effect is not as pronounced because oil becomes less viscous as the temperature is increased. The reduced oil viscosity offsets the temperature rise by a substantial amount.

Section Size Effects. The effect of section size on cooling rates when 12.7, 25.4, and 38.1 mm (0.50, 1.00, and 1.50 in.) diameter probes quenched in a fast oil at 65 °C (150 °F) and flowing at 0.50 m/s (100 ft/min) is illustrated in Fig. 15.

Cooling rates dramatically decrease with increased section thickness. Under the same operating conditions, the peak cooling rate in a 38.1 mm (1.50 in.) round was 24.5 °C/s (44.1 °F/s) compared to 135 °C/s (245 °F/s) in a 12.7 mm (0.50 in.) round.

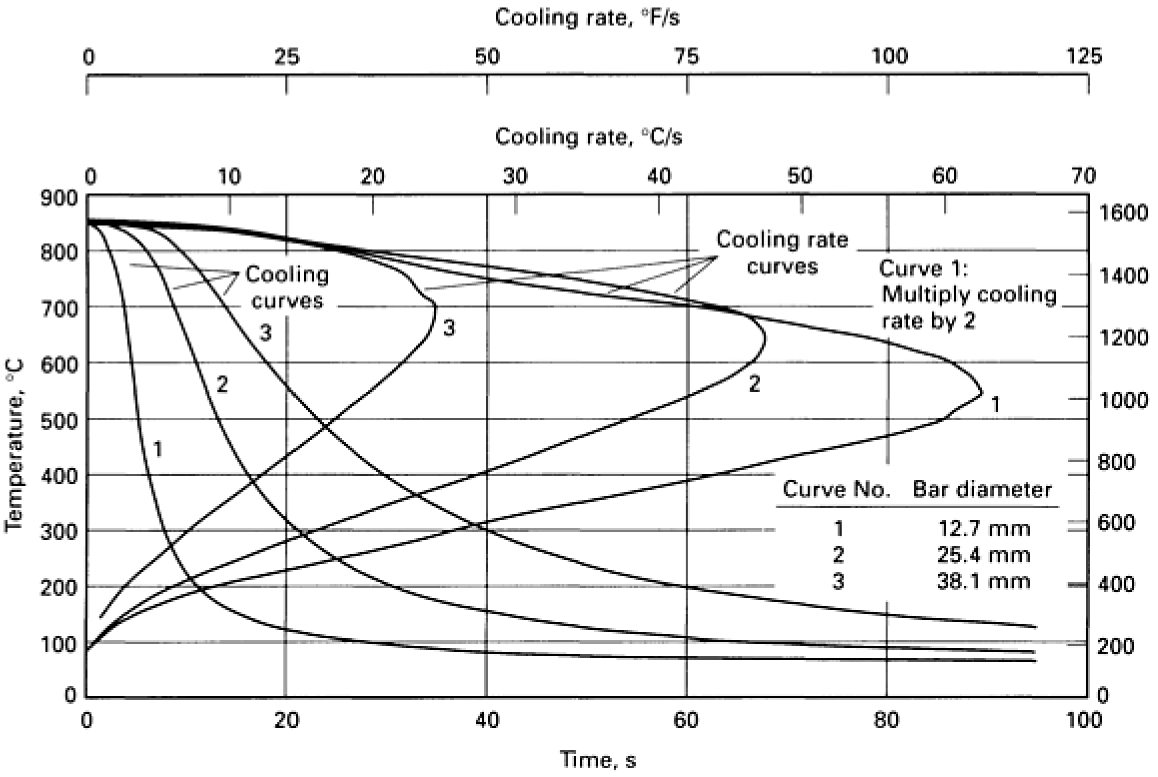

Fig. 15 Effect of section size on cooling curves and cooling rate curves in 65 °C (150 °F) fast oil that is flowing at 0.50 m/s (100 ft/min)

With heavy sections, the cooling rate is limited by the rate of heat conduction from the interior to the surface. Rapid cooling of the center of an extremely large section is impossible by any quenching method because of the mass effect. Therefore, when deep hardening a heavy section, it is necessary to use an alloy steel with higher hardenability.

The data in Fig. 13, 14, and 15 illustrate the fact that many factors, including the section thickness of parts, the characteristics of the quenchant, the type of quenchant, and the quenchant use conditions, affect the shape of cooling rates that can be obtained. Consequently, these factors may also affect the hardness and strength of parts being quenched.

Surface Oxidation Effects. The effects of surface oxidation have been evaluated by magnetic testing, observation of high-speed motion pictures, and cooling curve measurements. The heat transfer rate from nickel balls heated to 885 °C (1625 °F) in an oxidizing atmosphere was compared to that of similar balls heated to the same temperature in a protective, reducing atmosphere. Rates of heat transfer from 885 to 355 °C (1625 to 670 °F), as Shown in Tables 5 and 6, indicate that the balls heated in an oxidizing atmosphere cooled faster than the balls heated in a reducing atmosphere.

Table 5 Comparison of the cooling power of commercially available quenching and martempering oils according to magnetic quenchometer test results

High-speed motion-picture techniques have been used to reveal the influence of oxide coatings on the quenching rate of steel in water containing polyvinyl alcohol, trisodium phosphate, or carboxyl methylcellulose. When a steel specimen that had been heated in a protective atmosphere was submerged in the liquid, it was noted that a visible envelope surrounded the specimen preventing contact between the liquid and the steel surface. After a delay of many seconds, the envelope burst and quenching action commenced. The total quenching time in a 0.3% solution of polyvinyl alcohol in water was 37 s, a slower quenching rate than was obtained with conventional quenching oils. When an identical specimen that had been heated in an oxidizing atmosphere was quenched in the same polyvinyl alcohol solution, immediate contact was made between the solution and the specimen surface. The total quenching time was only 2.3 s, a value comparable to the rate obtained in plain water.

Cooling curves, such as those in Fig. 16, also indicate the effect of an oxide scale on quenching characteristics. These curves were obtained by still quenching in fast oil. A scale not more than 0.08 mm (0.003 in.) deep increases the rate of cooling of 1095 steel as compared to the rate obtained on a specimen without scale. However, a heavy scale, 0.13 mm (0.005 in.) deep, retards the cooling rate. A very light scale, 0.013 mm (0.0005 in.) deep, also increased the cooling rate of the 18-8 stainless steel over that obtained on a specimen without scale.

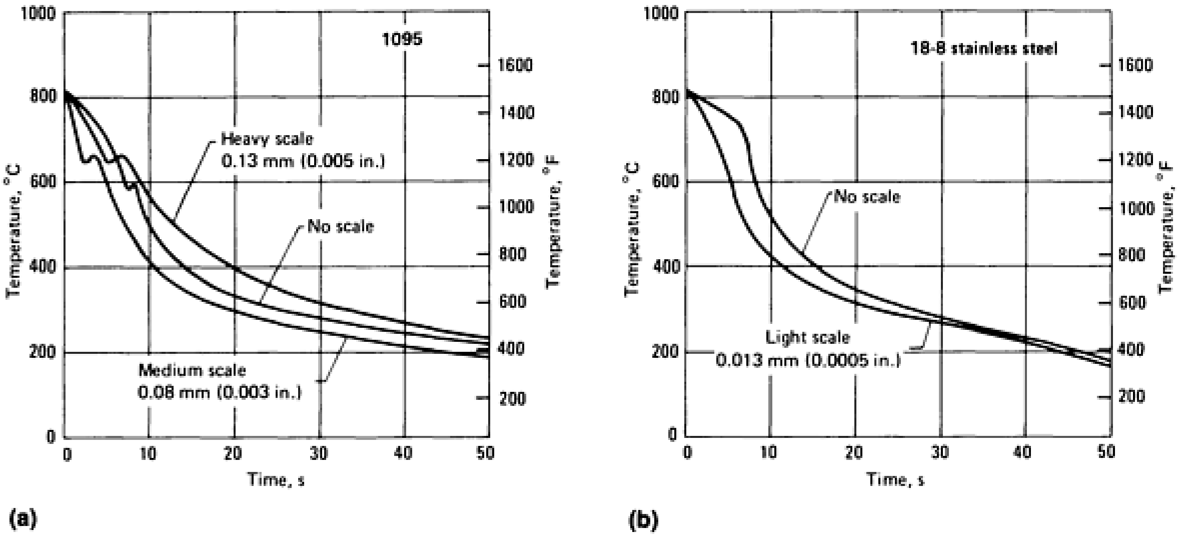

Fig. 16 Center cooling curves showing the effect on scale on the cooling curves of steels quenched without agitation in fast oil. (a) 1095 steel; oil at 50 °C (125 °F). (b) 18-8 stainless steel; oil at 25 °C (75 °F). Specimens were 13 mm ($\frac{1}{2}$ in.) diam by 64 mm ($2\frac{1}{2}$ in.) long.

Distortion and Cracking

Distortion and cracking during quenching limits the severity of the quenchant and equipment that may be used. A more severe quench produces martensite to a greater depth (with a steel of given hardenability), but it also increases the likelihood of distortion and cracking.

Distortion during quenching can be understood by remembering that:

- Steel has a higher strength when cold than when hot
- Steel shrinks while cooling and expands while hardening

Linear dimensional changes occurring during cooling and transformation are shown in Fig. 17 for both slow cooling and fast quenching conditions (Ref 20). Quenching to form martensite results in an expansion of the material compared to that achieved with a slow cooled pearlitic matrix. However, it is recognized that both pearlitic and martensitic materials contract over 1% during cooling from the austenite temperature, but martensitic materials have a lower net contraction.

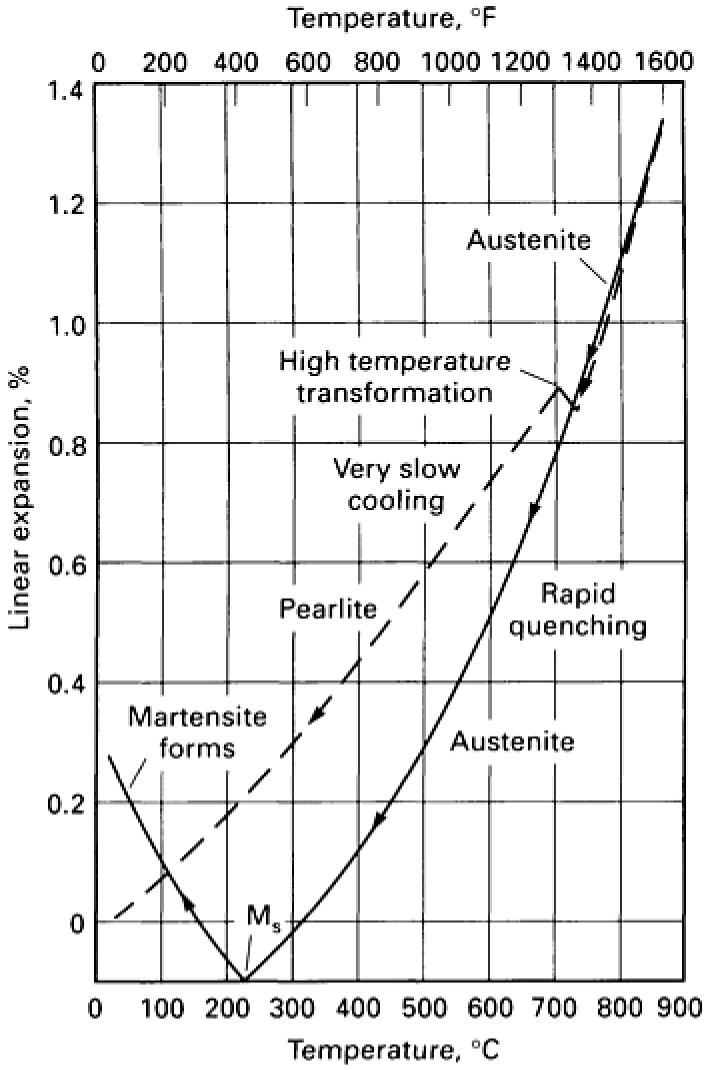

Fig. 17 Dilatometric study of steel cooled from a high temperature to show that the steel undergoes reversals of its dimensional contractions depending on variations in its quenching rate. Source: Ref 12

Distortion is a result of three phenomena: warping, thermally induced deformation, and martensite formation. Warping is the result of nonuniform heating or nonuniform support of a part during heating. Thermal deformation is a result of nonuniform contraction during cooling. These definitions are convenience definitions and there is some overlap in the two phenomena. The expansion associated with martensite formation also induces stresses that cause distortion.

Warping during nonuniform cooling is schematically illustrated in Fig. 18. Assume that the bar was initially at a uniformly high temperature (see Fig. 18a). If the bar were quenched on one side (see Fig. 18b), the more rapidly cooled side would contract earlier and at a higher rate than the opposite side. The rapidly cooled side becomes shorter and

stronger as it cools and causes plastic deformation in the hot side. The deformation is followed by cooling and contraction of the more slowly cooled side.

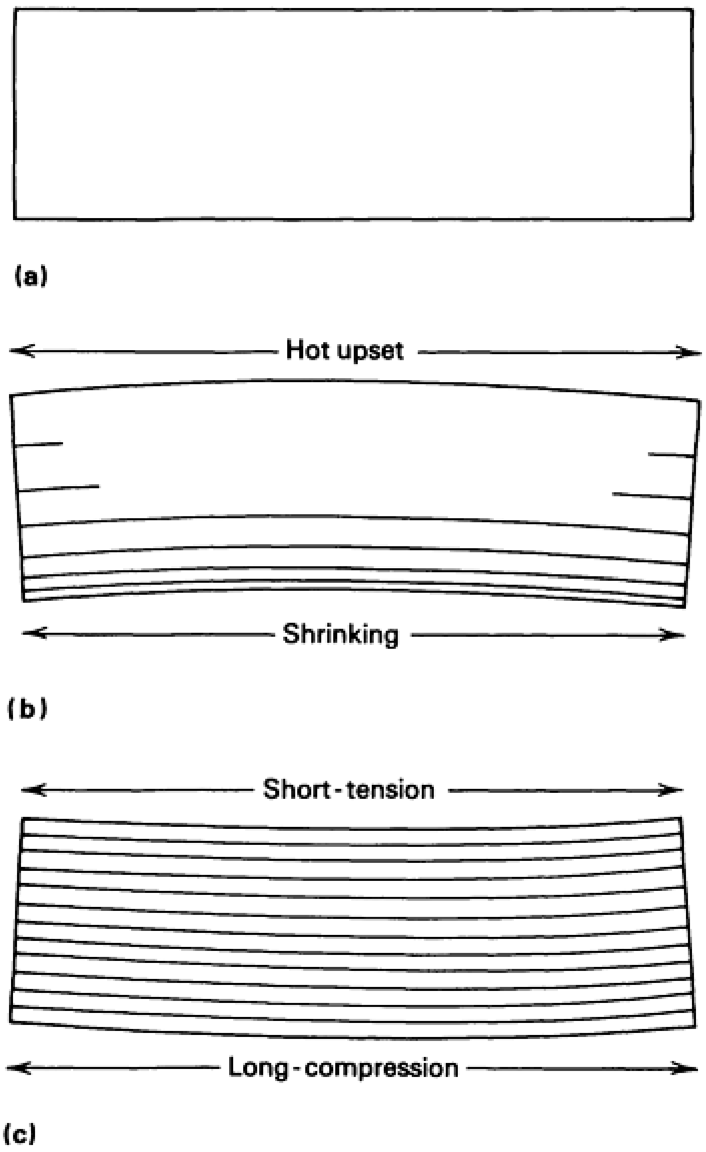

Fig. 18 Warpage caused by nonuniform quenching of a steel block. (a) Uniformly hot. (b) Nonuniform cooling. (c) Uniformly cold. Source: Ref 21

When the part has cooled, it will then be warped (if the stress exceeds the yield strength of the bar) with the slowly cooled side being shorter and warped concave (see Fig. 18c). The plastic deformation on the hot side results in compressive stresses on the rapidly cooled side and tensile stresses on the more slowly cooled side.

Thermally Induced Deformation. Deformation resulting from thermal gradients produced during cooling is illustrated in Fig. 19. If a part is initially uniformly hot, as shown in Fig. 19(a), and is rapidly quenched, the outer surface shrinks while the center is still relatively hot. This process puts the outer surface into tension and the inside into compression, causing internal plastic flow (Fig. 19b). As the center of the part cools and the temperature reaches a uniformly low value, thermal contraction in the center of the bar occurs, which reverses the stress state and places the center in tension (see Fig. 19c). Finish machining of the outer shell removes the tensile stress present in the core (see Fig. 19d).

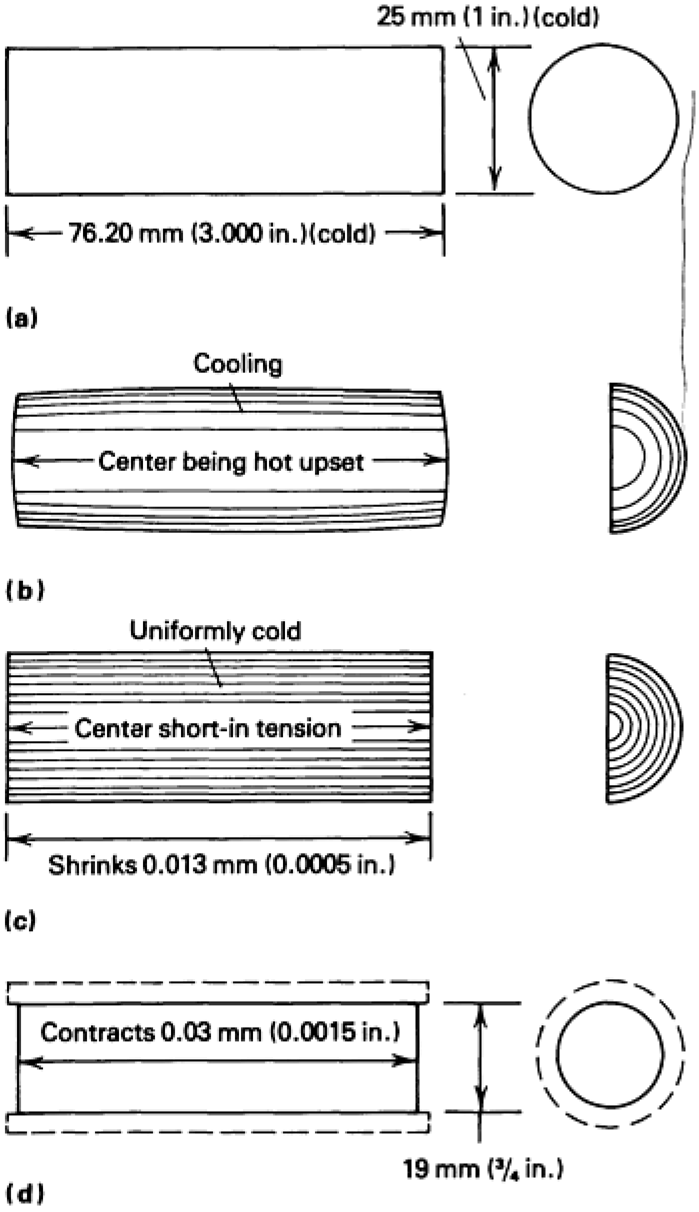

Fig. 19 Effect of quenching on a steel cylinder that was quenched in water from 775 °C (1425 °F). (a) Uniformly hot. (b) Center portion of cylinder is hot upset during quenching. (c) Center portion of cylinder is short in tension when uniformly cold. (d) Machining of the shell removes tensile stress from core to allow cylinder to decrease in length. Source: Ref 21

Martensite Formation. The same deformation processes can occur in a steel part being hardened to produce martensite. The martensitic transformation occurs with a net shrinkage of about 1% during cooling from the austenitizing temperature to room temperature. During rapid cooling, the outer surface is quenched to martensite and the subsequent contraction of the core produces surface compression and center tension (see Fig. 20).

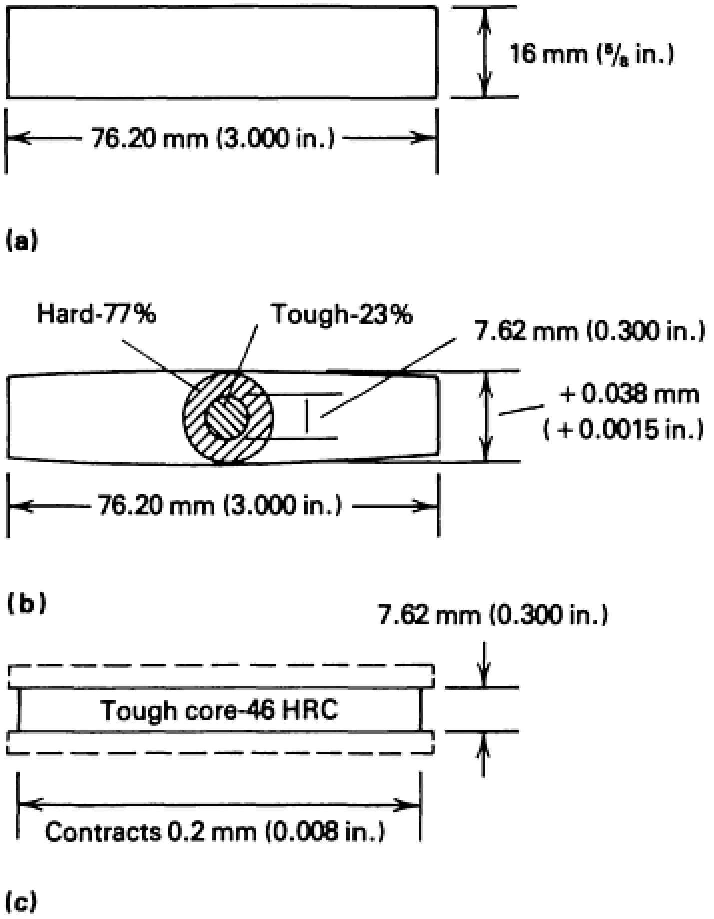

Fig. 20 Strains produced by hardening a cylinder of 1.10% C tool steel. (a) Dimensions of an annealed bar before quenching. (b) Hardness values at selected locations inside cylinder after water quenching at 775 °C (1425 °F) based on surface hardness of 68 HRC. (c) Core hardness after water-quenched cylinder diameter reduced from 16 mm ($\frac{5}{8}$ in.) to 7.62 mm (0.300 in.) by wet grinding. Source. Ref 21

Figure 20 schematically illustrates a bar that was initially 75 mm (3 in.) long and 16 mm ($\frac{5}{8}$ in.) in diameter. During water quenching from 775 °C (1425 °F), deformation occurred in the center of the bar, resulting in a bar diameter 0.038 mm (0.0015 in.) larger than the initial diameter. If the hardened surface of the bar were wet ground to relieve the internal stress and produce a final diameter of 7.62 mm (0.300 in.), the final length of the bar would be 0.2 mm (0.008 in.) less than the as-quenched length. A wide variety of similar experiments have been conducted to demonstrate that the tensile and compressive stress developed during cooling and martensite formation can result in significant deformation of steel parts.

The stress states in a through-hardened 0.6% C steel, an unhardened 0.6% C steel, and a hardened core 0.30% C steel are illustrated in Fig. 21. The length and diameter changes are shown, as well as the stress profiles in 50.0 mm (1.97 in.) bars after water quenching from 850 °C (1560 °F).

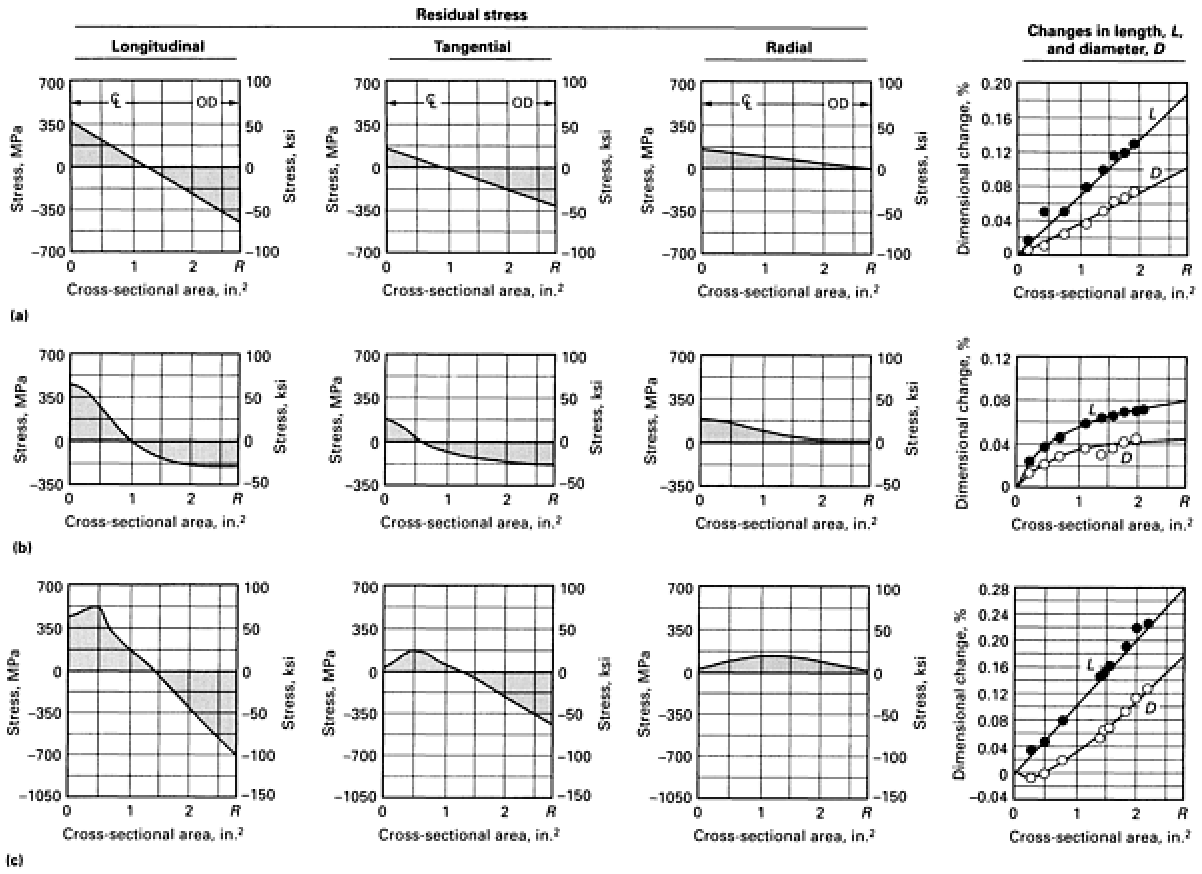

Fig. 21 Residual stress distribution and distortion in 50.0 mm (1.97 in.) diameter carbon steel bars water quenched from 850 °C (1560 °F). (a) Through hardened 0.6% C steel. (b) Unhardened 0.25% C steel. (C) Hardened core 0.30% C steel. OD, outside diameter. Source: Ref 22

Additional Sources of Distortion. In general, the distortion occurring during quenching depends on the size and shape of the bar, bar composition, and the characteristics of the quenchant employed. Parts with section size ratios greater than 1:4; large parts with relatively thin cross sections; and parts containing slots, keyholes, drilled holes, or grooves cause problems because of the difficulty in achieving uniform heating and cooling rates (see Fig. 22(a), 22(b), and 22(c)).

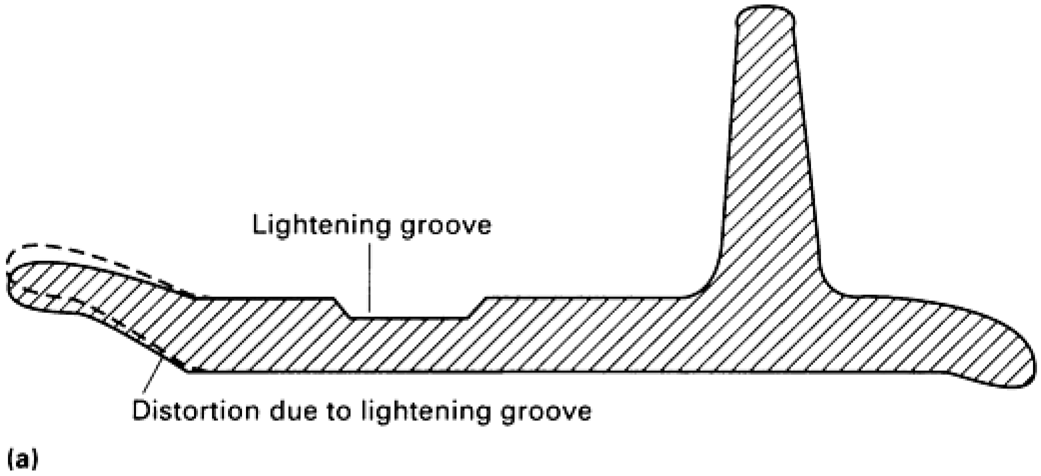

Fig. 22(a) Cross section of a water quenched SAE/AISI 1037 steel track shoe with 0.25 mm (0.010 in.) distortion caused by lightening groove. Redesigning of the shoe to remove the grooves improved uniformity of

the section and reduced the distortion to a maximum of 0.08 mm (0.003 in.). Source: Ref 23

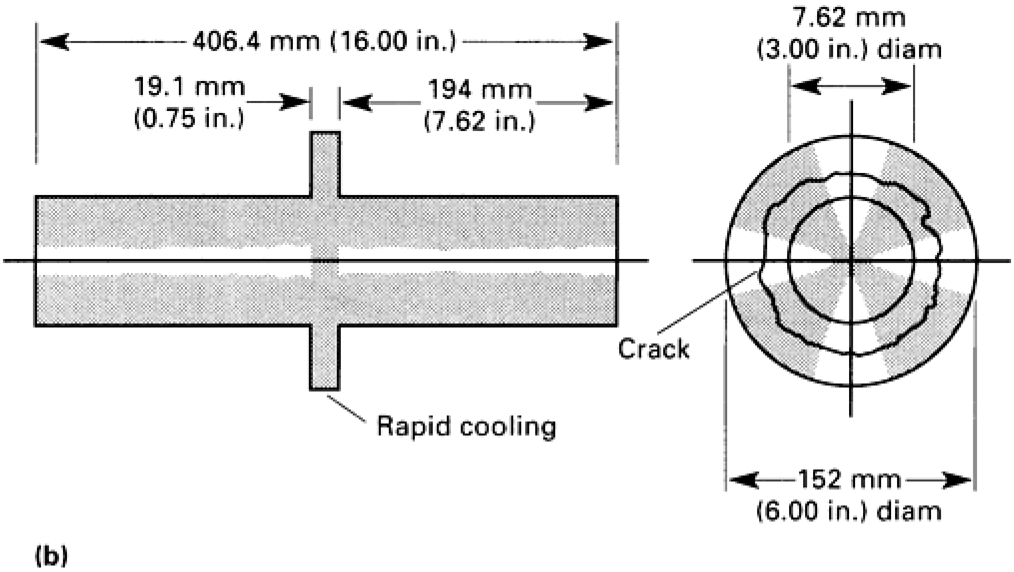

Fig. 22(b) The design of this steel flange on this shaft will cause the flange to crack during quenching. Source: Ref 23

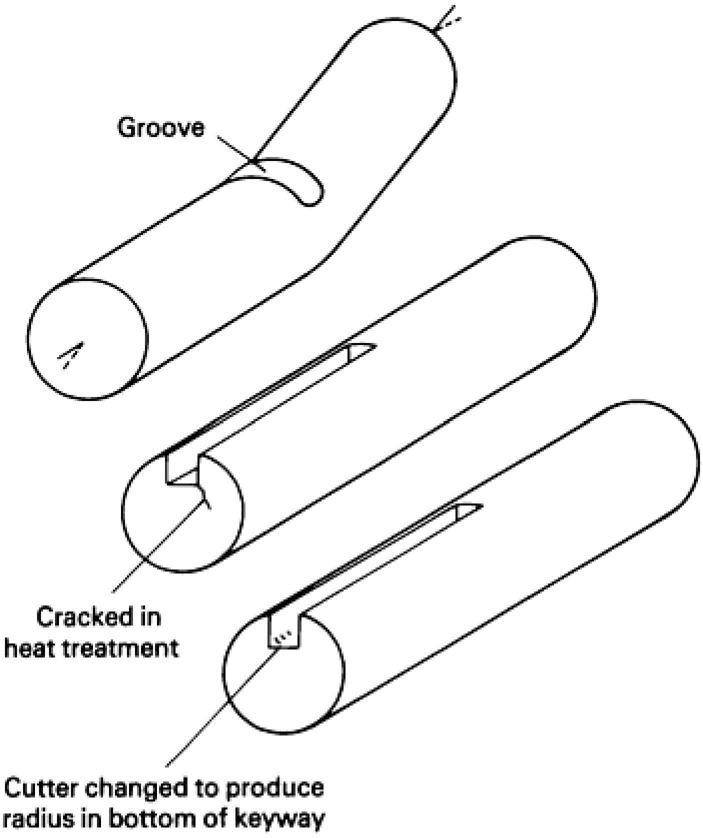

Fig. 22(c) Grooves will cause a shaft to warp in heat treating (top). A keyway with sharp corners often initiates cracks in quenching (center). The keyway crack problem is avoided with a radius (bottom). Source: Ref 23

The distortion that can occur in a track shoe, as a result of the presence of a lightening groove, is illustrated in Fig. 22(a). Flanges and bosses also create conditions that make it difficult to achieve uniform cooling rates (see Fig. 22(b)). The thin,

large diameter flange is very difficult to cool at a rate consistent with the bar, and this almost invariably produces quench cracks.

Keyholes and grooves often cause a shaft to warp during heat treating, and keyways with sharp corners often initiate cracks. The keyway cracking problem can be minimized to some extent with generous radii (see Fig. 22(c)).

The steel composition can also have a significant effect on warping and distortion. High-carbon alloys and those with high hardenability are prone to more distortion than low-carbon with low-hardenability alloys. Similarly, high austenitizing temperatures and low martensite start (M_s) temperatures tend to aggravate distortion.

The characteristics of the quench procedure, particularly conditions promoting high rates of cooling through the transformation range, aggravate distortion and cracking. Rapid quenching to a temperature just above the M_s temperature, followed by slow cooling through the martensite formation range, minimizes distortion. Uniform rates of heat removal per unit of surface area also tend to minimize distortion.

Cracking occurs for the same reasons as distortion, but cracks form when the localized strain exceeds the failure strain in the material. Usually, the cracks follow austenite grain boundaries, but cracking does not appear to be related to the austenite grain size.

The tendency for cracking typically decreases as the M_s temperature increases. The M_s temperature in °C can be approximated by using the following equation (Ref 24):

$$\begin{aligned} M_s = {} & 521 - 353(\%C) - 225(\%Si) \\ & -24.3(\%Mn) - 27.4(\%NI) \\ & - 17.7(\%Cr) - 25.8(\%Mo) \end{aligned} \qquad \textbf{(Eq 11)}$$

The correlation between the occurrence of quench cracks and the M_s temperature in two steels is illustrated in Fig. 23(a).

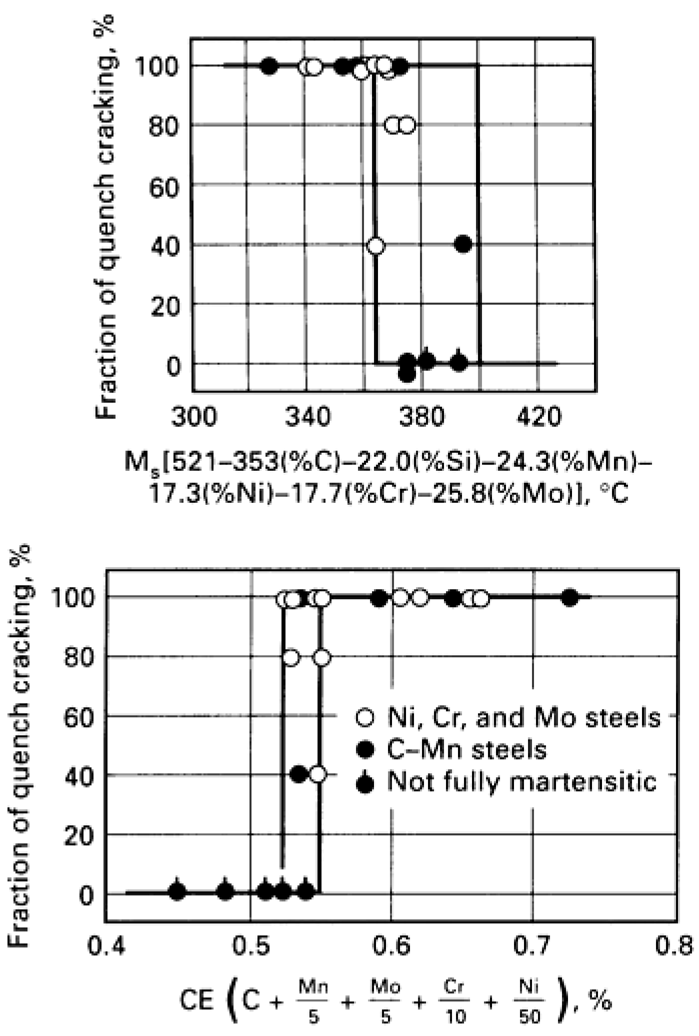

Fig. 23 Effect of M_s, temperature (a) and carbon equivalent (b) on the quench cracking of selected steels

Cracking has also been related to composition using the equation:

$$CE = C + Mn/5 + Mo/5 + Cr/10 + Ni/50 \quad \textbf{(Eq 12)}$$

where CE is the carbon equivalent and the elemental concentrations are expressed in percent by weight.

Quench cracks were prevalent at carbon equivalent values above 0.525, as illustrated in Fig. 23(b).

In general, quenchants must be selected to provide heat rates and cooling rates capable of producing acceptable microstructure in the section thicknesses of interest. However, it is not desirable to use quenchants with excessively high heat removal rates if distortion and cracking are to be minimized. High heat transfer coefficients result in rapid heat loss, high temperature gradients across thick sections, and large temperature differences between thick and thin sections. These conditions aggravate residual stress, distortion, and cracking problems.

High thermal gradients create high thermal stresses as cooler portions of a part try to contract but are restrained by hotter portions. At temperatures above the M_s temperature, steel is quite ductile and some of the stress can be relieved by plastic deformation which results in part distortion. However, when martensite forms, at and below the M_s temperature, the ability of the metal to deform is restricted because of the low ductility of martensite. In addition, there is a volumetric expansion associated with martensite formation that induces additional stress.

Thermal expansion and quench contraction curves for a 4340 steel are illustrated in Fig. 24. During heating, 4340 steel expanded almost linearly until austenite began to form at about 730 °C (1350 °F). After heating to 845 °C (1550 °F), the steel was rapidly cooled with the results shown by the flagged symbol. The volumetric expansion associated with martensite formation beginning at about 315 °C (600 °F), coupled with thermal stress in the austenite, may cause stresses that exceed the fracture stress of the martensite.

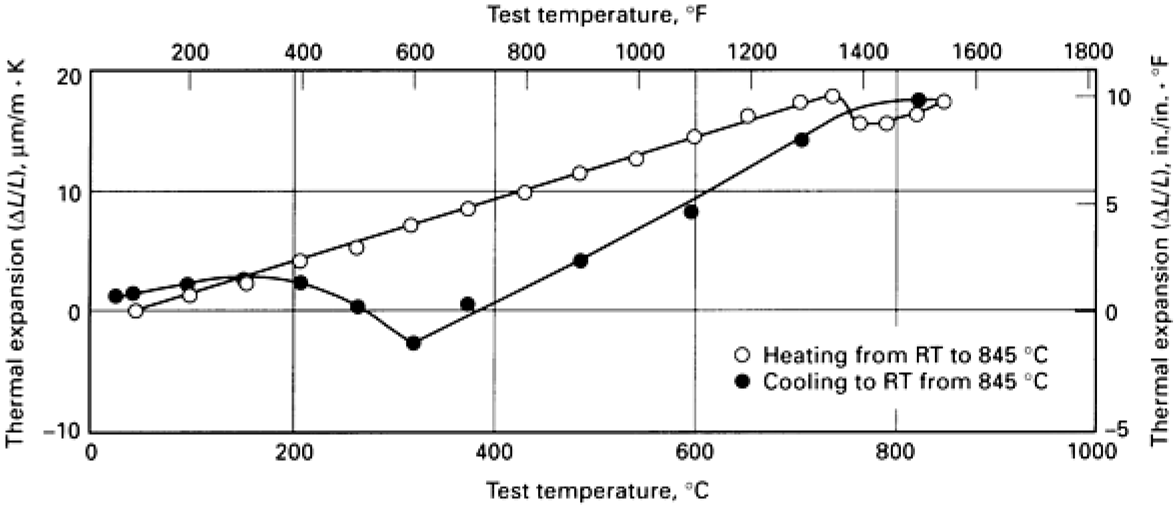

Fig. 24 Thermal expansion and contraction curves for 4340 steel. RT, room temperature

The volumetric changes associated with martensite formation can be controlled only by controlling the carbon concentration of the steel. The data illustrated in Fig. 25, calculated from x-ray diffraction data for fully martensitic microstructures, shows that the volumetric expansion increases linearly with the carbon concentration (Ref 25). Thelning (Ref 26) described volumetric changes occurring during quenching using the following equation:

$$(\Delta V/V) \cdot 100 = (100 - V_c - V_a) \cdot (1.68 \cdot C) + V_a (-4.64 + 2.21 \cdot C) \qquad \textbf{(Eq 13)}$$

where $\Delta V/V \cdot 100$ is the change in volume in %; V_c is the % by volume undissolved cementite; V_a is the % by volume austenite; $100 - V_c - V_a$ is the % by volume martensite; and C is the % by weight of carbon dissolved in austenite and martensite, respectively.

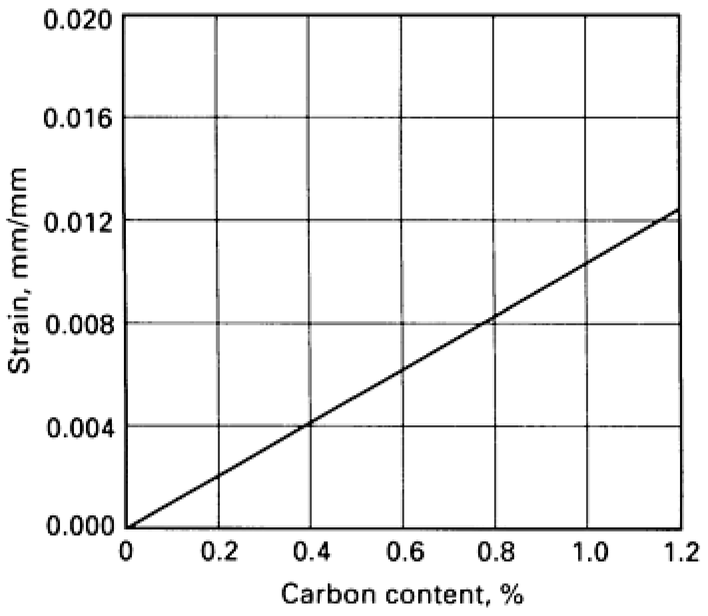

Fig. 25 Linear expansion in steel after quenching to produce fully martensitic microstructures

While low carbon concentrations reduce the probability of cracking, in practice a sufficiently high carbon concentration must be present to produce the desired hardness and strength.

Differential Temperatures in Quenched Probes. Temperature-time curves at two locations in a 50 mm (2 in.) diameter probe quenched in 32 °C (90 °F) water flowing at 0.50 m/s (100 ft/min) and producing an interface heat transfer coefficient of about 1.15 × 10^4 W/m^2 · K (6.53 × 10^4 Btu/ft^2 · h · °F) are illustrated in Fig. 26. These temperature-time curves were obtained with one thermocouple on the probe centerline and the second thermocouple 18 mm (0.7 in.) from the centerline.

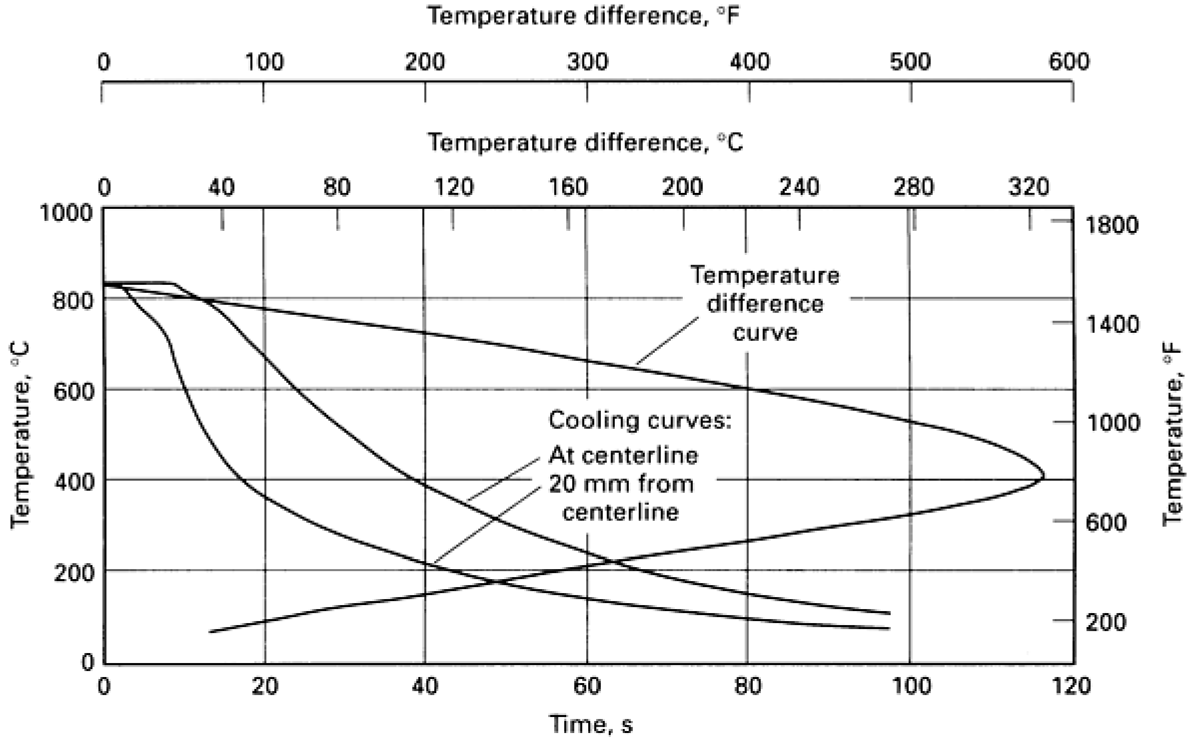

Fig. 26 Cooling curves and temperature difference curve between thermocouple A on centerline and thermocouple B 20 mm ($\frac{25}{32}$ in.) from centerline of 50 mm (2 in.) diameter probe quenched in 32 °C (90 °F) water that is flowing at 0.50 m/s (100 ft/min)

The temperature difference between the two thermocouples, calculated as the center temperature minus the near-surface temperature, is plotted as a function of the near-surface temperature. It is observed that the maximum temperature difference across the bar quenched in water was approximately 320 °C (575 °F) and the maximum value occurred when the near-surface temperature was approximately 420 °C (790 °F).

The maximum gradient occurred when the near-surface temperature was close to 300 °C (570 °F)· The high gradient, which is near the M_s temperature of many steels, coupled with a loss of ductility when martensite forms, can lead to cracking of parts quenched in water.

Similar near-surface and centerline cooling curves in a 50 mm (2.0 in.) diameter bar quenched with an interface heat transfer coefficient of 4300 W/m^2 · K (760 Btu/ft^2 · h · °F), such as produced by an agitated fast oil, are illustrated in Fig. 27. The maximum temperature gradient was 209 °C (376 °F) and occurred at a surface temperature of about 575 °C (1065 °F), substantially above the M_s temperature. The reduced gradient causes oil quenched parts to be less prone to cracking compared to water quenched parts.

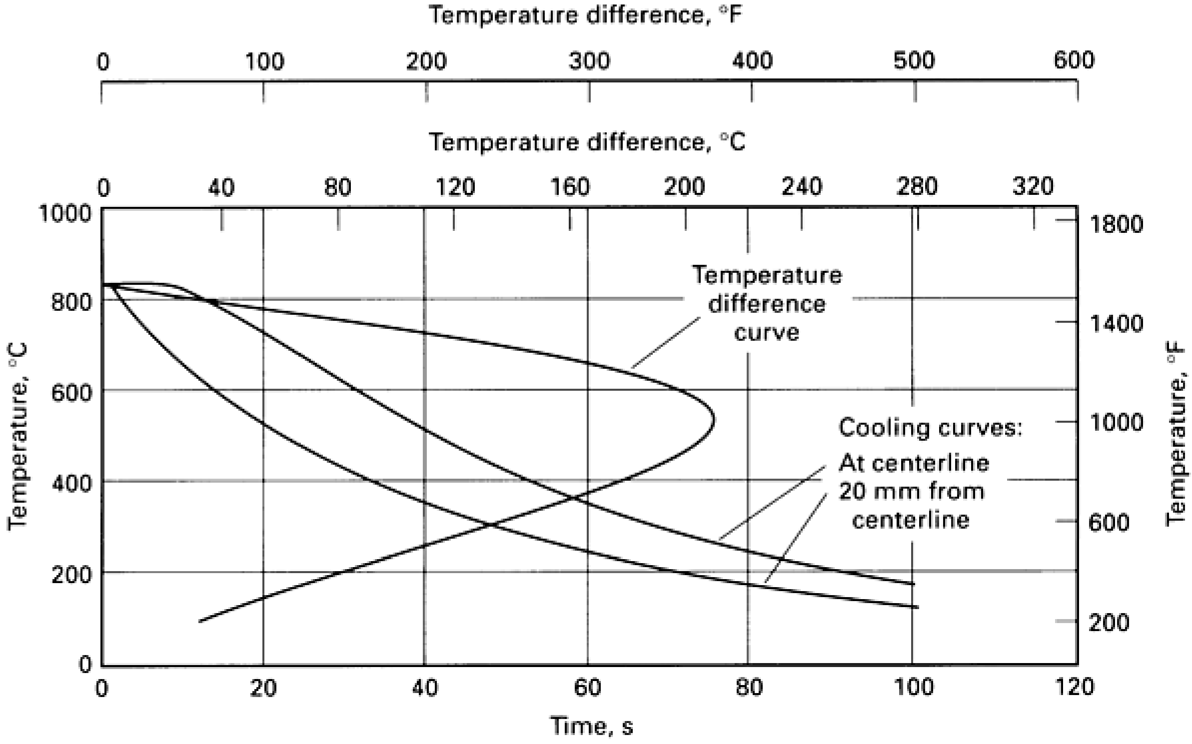

Fig. 27 Cooling curves and temperature difference curve between thermocouple A on centerline and thermocouple B 20 mm ($\frac{25}{32}$ in.) from centerline and thermocouple B 20 mm ($\frac{25}{32}$ in.) from centerline of 50 mm (2 in.) diameter probe quenched in fast oil with film coefficient of 4300 W/m^2 · K (760 Btu/ft^2 · h · °F)

High interface heat transfer coefficients can produce very large differences in temperature between thick and thin sections of a part. Cooling curves associated with a 38 mm ($1\frac{1}{2}$ in.) section and a 25.4 mm (1.00 in.) section quenched in 60 °C (140 °F) conventional oil flowing over the part at a velocity of 0.50 m/s (100 ft/min) are shown in Fig. 28. Oil at this temperature and velocity had an interface heat transfer coefficient of about 3500 W/m^2 · K and produced a maximum

temperature difference between the two sections of approximately 260 °C (470 °F). The peak difference occurred when the smaller section center temperature was about 500 °C (930 °F), which is well above the M_s temperature and unlikely to cause cracking.

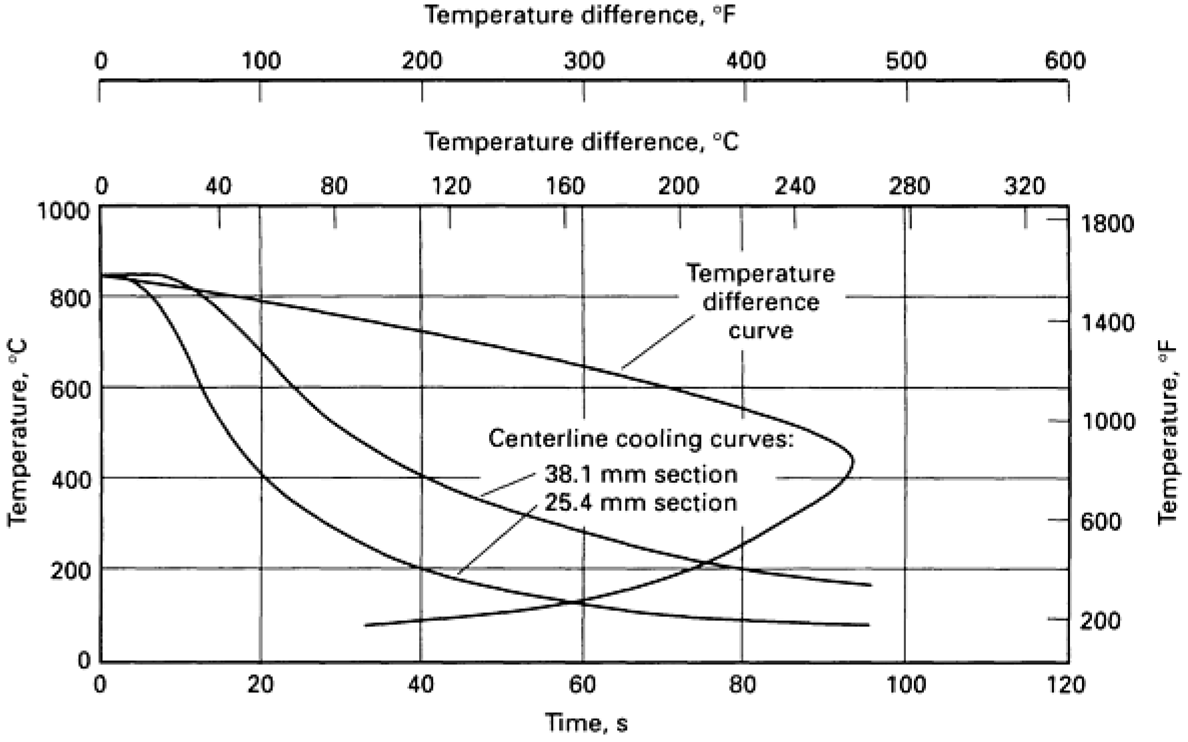

Fig. 28 Cooling curves and temperature differences curves between 38.1 mm(1.5 in.) section and 25.4 mm (1.0 in.) section of steel quenched in conventional oil at 60 °C (140 °F) that is flowing at 0.5 m/s (100 ft/min)

The thermal stress in a part which causes distortion during quenching is a function of the alloy thermal expansion coefficient, elastic modulus, volumetric expansion when martensite forms, and temperature differences within the part. Minimizing the thermal stress requires that temperature differences be minimized because no control can be exercised over either the expansion coefficient or elastic modulus.

When a part is quenched in a solution such as water that produces a high heat transfer coefficient, the temperature in the thin sections drops far more quickly than the temperature in heavier sections. The large temperature differences create high thermal stresses which often cause deformation. The only feasible approach to reducing the stress and cracking tendency is to reduce the heat transfer coefficient and hence minimize temperature differences. The interface heat transfer coefficient should be as low as possible while maintaining a sufficiently high cooling rate to ensure that the required microstructure, hardness, and strength can be obtained in critical sections of the part.

Hardness and Hardening Characteristics of Steel

Hardenability refers to the ability of a steel to be transformed partially or completely from austenite to martensite at a given depth when cooled under prescribed conditions. This definition reflects the empirical nature of steel hardenability, and many types of experiments have been devised to measure or describe the hardenability of various kinds of steel.

Martensite is the microstructure usually desired in quenched carbon and low-alloy steels. The cooling rate must be fast enough to avoid the nose of the time-temperature-transformation (TTT) curve of the steel being quenched, as indicated by curve A in Fig. 29, to obtain the maximum amount of martensite. If the cooling rate is not fast enough to miss the nose of the TTT curve (curves B, C, and D in Fig. 29), some transformation to bainite, pearlite, or ferrite will take place, with a corresponding decrease in the amount of martensite formed and a decrease in the as-quenched hardness developed.

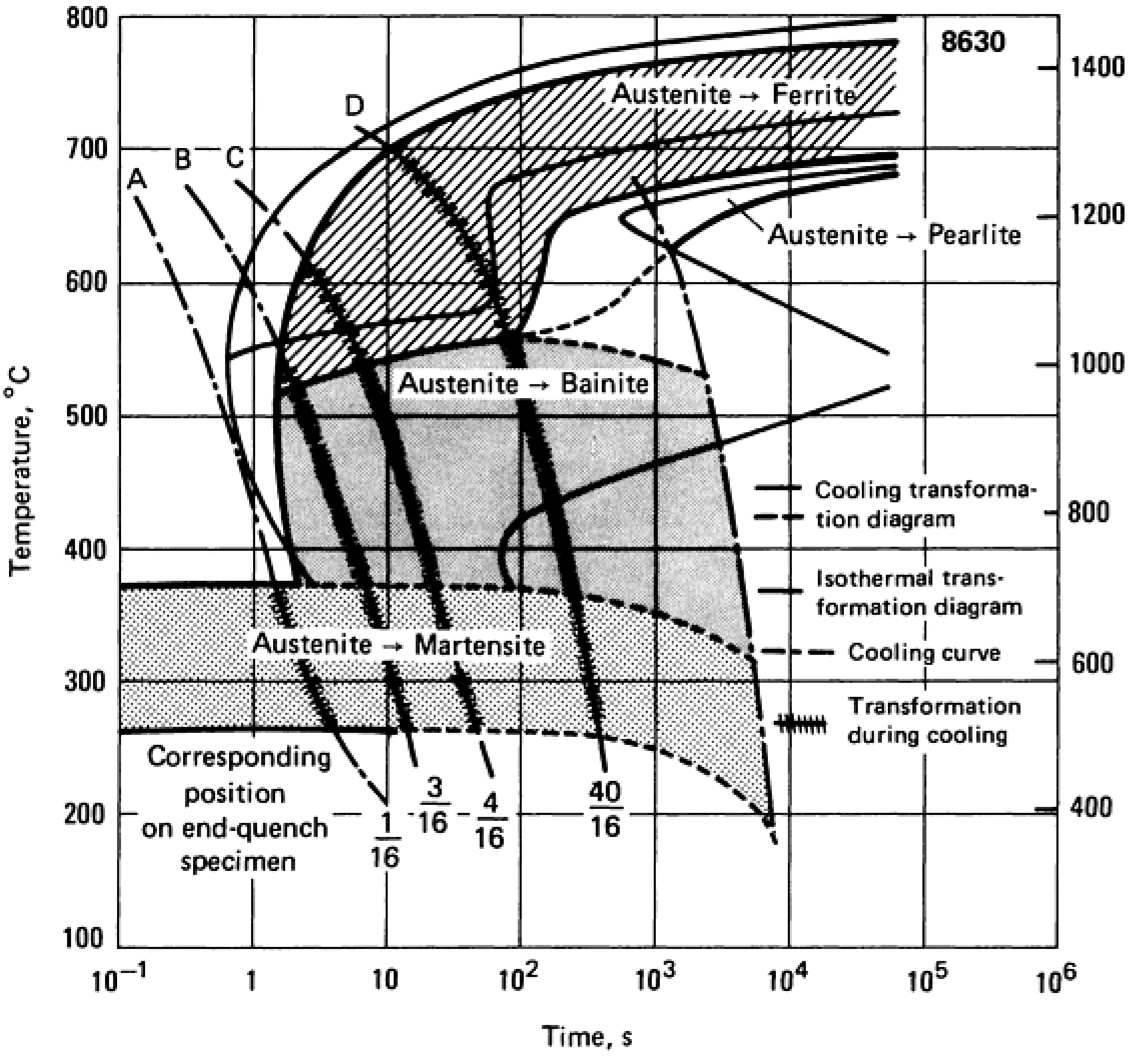

Fig. 29 Transformation diagrams and cooling curves for 8630 steel, indicating the transformation of austenite to other constituents as a function of cooling rate

The cooling rate in quenched parts should be fast enough so that a high percentage of martensite is produced in critically stressed areas of the part. Higher percentages of martensite result in higher fatigue and impact properties after tempering.

The maximum hardness obtainable in a steel depends almost exclusively on the carbon concentration. The relation of carbon concentration and percentage martensite to the approximate maximum as-quenched hardness is shown in Fig. 30 and Table 7.

Table 7 Effect of carbon concentration and % martensite on the as-quenched hardness of steel

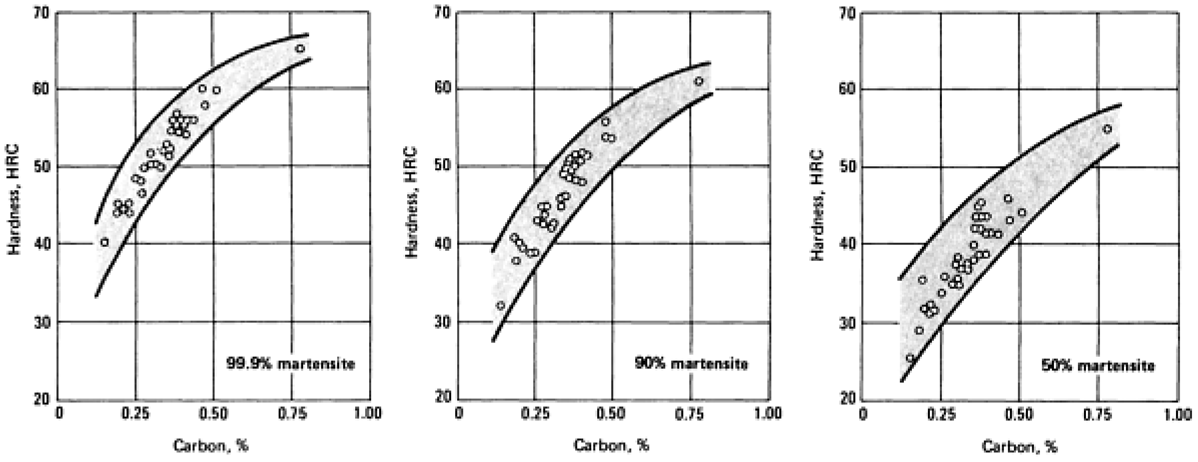

Fig. 30 Relation of carbon content and percentage martensite to HRC hardness

Ideal Critical Diameter

Hardenability is generally calculated in terms of the ideal critical diameter (D_I), and equations most often used for this prediction are base multiplicative factors. The base ideal diameter, DI_{base}, is determined from the carbon content and austenite grain size. The base ideal diameter is then multiplied by the various factors, which take into account the hardenability effects of the other elements present. The following equation is one expression for calculating the ideal critical diameter:

$$D_I = DI_{base} \cdot f_{Mn} \cdot f_{Si} \cdot f_{Cr} \cdot f_{Mo} \cdot f_v \cdot f_{Cu} \quad \textbf{(Eq 14)}$$

where f_x is the multiplicative factor for the particular alloying element.

One set of D_I and alloy factors are presented in Table 8. These alloy factors were developed based on data from medium-carbon steels of medium hardenability, and have been incorporated in a slide rule (Ref 27). An alternative set of alloy factors have also been developed for low-carbon steels and more recently computerized calculators have been developed (Ref 28).

Table 8 Tabulated hardenability factors of steels as a function of carbon content, carbon grain size, and selected alloying elements

The general procedure for calculating the hardenability of a steel from the composition includes the following steps:

- *Step 1:* Determine the ASTM grain size
- *Step 2:* Obtain a chemical composition
- *Step 3:* Determine DI_{base} from the carbon content and the grain size (see Table 8)
- *Step 4:* Determine alloy factors (see Table 8)
- *Step 5:* Multiply the factors according to the above equation to provide the calculated ideal critical diameter

These methods for determining the ideal critical diameter of an alloy from the composition and grain size have been compared for a large number of steels (Ref 29). In general, the United States Steel (USS) calculator has been found to predict hardenability well in medium- and high-carbon steels of high hardenability. The Climax Molybdenum calculator is reported to more accurately predict the hardenability in low- to medium-carbon steels.

Jominy Hardenability

The most familiar and commonly used procedure for evaluating the hardenability of steel is the Jominy end-quench test (ASTM A 255). In this test, a 100 mm (4 in.) long by 25 mm (1 in.) diameter bar is austenitized at the proper temperature for the alloy, dropped into a fixture, and one end rapidly cooled with 27 °C (80 °F) water. The end quenching process produces a range of cooling curves with progressively lower cooling rates with increasing distance from the water quenched surface. After cooling to room temperature, parallel flats are ground on opposite sides of the bar and hardness measurements are made at 1.6 mm ($\frac{1}{16}$ in.) intervals along the bar length. This process provides hardness values associated with various positions on the bar that are cooled at different rates. Additional information is available in the articles "Hardenability of Carbon and Low-Alloy Steels" and "Hardenability Curves" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

In general, the Jominy test is considered to provide valid data on steels having an ideal diameter in the range of from about 25 to 150 mm (1 to 6 in.). D_I can be less than 25 mm (1 in.), but this normally requires that Vickers hardness readings be taken closer to the quenched end of the bar and closer together than is possible using standard Rockwell hardness measuring equipment.

Jominy data for an AISI 4130 steel austenitized and quenched from 855 °C (1575 °F) are illustrated in Fig. 31. This steel contained 0.29% C, 0.25% Si, 0.55% Mn, 0.16% Ni, 1.02% Cr, 0.15% Mo, and 0.15% Cu and had a calculated ideal critical diameter of 68.3 mm (2.69 in.). The ideal critical diameter (D_I) is the diameter of a bar that can be quenched to 50% martensite in the center when given a sufficiently severe quench that the heat removal rate is controlled by the thermal diffusivity of the metal and not by the surface heat transfer rate.

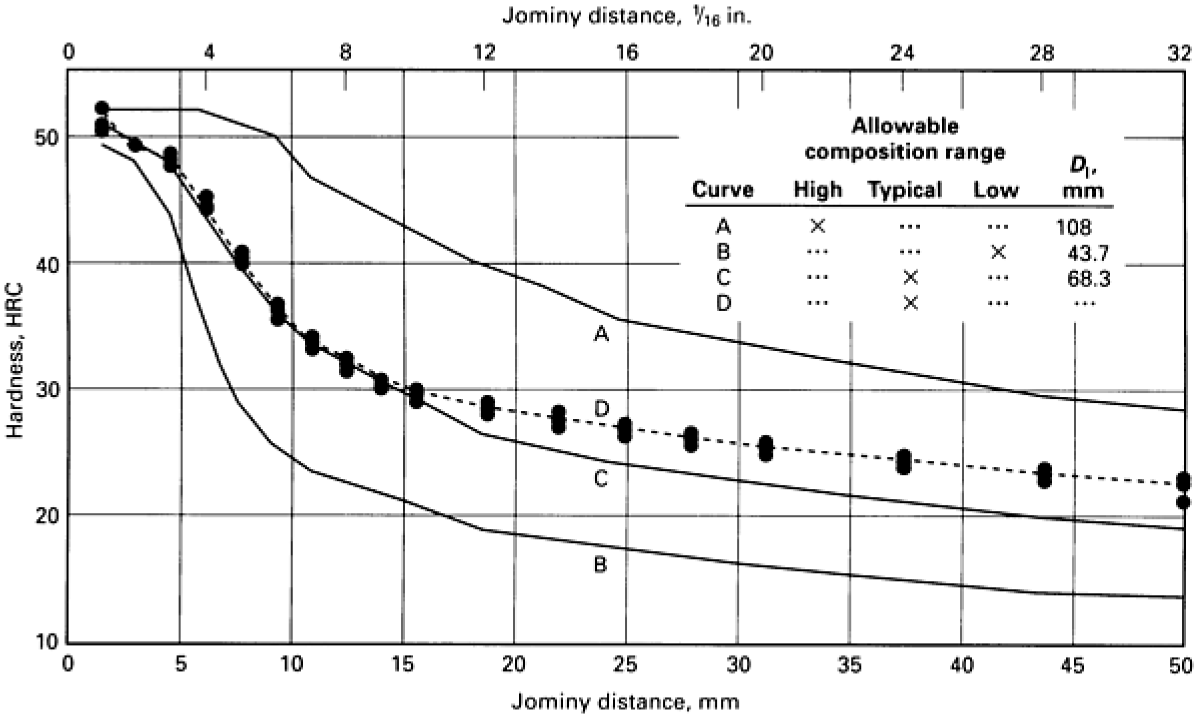

Fig. 31 Calculated and experimental Jominy hardness values of AISI 4130 steel that was austenitized and quenched from 855 °C (1575 °F). Curves A, B, and C were calculated from D_I values; curve D obtained from measured hardness values

The solid curves in Fig. 31 represent calculated hardness distributions. The lower solid curve represents the calculated Jominy hardness distribution assuming all elements to be at the low end of the allowable composition range, and the top curve represents the calculated hardness distribution if all of the elements are assumed to be on the high end of the range. The intermediate curve represents the calculated Jominy hardness distribution for a sample of 4130 steel. The stars represent measured hardness values after end quenching.

This representation of Jominy data provides hardness as a function of distance from the water quenched end of the bar which is related to the cooling rate and hardenability of the alloy. The hardness at the water quenched end of the bar should correspond to the maximum hardness attainable in the steel based on the carbon concentration. The hardness usually decreases with increasing distance from the quenched end. Steels of low hardenability will drop in hardness rather quickly. Steels with higher hardenability will drop less rapidly because higher hardenability steels are able to maintain their hardness at lower cooling rates.

For example, the cooling rate 1.6 mm ($\frac{1}{16}$ in.) from the end of the bar is reported to be about 270 °C/s (490 °F/s) through 700 °C (1290 °F), and this cooling rate is associated with a hardness of HRC 52 in this steel. Similarly, the cooling rates are reported to be about 110 °C/s (195 °F/s) 4.75 mm ($\frac{3}{6}$ in.) from the end and 43 °C/s (77 °F/s) 7.9 mm ($\frac{5}{16}$ in.) from the end of the bar (Ref 30). The hardness values associated with those locations were HRC 52, 49, and 40, respectively. The approximate cooling rates in a Jominy specimen are given in Table 9 as a function of distance from the quenched end (Ref 30).

Table 9 Typical cooling rates at 705 °C (1300 °F) in a Jominy specimen as a function of distance from the quenched end

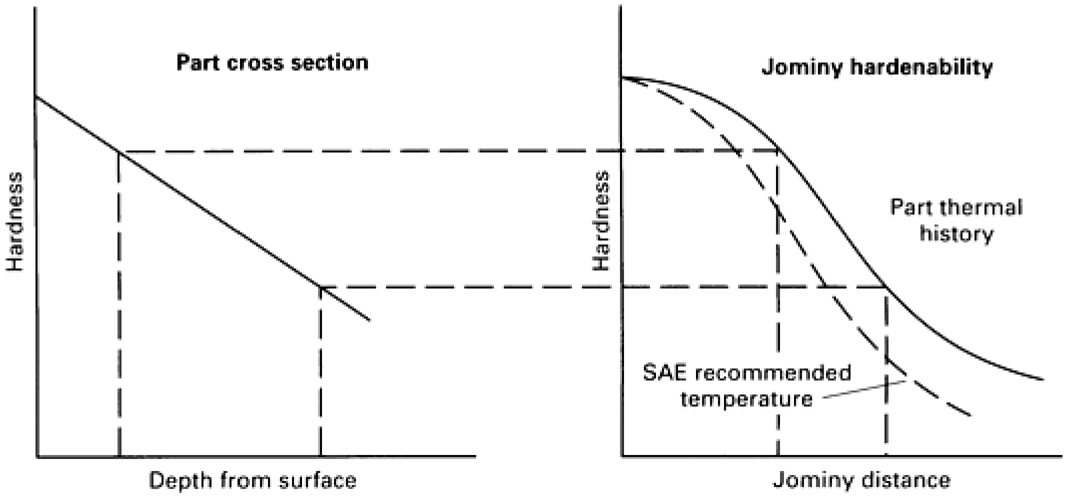
Distance from water	Cooling rate

quenched end, $\frac{1}{16}$ in.	°C/s	°F/s
1	270	490
2	170	305
3	110	195
4	70	125
5	43	77
6	31	56
7	23	42
8	18	33
9	14	26
10	11.9	21.4
12	9.1	16.3
14	6.9	12.4
16	5.6	10.0
18	4.6	8.3
20	3.9	7.0

The cooling rates, as a function of distance from the quenched end, are approximate and vary with the conductivity and transformation products of the particular alloy being quenched. Cooling rates at 705 °C (1300 °F) cannot reliably be used to predict hardness in carbon and low-alloy steels because the critical temperature range moves to higher or lower temperatures as the concentration of alloy elements changes between the different grades (Ref 12).

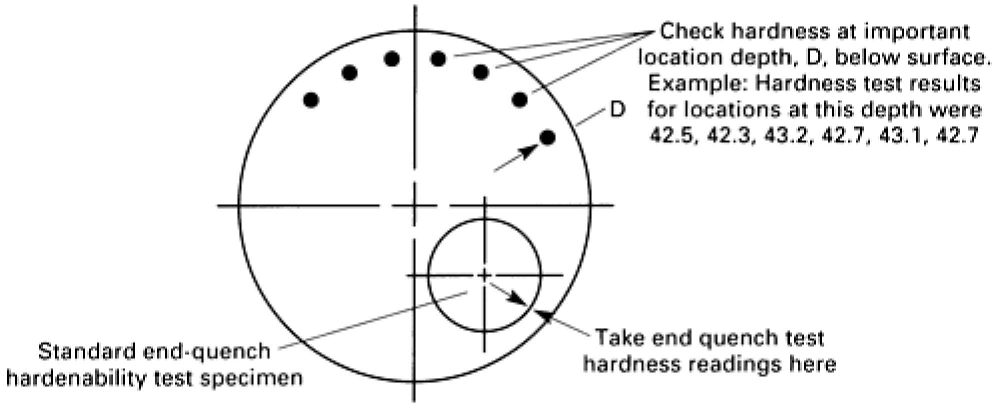
Jominy Equivalence

Once the Jominy curve has been determined, the cooling rate in critical areas of quenched parts must be estimated. One method of establishing the cooling rate is to determine the Jominy equivalent (J_{eq}). The procedure for determining the Jominy equivalent distance is outlined in Fig. 32.



Procedure to determine quench cooling rates at important locations in a workpiece:

- *Step 1:* Obtain at least two test parts (a) made from the same heat of steel and manufactured as close as possible to the proposed production method. Castings will do if forging dies are not available
- *Step 2:* Machine parts to condition in which they will be hardened. Copper plate or otherwise protect parts from any carburizing or decarburizing action. Process parts through heat-treating operations for times estimated to be approximately that for the production part. Quench part No. 1 in a manner as close to production as possible (no temper)
- *Step 3:* Cut, grind, and polish hardened sections from part No. 1 so hardness readings may be taken as shown on example below:



- *Step 4:* Machine end-quench hardenability test specimens from part No. 2 test location on hardenability specimens to correspond to depth D, below surface. Harden end-quench specimens from same temperature as part No. 1. Example test results as follows:

Distance from quenched end, $\frac{1}{16}$ in.	1	2	3	4	5	6	8
Hardness, HRC	56	55	55	54	52	48	43

- *Step 5:* By comparing hardness results obtained at reference location of step 3 (HRC 42.7) to end-quench results (step 4), it can be seen that this hardness occurs at $\frac{8}{16}$ in. on end-quench curve. Quench cooling rate at reference point is approximately equal to $\frac{8}{16}$ in. in end-quench test
- *Step 6:* Confirm cooling rate subsequently on a number of different heats of production parts and adjust material or heat treatment or both to obtain the engineering requirements more precisely

(a) Can be used on gear teeth, roots of splines, and other part shapes. If section in which cooling rate must be determined (such as a gear tooth) is too small for an end-quench hardenability specimen, test results from a separate test may be used. An attempt should be made to make end-quench hardness tests on metal of same location in cross section as gear tooth.

Fig. 32 Determination of Jominy equivalent condition (J_{eq}). Source. Ref 31

The cooling rate can be determined based on a knowledge of the quenchant and the cross section of the part. Approximate cooling rate data through 705 °C (1300 °F) are illustrated in Fig. 33(a) and 33(b) for various bar diameters ranging from about 13 to 100 mm ($\frac{1}{2}$ to 4 in.). The cooling rates at the surface, three-quarter radius, half-radius, and center, are related to the cooling rates at an equivalent distance from the end of a quenched Jominy bar. Thus, the cooling rate at the center of a 50 mm (2 in.) diameter bar quenched in water has a cooling rate equivalent to the value at a distance of about $\frac{6}{16}$ in. from the end of the Jominy bar. The cooling rate at the center of a 50 mm (2 in.) diameter bar quenched in oil has a cooling rate comparable to a point $\frac{10}{16}$ in. from the water quenched end of a Jominy bar.

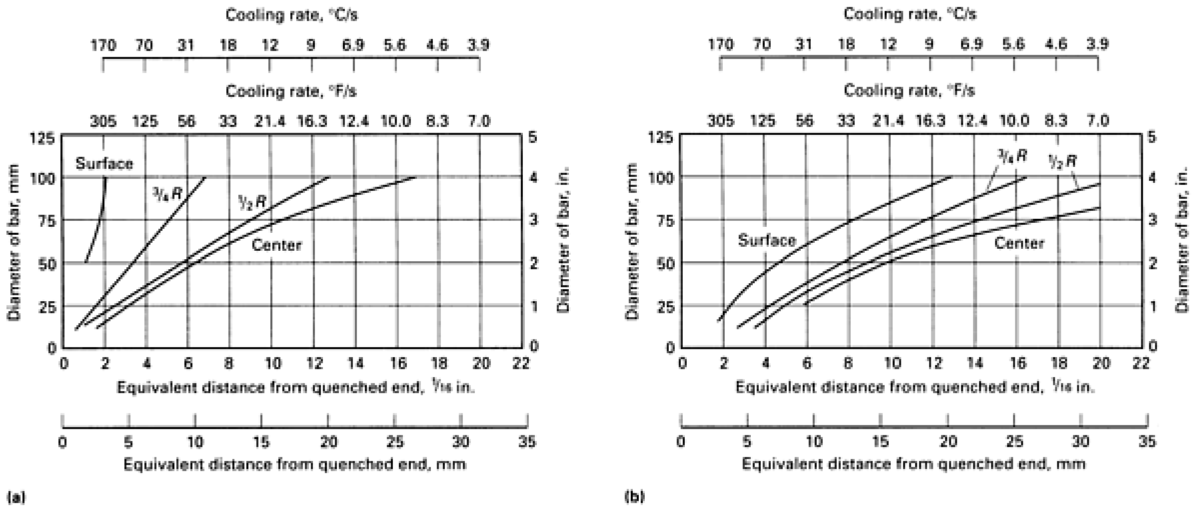


Fig. 33 Equivalent cooling rates at 705 °C (1300 °F) for round bars quenched in (a) water and (b) oil. Fluid viscosity is 1.0 m/s (200 ft/min). Correlation of equivalent cooling rates in the end-quenched hardenability specimen and quenched round bars free from scale. Data for surface hardness are for mild agitation.

Relationships between bar diameter and other simple part geometries such as squares and plates are shown in Fig. 34.

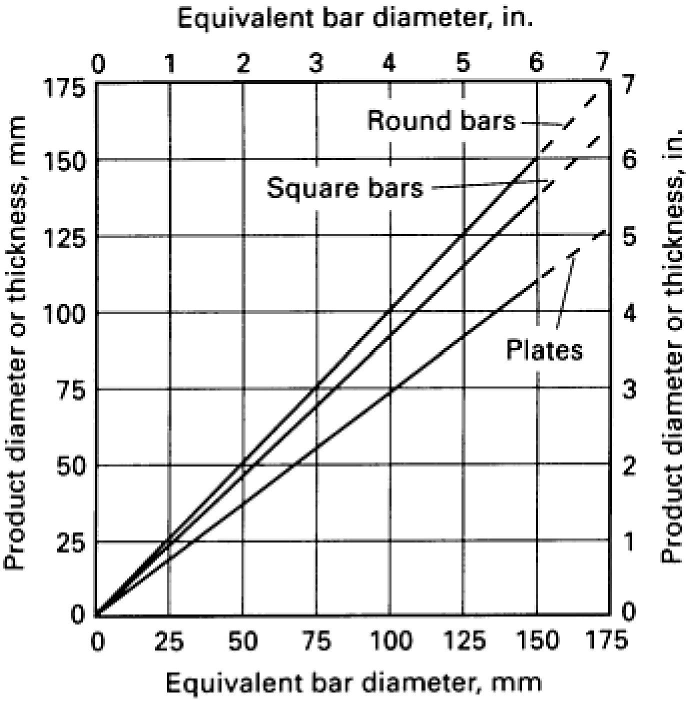

Fig. 34 Relation between through-quenched bar diameter and the through-quenched thickness of plates and square bars

Basically, the Jominy equivalence technique involves:

- Choosing an equivalent bar diameter for estimating the necessary cooling rate from Fig. 34
- Using the equivalent bar diameter to choose the J_{eq} distance for a water quenchant from Fig. 33(a) and an oil quenchant from Fig. 33(b)

TTT and CCT Diagrams

The cooling rates required to achieve particular microstructures are often represented by time-temperature-transformation (TTT) diagrams and continuous-cooling-transformation (CCT) diagrams.

TTT Diagrams. TTT curves are usually produced by solution treating (austenitizing) small samples of steel at the appropriate temperature for the alloy, quickly transferring samples to a lead or salt bath, holding for selected periods of time, and water quenching. The microstructure of each sample after quenching is examined to determine the point in time when the transformation to ferrite, pearlite, or bainite began and the rate at which the transformation progressed with increasing isothermal holding time. The start of transformation in TTT curves is usually defined as the time required to produce 0.1% transformation at the specified holding temperature.

The TTT curve for 4130 steel (see Fig. 35) is usually interpreted to mean that the steel must be cooled past 540 °C (1000 °F) and to the start of the martensitic transformation (M_s) in less than about 1.5 s to produce a fully martensitic structure or must be cooled from the austenitizing temperatures and to the M_s in about 10 s to produce a 50% martensitic structure. Slower cooling rates may result in less than 50% hardening.

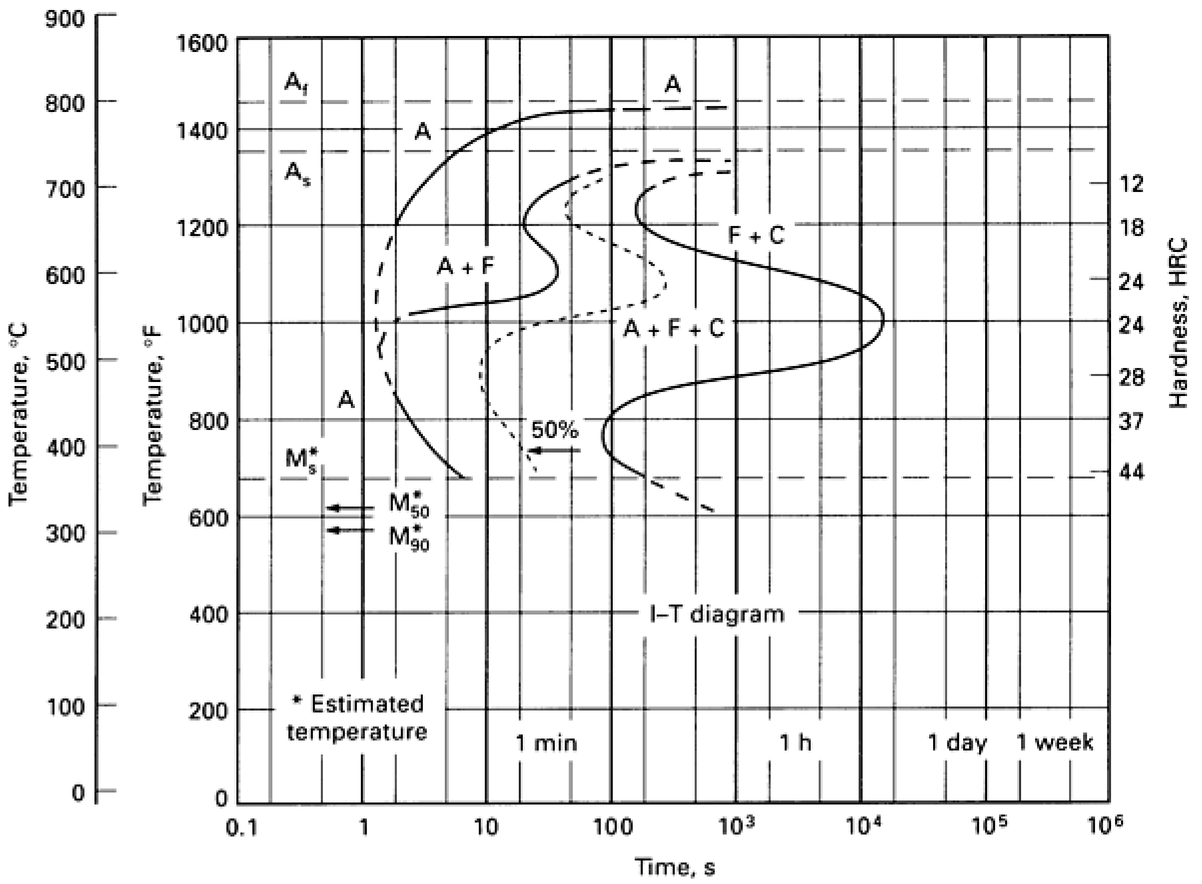

Fig. 35 TTT diagram for 4130 low-alloy steel

Many TTT curves have been published and provide valuable assistance to metallurgists regarding the relative hardenability of different alloys (Ref 31, 32). However, it is difficult to quantitatively determine from a TTT curve whether a steel of a particular composition and section size can be hardened in a particular quenchant.

CCT diagrams are constructed by cooling samples of alloys and examining the resulting microstructures to determine the phases associated with particular cooling rates. CCT diagrams for a wide variety of alloys have also been published (Ref 33, 34).

The CCT diagram for an AISI 4130 steel is shown in Fig. 36. This diagram indicates that a fully martensitic microstructure in this alloy requires a cooling rate above 170 °C/s (300 °F/s) at 705 °C (1300 °F). Achieving a 50% martensitic microstructure requires a minimum cooling rate of about 65 °C/s (120 °F/s) at 705 °C (1300 °F).

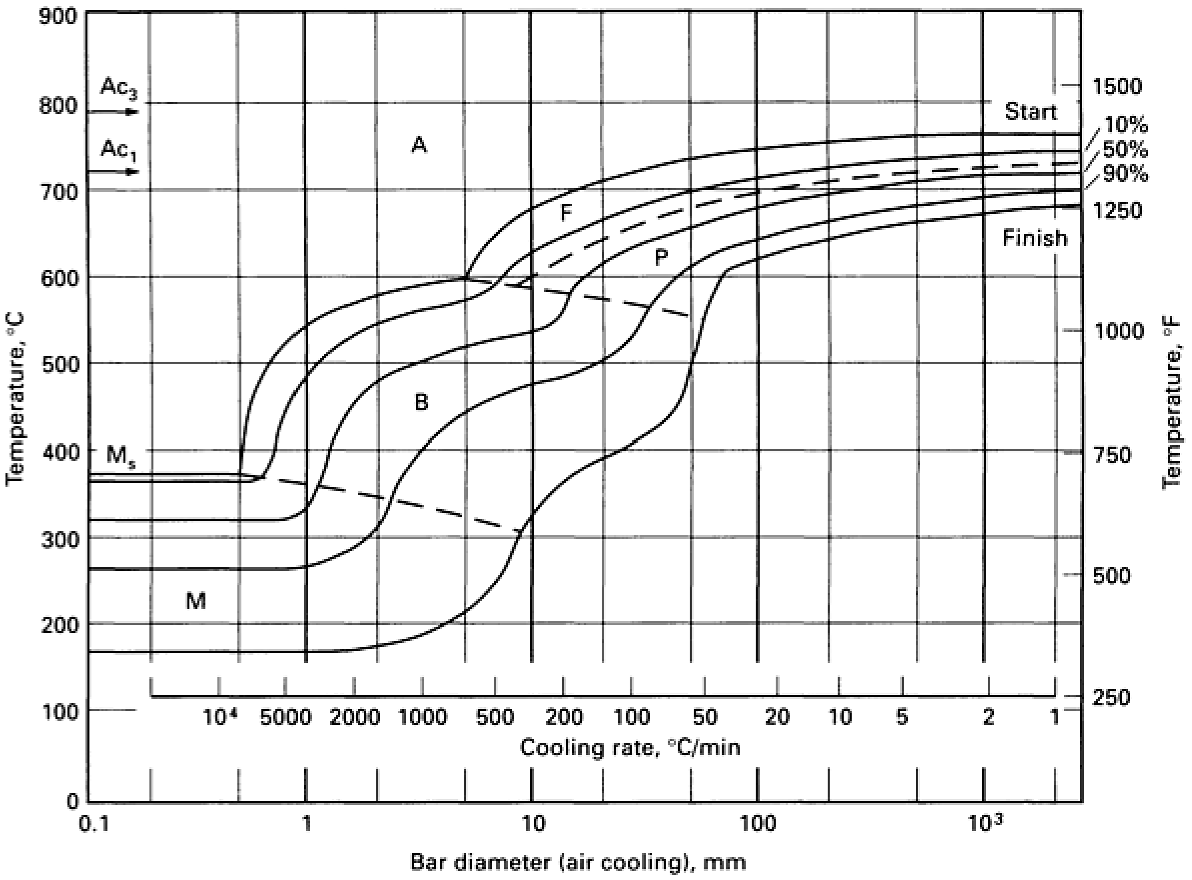

Fig. 36 CCT diagram for 4130 low-alloy steel with 0.30C-0.25Si-0.50Mn-0.020P-0.020S-1.00Cr-0.20Mo composition tested at 750 °C (1380 °F). Calculated critical cooling rate is 143 °C/s (258 °F/s).

These and other published diagrams present approximate cooling rates needed during quenching various alloys to obtain desired microstructures (Ref 15, 35). The actual rates depend to some extent on the specific composition of the steel being quenched. Quenching facilities rely on the quenchant, alloy composition, and attainable quench rates to achieve hardness levels in critical sections of parts without inducing cracks.

Quench Factor Analysis

Jominy, CCT, and TTT curves have been used to represent hardenability of various grades of steel for many years. A more recently introduced concept is that of quench factors (Ref 12, 36, 37).

Quench factor analysis provides a single number, *Q*, that interrelates the cooling rate in a part and the transformation kinetics of the particular alloy being quenched. Cooling rates used in the analyses may be experimentally measured or calculated from heat transfer data.

Alloy hardening characteristics are described by the time-temperature-property (TTP) function, which is the mathematical expression relating transformation temperatures and times to as-quenched properties, usually as-quenched hardness.

The basic hypothesis behind the quench factor concept is that the hardening behavior of steel during continuous cooling can be predicted by dividing a cooling curve into discrete temperature-time increments and determining the ratio of the amount of time the steel was at each temperature divided by the amount of time required to obtain a specified amount of transformation at that temperature. The sum of the incremental quench factor values over the transformation range between the A_3 and the M_s temperatures is the quench factor, *Q*. This approach is usually referred to as the Avrami or additivity rule.

Scheil first proposed the additivity rule to describe incubation or nucleation during phase transformations (Ref 38). Avrami continued the analysis and showed that when the nucleation rate is proportional to the growth rate, the additivity rule is applicable (Ref 39, 40). Avrami developed different expressions to describe the rate of transformation during phase changes depending on whether there were a few or many nuclei present and depending on the type of phase growth that occurred. Transformation rate laws were derived for transformations that nucleated on grain boundary surfaces, grain edges, and grain corners.

Cahn showed that transformations that nucleate heterogeneously often obey the Avrami rule according to rate laws that could be calculated from isothermal transformation data (Ref 41, 42).

Kirkaldy used the Avrami principle and compared the predicted start of the transformation curve with the experimental start of the transformation curve for nine different steels. Good agreement was found in most cases, especially in view of uncertainties in the experimental curves and the assumptions made to calculate the theoretical curves (Ref 43). Kirkaldy has used the Avrami principle to develop computer programs for predicting the transformation rates and hardness of steel under a wide variety of cooling rates (Ref 44).

Tamura studied effects of section size and austenite grain size on the transformation rate of steel and found the additivity rule to be approximately correct during step quenching (Ref 45). Tamura applied the additivity rule to the transformation of a eutectoid steel and was able to obtain equations describing the hardenability that gave predictions similar but slightly lower than those of Grossmann (Ref 46). The basic principles have also been used for several years to predict properties in quenched and tempered aluminum alloys (Ref 47, 48).

Quench factors can be calculated relatively easily from digitally recorded time-temperature curves (cooling curves) obtained in instrumented parts and the equation describing the C curve for the alloy of interest (C_T function).

The C_T function for the alloy of interest is usually described with an equation of the form:

$$C_T = -K_1 \cdot K_2 \cdot \exp\left[\frac{K_3 \cdot K_4^2}{R \cdot T(K_4 - T)^2}\right] \cdot \exp\left(\frac{K_5}{R \cdot T}\right) \quad \textbf{(Eq 15)}$$

where C_T is the critical time required to transform a constant amount of ferrite, pearlite, or bainite, typically 0.1 or 0.5% (the locus of the critical times is the start of the transformation C-curve); K_1 is the constant which equals the natural logarithm of the volume fraction austenite not transformed above the M_s during cooling, that is, the fraction defined by the C-curve, typically ln 0.999 or ln 0.995; K_2 is the constant related to the reciprocal of the number of nucleation sites; K_3 is the constant related to the energy required to form a nucleus for a diffusion controlled transformation; K_4 is the constant related to the carbon solvus temperature (A_3); K_5 is the constant related to the activation energy for diffusion; R is the 8.3143 J/K · mol (gas constant); and T is the average temperature between successive time steps (K).

When making a quench factor calculation, an incremental quench factor, q, for each time step in the transformation range is first calculated using the following equation:

$$q = \frac{\Delta t}{C_T} \quad \textbf{(Eq 16)}$$

where Δt is the time step used in data acquisition, and C_T is the time for the start of transformation at the sample temperature.

The incremental quench factor values are summed over the transformation range between Ar_3 and M_s to produce the cumulative quench factor, Q, according to the equation:

$$xQ = \sum q = \sum_{T = M_s}^{T = Ar_3} \frac{\Delta t_i}{C_{T_i}} \quad \text{(Eq 17)}$$

The cumulative quench factor reflects the heat extraction characteristics of the quenchant as a function of the quenchant type, velocity, and temperature over the transformation range of the steel being quenched. This factor includes section thickness effects, agitation, and surface finish effects on cooling rate as well as the transformation rate of the alloy. The calculation process is schematically illustrated in Fig. 37.

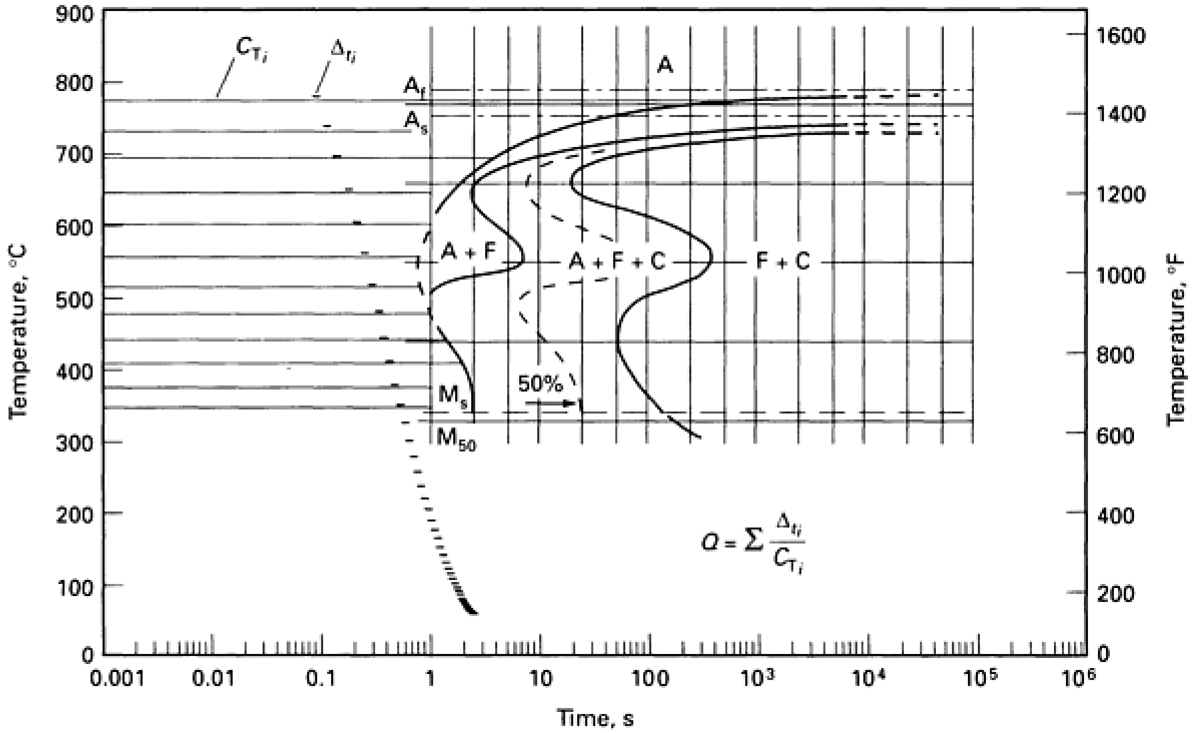

Fig. 37 Schematic illustration showing method for calculating a quench factor

The quench factor can be used to predict the as-quenched hardness in steel using the following equation:

$$H_P = H_{min} + (H_{max} - H_{min}) \exp (K_1 Q) \quad \text{(Eq 18)}$$

where H_P is the predicted hardness; H_{min} is the minimum hardness for alloy; H_{max} is the maximum hardness for alloy; exp is the base of the natural logarithm; K_1 is the ln (0.995) = -0.00501; and Q is the quench factor.

The critical value of the quench factor is the maximum value that will produce the desired as-quenched hardness in the particular steel being quenched. Maximum hardness and strength values are obtained with low quench factors, but minimum quenching stresses are obtained with high quench factors. Minimum residual stress and distortion consistent with the desired hardness is achieved when the quench factor is just below the critical value.

The goal of quench factor analysis is to interrelate alloy hardenability and quenching variables and allow predictions to be made about hardness and strength in specific alloys and specific locations in parts. Once a quench factor is established that will provide the required hardness and strength, a quenchant should be selected and used in such a way that thermal stress and the tendency for distortion and quench cracking is minimized.

Approximate TTP curves have been developed for the compositions of 4130 steel in Table 10. These TTP curves are illustrated in Fig. 38. These C curves are plotted for times to 1000 s (16.7 min) rather than the usual 10^6 s (20 days) used

in many published diagrams. Transformations that occur over a 20 day period are of little interest in heat-treating operations. At 595 °C (1100 °F), the transformation begins in about 0.15 s in the low specification composition, in 1 s in the actual composition, and after about 3 s in the high specification composition. The C curves illustrate the shift in the start of transformation with alloy content. The mathematical expression describing the curves allows hardness predictions to be made under a wide variety of quenching conditions.

Table 10 Comparison of actual chemical composition with chemical composition limits of AISI 4130 steel

Steel designation	Composition, wt%						
	C	Si	Mn	Ni	Cr	Mo	Cu
Low specification	0.280	0.150	0.400	0.160	0.800	0.150	0.150
Actual composition	0.290	0.240	0.550	0.160	1.020	0.150	0.150

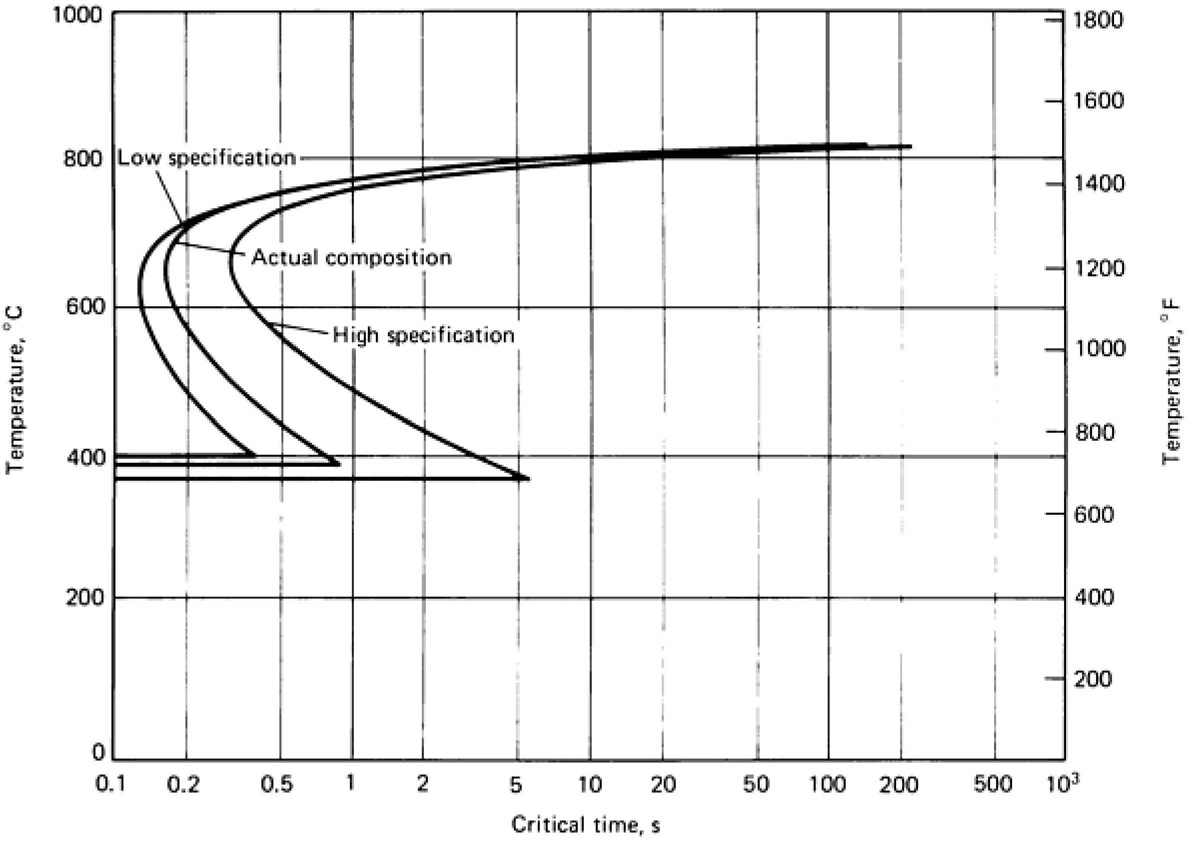

Fig. 38 Approximate TTP curves for 4130 low-alloy steel compositions in Table 10

Some correlations between quench factor, predicted hardness, and measured hardness in cast 4130 are presented in Table 11 and the results are graphically illustrated in Fig. 39. The solid line in Fig. 39 represents the predicted hardness as a function of quench factor, and the data points are measured hardness values at locations in a quenched part where cooling curves were available.

Table 11 Measured and predicted hardness at 17 positions in a water quenched 4130 low-alloy steel casting

Casting position	Cooling rate at 705 °C (1300 °F)		Quench factor, *H*	Hardness, HRC

While quench factor analysis appears to be an excellent technique of correlating cooling curves with metallurgical response, it suffers from a lack of availability of constants for the C_T function. However, these can be determined experimentally. Once computerized, this technique is one of the simplest to use by both the heat treater and metallurgical researcher.

Grossmann Quench Severity

A practical method for evaluating quench severity and determining the response of a steel to the imposed quenchant conditions is to determine the Grossmann quench severity or *H* value (Ref 49). The *H* value reflects the ability of the quenching medium to extract heat from a hot steel workpiece. If the *H* value of still water is taken as 1.0, the *H* values of oil, water, and brine are as presented in Tables 1 and 3.

The relations between bar diameter, inherent hardenability, and *H* value may be plotted as shown in Fig. 40, which is referred to as a Grossmann chart. The *H* values of a material are plotted as follows: If a 25 mm (1 in.) diameter part is quenched in oil with good agitation (0.50 *H* value), the chart shows that, reading across the 25 mm (1 in.) diameter horizontal line to the 0.50 *H* value and then down, a value of 8 mm ($\frac{5}{16}$ in.) on the end-quench hardenability specimen is obtained. This means that the center of the bar can be expected to have the same hardness as that shown at 8 mm ($\frac{5}{16}$ in.) from the quenched end of a standard Jominy hardenability specimen made from the steel being quenched.

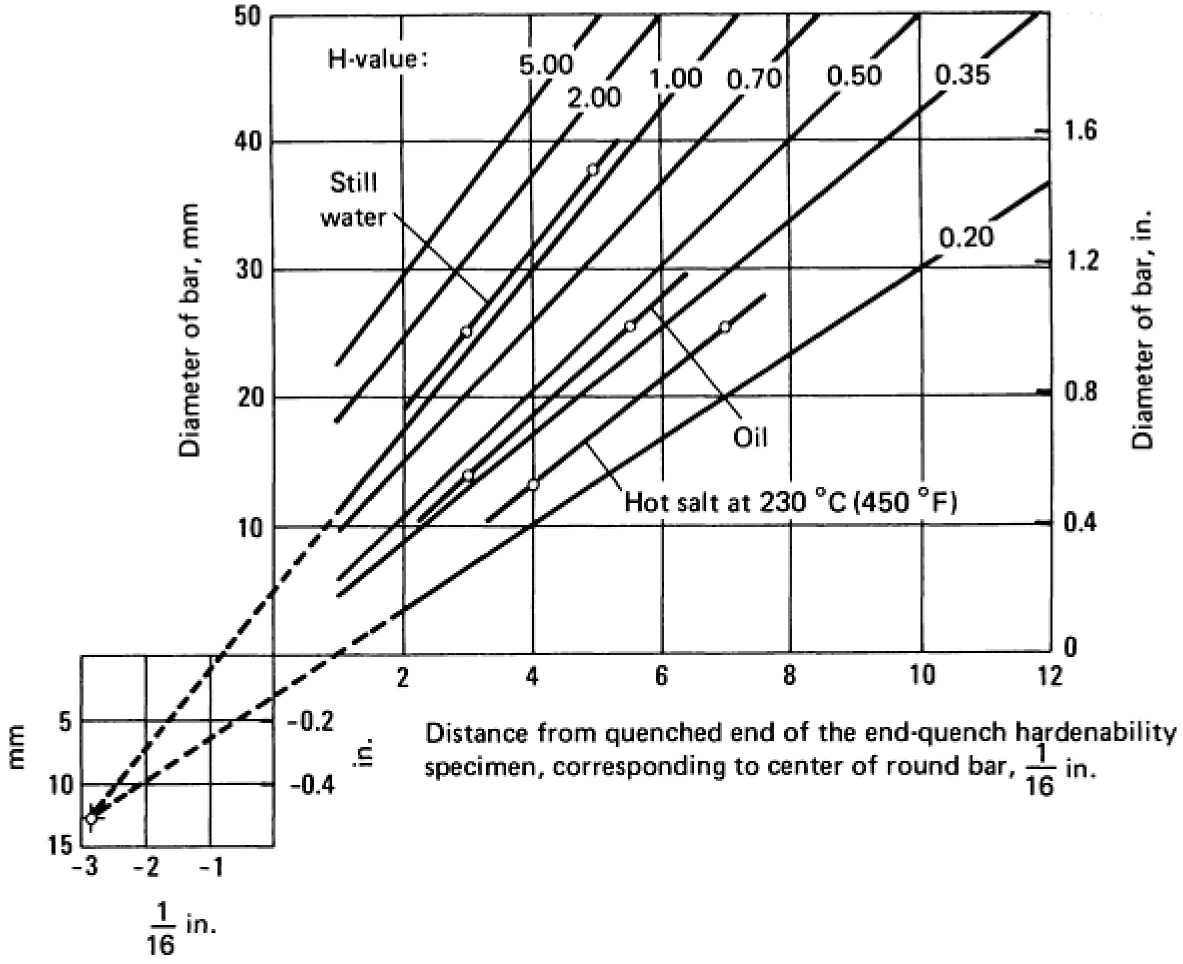

Fig. 40 Grossmann chart relating bar diameter, hardenability of steel, and severity of quench. *H*-value (severity of quench): 5.00, strong brine quench, violent agitation; 2.00, poor brine quench, no agitation; 1.00, poor water quench, no agitation; 0.70, strong oil quench, good agitation; 0.50, good oil quench, good agitation; 0.35, good oil quench, moderate agitation; and 0.20, poor oil quench, no agitation

The cooling power of a quench bath under any loading condition can also be determined using Fig. 40. If the hardenability of the steel and the bar diameter are known, it is possible to plot a point on the quench-severity curve. For example, if the 8 mm ($\frac{5}{16}$ in.) point on the end-quench specimen shows a hardness of 45 HRC, and a 25 mm (1 in.) diameter bar of the same steel quenched in the bath to be evaluated has a center hardness of 45 HRC, the result indicates a quench severity of 0.50.

Regardless of the hardness obtained at the center of the 25 mm (1 in.) diameter test bar, it can be plotted on Fig. 40 at the correct location. If the center hardness had been 48 HRC, and if the hardenability curve for the bar of steel tested had shown 48 HRC at 6 mm ($\frac{1}{4}$ in.), the 6 mm line and the 25 mm diameter line would intersect at a quench severity of 0.70.

The various quench severity lines of the Grossmann chart converge at a point outside the normal chart range. The point of intersection can be used as a second point in drawing new quench-severity lines. An example is illustrated by the line labeled oil. The two experimental points on this line were obtained by quenching a stepped bar of steel of known hardenability having two different diameters, 25 and 12.5 mm (1 and $\frac{1}{2}$ in.). The use of a bar with two diameters offers a means of checking results because it provides three points on the line. The results obtained from hot salt, oil, and still water, as determined with stepped test bars, are plotted on Fig. 40.

The principal advantage of this test is that the specimen can be treated along with other work just as if it were a production part; thus, the quench is evaluated under the conditions of temperature and agitation that actually prevail in production quenching of a load of parts. The test bar should be of such diameter that the as-quenched hardness at the center of the bar falls on the sloping portion of the Jominy hardenability curve for the steel being quenched. The test can be performed most conveniently with a shallow-hardening steel because this type of steel permits the use of smaller diameter test bars, which are easier to prepare and section after being quenched. The use of shallow-hardening steel in no way detracts from the validity of the test results, because severity of quench is an inherent characteristic of the bath and is not affected by part size or hardenability.

The Rushman-Lamont method is a variation of the bar quenching technique. Two bars having the same composition, intermediate hardenability (typically 1141), and different diameters are quenched in the facility of interest. The bars are then cut in two and the hardness at the bar center or mid-radius measured. Using the bar diameter and the equivalent Jominy distance based on the hardness achieved when the two bars were quenched, the data points are placed on a Lamont diagram, illustrated in Fig. 41 (Ref 30, 50).

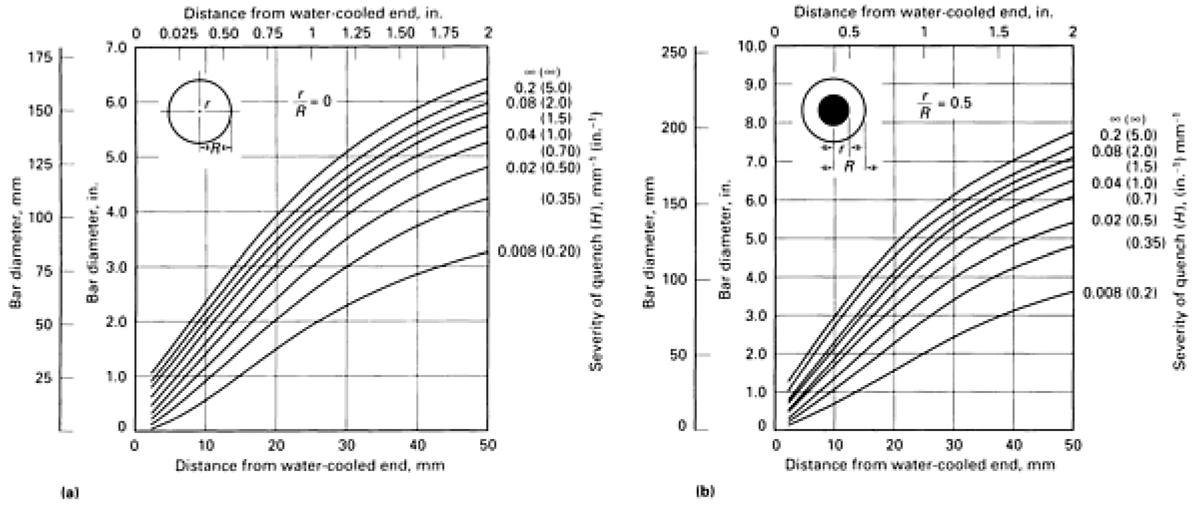

Fig. 41 Location in end-quenched Jominy hardenability round bar specimen corresponding to (a) center position and (b) half-radius position. Source: Ref 30, 50

This procedure involves:

- *Step 1:* Quenching 2 bars (typically 1141) of different diameters (typically 13 mm and 25 mm, or $\frac{1}{2}$ and 1 in.) in the quenchant or quench facility of interest
- *Step 2:* Determining the Jominy curve for the steel used in the bars
- *Step 3:* Comparing center or mid-radius hardnesses in the bar with the Jominy curve and assigning a Jominy distance to the cooling rate
- *Step 4:* By comparison with Fig. 41 or Table 12, an *H* value for the quenchant can be assigned

Table 12 Effect of end-quench distance and Grossmann quench severity, *H*, on the equivalent bar diameter of 1141 resulfurized carbon steel

(a) When the end-quench hardness curve of a steel has been found, this table enables the user to estimate the hardnesses that would be obtained at the centers of quenched round bars of different diameters, when that same steel is quenched with various severities of quench. For each

successive in. position, the hardness obtained in the end-quench test would be found at the center of the bar size shown.

Quenching Media

Many different media have been used for quenching. Most are included in the list that follows, but some (indicated by *) are used only to a limited extent:

- Water
- Aqueous brine solutions
- Aqueous caustic solutions*
- Oils
- Aqueous polymer solutions
- Molten salts
- Molten metals*
- Gases
- Fluid beds*
- Fogs*
- Sprays
- Dry dies*

Water

Vigorously agitated water produces cooling rates approaching the maximum rates attainable with liquid quenchants. Water is inexpensive, readily available, and, unless contaminated, it is easily disposed of with a minimum of pollution or health hazard. Water is also effective in breaking scale from the surface of steel parts quenched from furnaces without protective atmospheres.

Water, therefore, is used wherever a severe quench does not result in excessive distortion or cracking. Water is widely used for quenching nonferrous metals, austenitic stainless steels, and other metals that have been solution treated at elevated temperatures.

One disadvantage of water is that its rapid cooling rate persists at lower temperatures where distortion and cracking are more likely to occur. Consequently, water quenching is usually restricted to the quenching of simple, symmetrical parts made of shallow hardening grades of steel. A second disadvantage of using plain water is that it may have an extended vapor blanket stage. Complex parts encourage vapor entrapment which may produce an uneven hardness and unfavorable stress distribution leading to distortion or soft spots. Water quenched steel parts may also rust unless immediately treated with a rust preventative.

Facility Operation. To obtain reproducible results by water quenching, the temperature, agitation, and extent of contamination must be controlled. Generally, water will provide uniform quenching speed and reproducible results if maintained at a temperature of 15 to 25 °C (55 to 75 °F) and agitated to produce velocities greater than 0.25 m/s (50 ft/min).

The effects of water temperature on cooling curves and cooling rate curves in an Inconel 600 probe (12.5 mm diameter), are illustrated in Fig. 42 (a) and (b), respectively. Similar cooling curves and cooling rate curves obtained at a water temperature of 55 °C (130 °F) using quenchant velocities between 0 and 0.75 m/s (0 and 150 ft/min) are illustrated in Fig. 43.

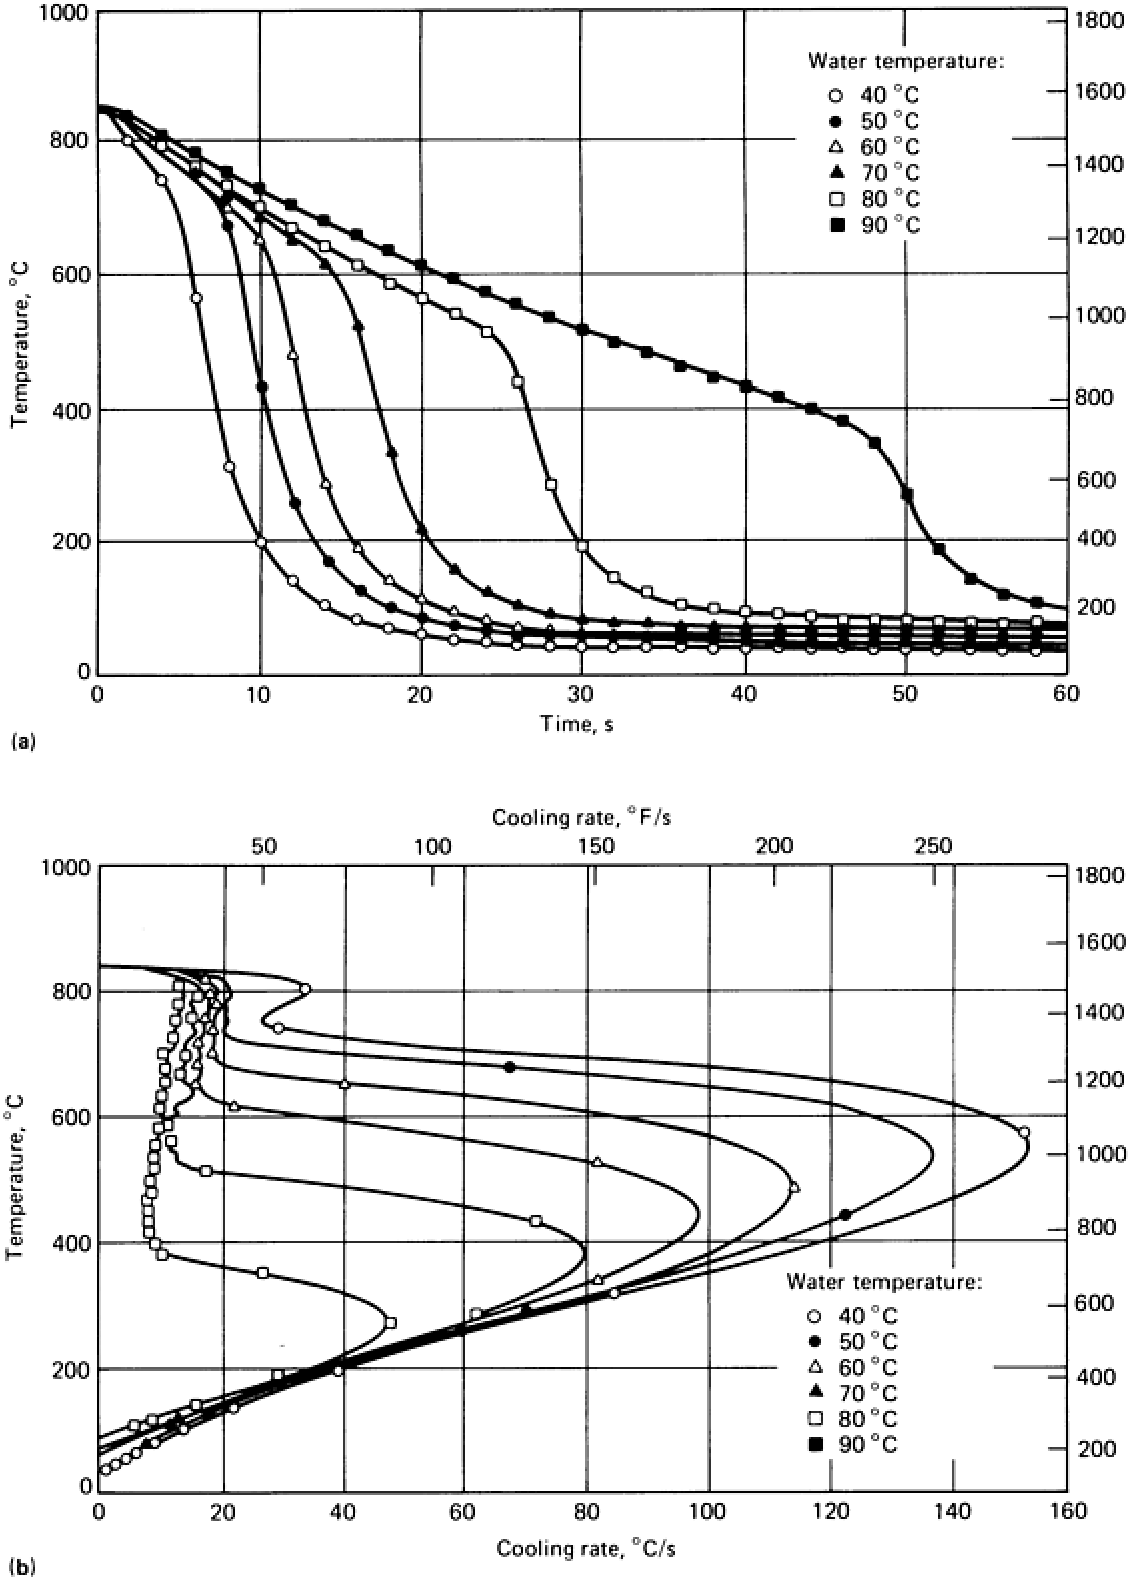

Fig. 42 Effect of bath temperature on heat removal in a Wolfson probe. (a) Cooling curves. (b) Cooling rate curves. Quenchant is water having 0.25 m/s (50 ft/min) velocity.

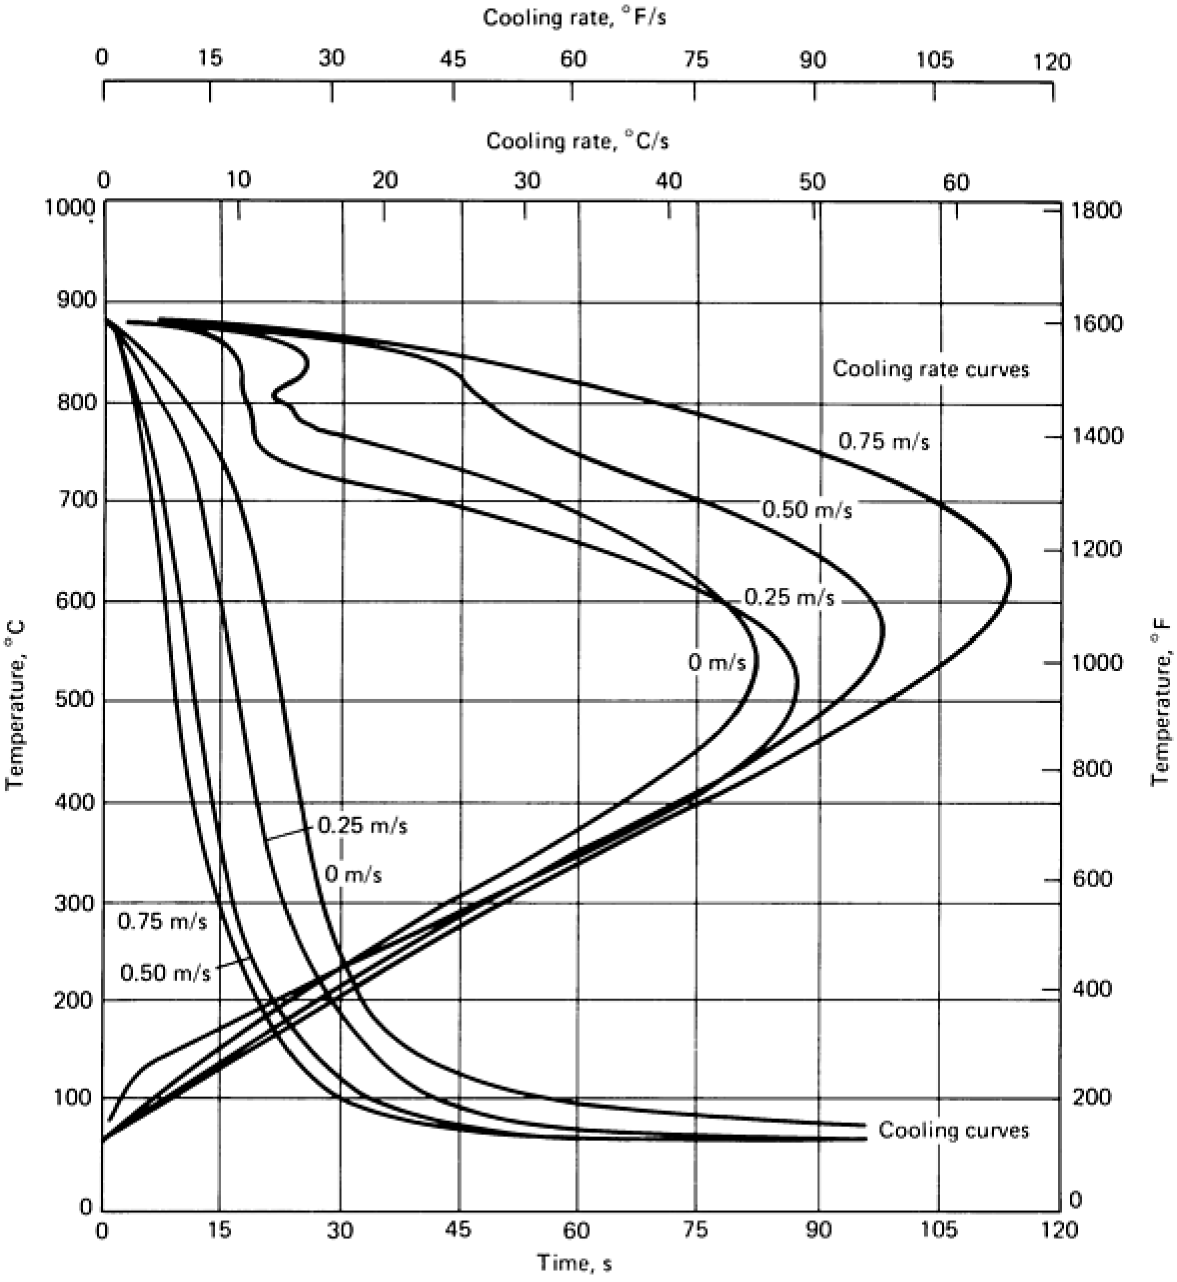

Fig. 43 Cooling curves and cooling rate curves for a 25 mm (1 in.) diameter stainless steel probe quenched in 55 °C (130 °F) water that is flowing at selected velocities from 0 to 0.75 m/s (0 to 150 ft/min)

The time-temperature and rate curves shown in Fig. 42 also illustrate that quenching into water of increasing temperature increases the duration of A-stage cooling and decreases the A- and B-stage cooling rates. Both of these effects will increase the difficulty of achieving desirable as-quenched hardness values.

There is relatively little impact of increasing water temperature on C-stage cooling rates. Since the objective of raising the water temperature is to decrease cracking and distortion and since the tendency for cracking to occur is often proportional to C-stage cooling rates, these figures show that raising the water temperature is a relatively ineffective procedure. This data explains why alternative quenchants such as oils and aqueous polymers are used. Another reason for the use of these quenchants as alternatives to hot water is that these media produce much more uniform wetting of the metal surface during the quenching. This is critically important if localized surface cracking and distortion are to be avoided.

In some applications, it is desirable to increase the quench severity of water and avoid the use of caustic and brine quenchants. This may be done by increasing the agitation rate. The cooling rate data shown in Table 3 and Fig. 43 show

that substantial increases in cooling rates are attainable by increasing the agitation rate. At least some agitation is recommended in order to improve the uniformity of the quenching process. The cooling power of water decreases rapidly as water temperature increases, as indicated in Fig. 44. Agitation is especially important during water quenching because it disperses vapor bubbles and directs cooler water against the workpiece.

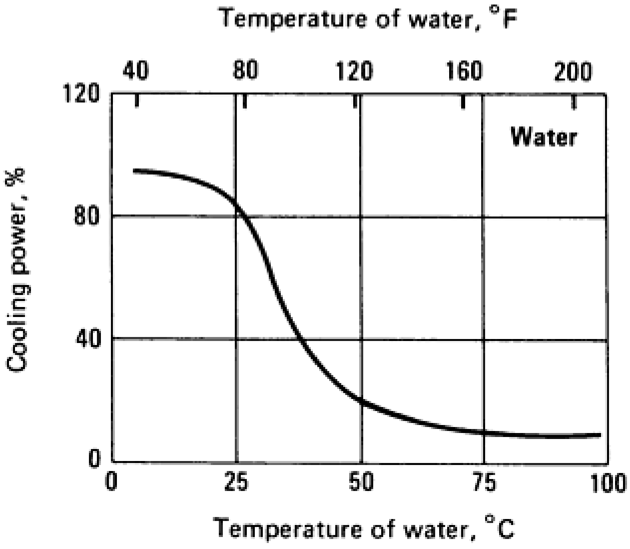

Fig. 44 Relation of the surface cooling power of moderately agitated water to water temperature

Contamination Effects. Contamination of quench baths with heat-treating salts is likely to further increase the cooling rate because salts reduce the duration of the vapor blanket stage. Insoluble salts carried into the quench tank from activated salt baths may interfere with the operation of the pumping system and reduce the volume of water in the quench tank. Periodic desludging or replacement of the quench water is therefore recommended. Contaminants such as soaps, algae, slimes, or emulsion-formers reduce the cooling rate by creating films that retard heat transfer from the surface and prevent cooler water from contacting the part.

Brine Solutions

The term brine, as applied to quenching, refers to aqueous solutions containing various percentages of salts such as sodium or calcium chloride. The cooling rates produced by brine are higher than provided by water for the same degree of agitation, or alternatively, less agitation is required to achieve a given cooling rate. The higher cooling rates reduce the possibility of soft spots from steam pockets. However, the higher cooling rates generally increase the likelihood of distortion or cracking. Complex baffling patterns in the quench tank and propeller agitation, both of which are often necessary with oil and water quenchants, are not always required with a brine quench, but may be required for steels with very low hardenability.

Brine quenching is used only where oil or water quenchants do not provide desired hardness due to insufficient quench severity. Some of the disadvantages of brine are that it is corrosive, and for reasonable service life, the quench tank, pumps, conveyors, and other equipment in contact with the brine must be either protected by a coating, or made of corrosion-resistant metals such as copper-base alloys or stainless steels. In addition, a hood may be needed to carry off the corrosive fumes to protect nearby equipment from attack. The cost of brine quenching is higher than water because of the required use of special pumps, quenching facilities, and corrosion inhibitors.

Concentration Effects. The concentration of the brine can be expressed in several ways (see Table 13). Although brine solutions containing up to 24% NaCl progressively reduce the vapor stage, such high concentrations are generally impractical.

Table 13 Relation of brine density to brine concentration

Salt, %	Specific gravity		Salt concentration

(a) °Bé, Baumé; specific gravity for liquids heavier than water is 145/(145 - *n*), where *n* is reading on Bé scale in °Bé

In conventional quenching, it has been found that a 10% NaCl solution is quite effective from the viewpoint of hardening. The value of the 10% NaCl solution in developing maximum surface hardness in conventional quenching is illustrated in Fig. 45. It should be noted that although end-quench values are used in Fig. 45, the specimen was not quenched as in the standard end-quench test but was quenched in still water with only the end face contacting the water to simulate surface quenching.

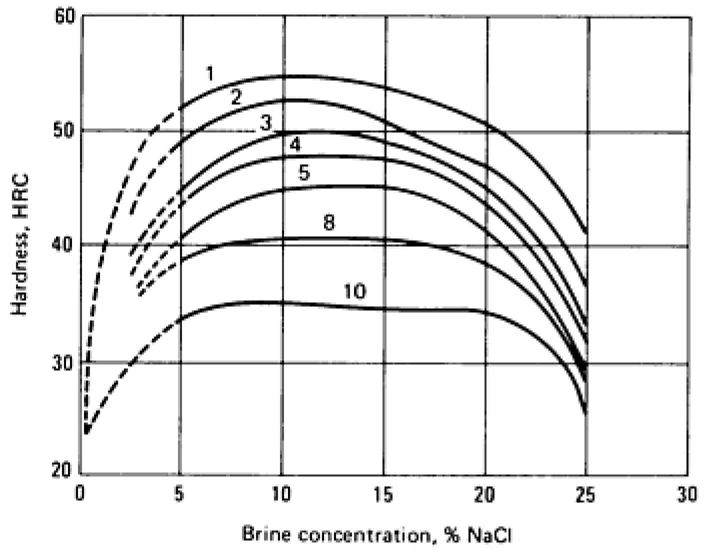

Fig. 45 Relation of hardness to brine concentration when still-quenching end-quench specimens in a 99 °C (210 °F) brine solution. Numbers above curves indicate distance from quenched end in units of $\frac{1}{16}$ in.

Kobasco characterized the quenching performance of aqueous brines by determining the heat transfer coefficients from cooling curve analysis. The results of this study, illustrated in Fig. 46, also showed that the optimal level of both aqueous NaCl and caustic (sodium hydroxide) solutions was approximately 10% (Ref 51). These results emphasize the point that it is important to monitor the concentration of the brine if reproducible results are to be obtained.

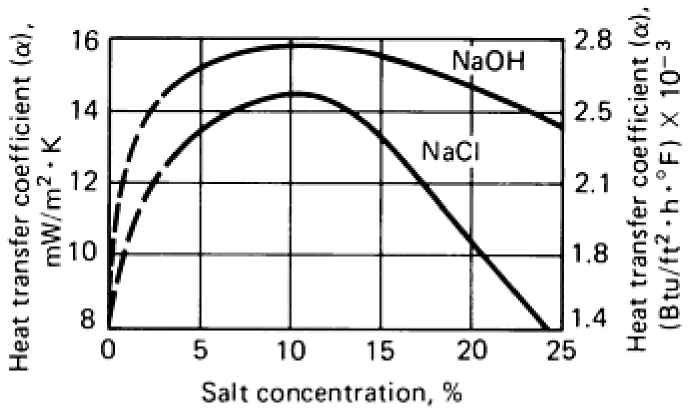

Fig. 46 Effect of salt concentration on the heat transfer coefficient of sodium hydroxide and sodium chloride brine solutions

Temperature Effects. The cooling power of brine solutions is not critically affected by small variations in operating temperature. Although such solutions can be used at or near the temperature of boiling water, they provide maximum cooling power at about 20 °C (70 °F). The relatively small effect of temperature on cooling power of brine compared with water is illustrated in Fig. 47.

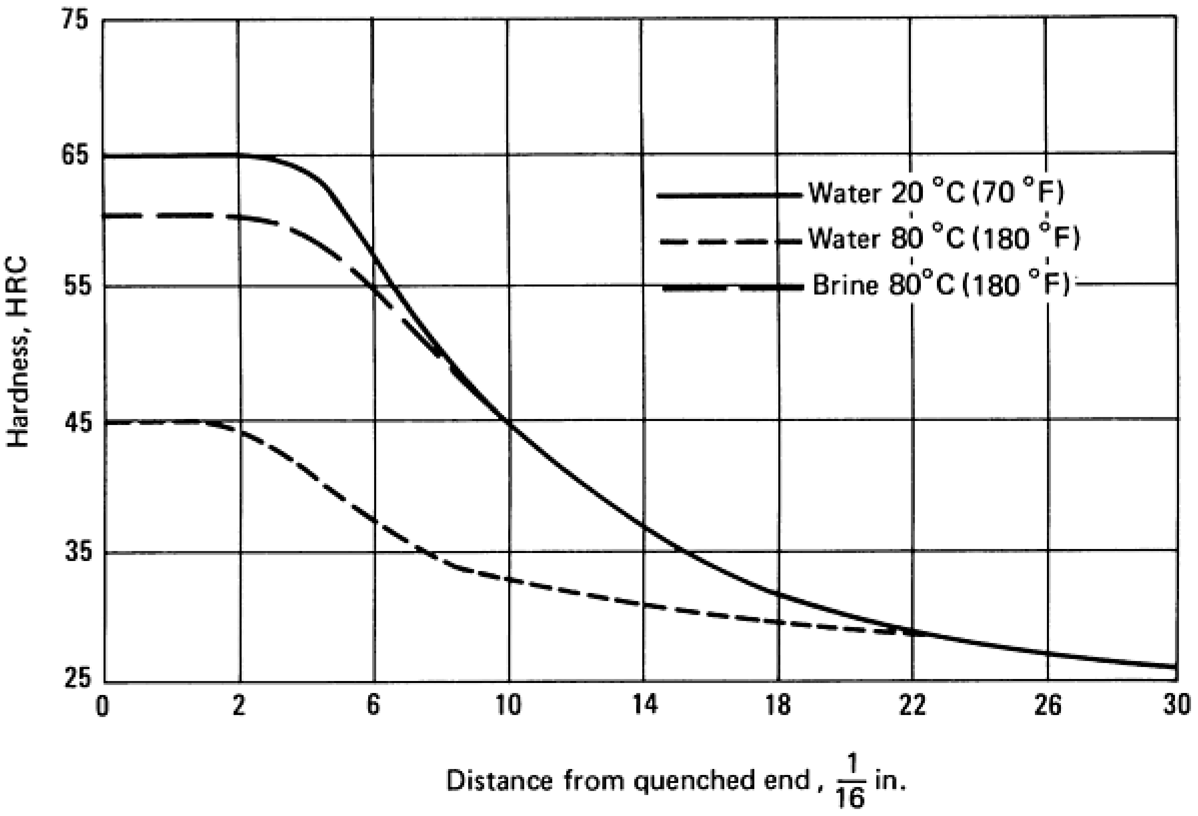

Fig. 47 Relation of hardness to the distance from quenched end of specimens quenched in water and brine. Cooling power of brine is greater than water at 80 °C (180 °F).

Contamination Effects. Sludge and scale should be removed periodically, because both act to clog pumps and recirculating systems as well as reduce the volume and cooling rate of the brine quench bath. Excess water reduces the solution strength and quenching power of the brine.

Caustic Solutions

Aqueous solutions of 5 to 10 wt% sodium hydroxide (NaOH) are also sometimes used for quenching. The performance of such solutions is similar to brine solutions sharing about the same advantages as a quenchant (Ref 51). The main shortcoming of caustic solutions is its high alkalinity which is harmful to human skin.

Cooling curves indicate that at 20 °C (70 °F) and moving at 0.9 m/s (3 ft/s), a solution containing 5 wt% NaOH can cool the surface of a cylinder 12.5 mm ($\frac{1}{2}$ in.) in diameter and 50 mm (2 in.) long from 870 to 200 °C (1600 to 390 °F) in 0.31 s. Under the same conditions, a 5% NaCl solution required 0.48 s, while plain water requires 1.2 s. However, a sodium chloride solution is safer, less costly, and easier to handle than a sodium hydroxide solution, and may be preferred even though the latter provides faster cooling rates.

Oils

Quenching oils can be divided into several distinctive groups based on composition, the presence of additives, and application temperature.

Classification. Quenching oils are usually categorized as slow, conventional, fast, and martempering or hot quenching oils. An additional group of oil-base quenchants are oil-in-water emulsions. These find only limited use because of their unpredictable quenching characteristics.

Mineral-oil-base quenchants are often classified by their quench severity according to the GM Quenchometer (nickel ball) test (ASTM A 235). In this test, a standard nickel ball is quenched into an oil at 25 °C (80 °F) and the time for the nickel

ball to cool to its Curie point is recorded. Shorter times for cooling to the Curie temperature imply an increase in the quench severity. The oils are classified in Table 14.

Table 14 Oil classification by the magnetic quenchometer test per ASTM D 3520

Oil classification	Cooling time, s
Fast	8-10
Medium	11-14
Slow	15-20

All modern quenching oils are based on mineral oils, usually paraffin-base, and do not contain fatty oils formerly used. The mineral oils have better aging stability and some of the historically used fatty oils are now unavailable. Sperm oil, which has been used successfully as quenchant for bright quenching of small workpieces, is banned from importation and use in the United States.

Slow and conventional quenching oils sometimes contain antioxidants but are free of additives that might accelerate their quenching effects. The typical viscosity lies in the range of 100 to 110 Saybolt universal second (SUS) at 40 °C (100 °F) but can reach about 200 SUS at 40 °C (100 °F).

Fast quenching oils are mineral oil blends with a viscosity between 50 and 110 SUS at 40 °C (100 °F) but more typically with a viscosity between 85 and 105 SUS. They contain proprietary additives to enhance quenching and often contain antioxidants and wetting agents.

Martempering or hot quenching oils are solvent-refined paraffin-base mineral oils with good thermal stability and oxidation resistance. They are used at temperatures between about 95 °C (200 °F) and 230 °C (450 °F) for modified and actual martempering of ferrous metals. Martempering oils may also contain antioxidants to improve their aging stability. They are available with comparatively high quenching effects, even at high use temperatures, because of the addition of effective speed improvers. Also, the increased viscosity has a tendency to eliminate vapor phase cooling.

Emulsions of soluble oils, usually employed as coolants in metal-working processes such as grinding, cutting, and sometimes forming, are used for quenching with concentrations of 3 to about 15%. Oil emulsions, when used as quenchants, provide a quench similar to water. However, it is difficult to maintain a constant severity over time since the emulsion is usually unstable under quenching conditions.

Typical physical and chemical properties of several commercially available quenching oils are listed in Table 15. This table shows the appropriate ASTM test methods for the determination of the properties listed. These tests are commonly used by vendors for quality control of new and used quenching oils. Oils from different producers may differ in general properties and quenching effects as a result of variations in composition and additives present.

Table 15 Typical properties of commercially available quenching and martempering oils

Type of quenching oil	No.	API gravity[(a)]	Flash point[(b)]		Pour point[(c)]		Viscosity at 40 °C (100 °F), SUS[(d)]	Saponification[(e)]	Ash[(f)], %	Water[(g)], %

Cooling Characteristics. The ideal quenchant would produce low cooling rates from the solution treating temperature to the A_3 temperature, fast cooling rates from the A_3 to near the M_s, and low rates from the M_s temperature to room temperature. Cold water, and especially aqueous solutions containing inorganic salts, show the highest quenching speeds in the A_3 to A_1 range, but they also quench very fast toward the end of the quenching process. Thus, they are restricted to quenching simple shapes and steels of comparatively low hardenability. For complex workpieces, water and brine solutions usually cause intolerable distortion, warpage, and quench cracks.

Almost all quench oils produce lower quench rates than water or aqueous inorganic salt solutions. However, heat removal is more uniform than typically achievable with water. As a result, the dangers of distortion or cracking are considerably diminished.

Slow and conventional quenching oils exhibit comparatively long A-stage cooling times, during which period the quenching speed is relatively low. The rate of cooling increases during B-stage cooling, followed again by slow cooling in the C-stage or convective cooling stage. The quench severity of conventional oils is substantially less than that of water and, therefore, may be inadequate for steels of lower hardenability.

The effect of bath temperature, agitation rate, and cross-section size on the maximum cooling rates and the cooling rate at 345 °C (650 °F) for a slow oil quenchant are illustrated by contour plots in Fig. 48. The data show that the maximum cooling rate and the cooling rate at 345 °C (650 °F) increase with increasing circulation rate and decreasing cross-section size. As expected, both parameters are essentially independent of bath temperature.

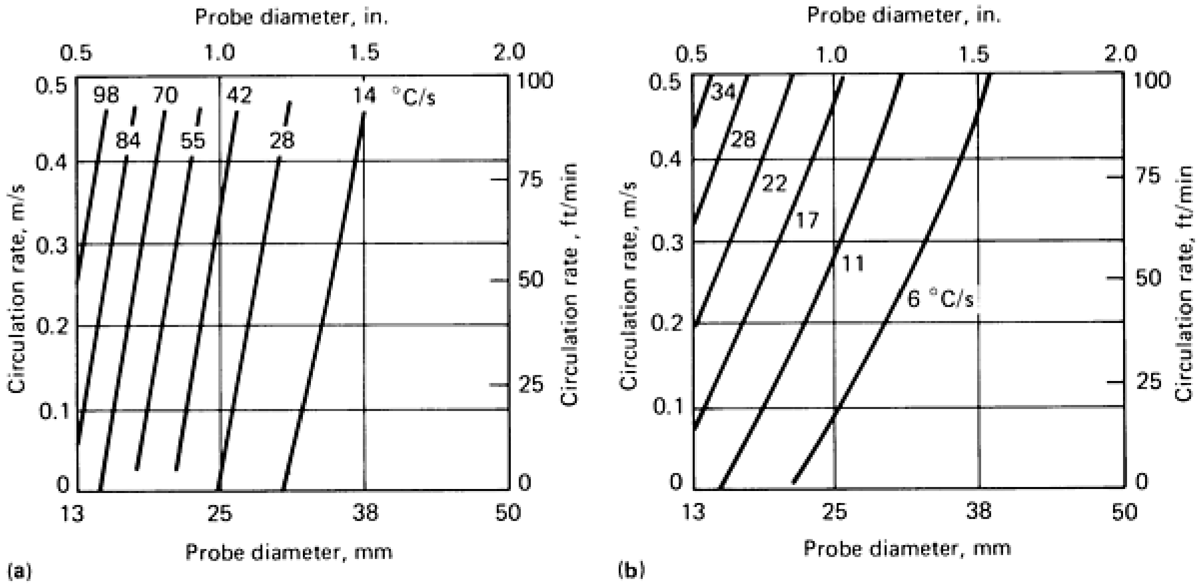

Fig. 48 Contour plots that show quenching properties of a typical slow quench oil. (a) Maximum cooling rate. (b) Cooling rate at 345 °C (650 °F), Data are independent of bath temperature.

Contour plots illustrating the effect of probe diameter and circulation rate on maximum cooling rate, cooling rate at 345 °C (650 °F), predicted hardness in AISI 1045 and 4140 steels, and Grossmann *H* values as produced by a conventional oil are illustrated in Fig. 49. Again, modest changes in oil temperature had no effect on quenchant performance.

Fast quenching oils exhibit higher quenching speeds, especially during A-stage cooling and, in some situations, approach the rates exhibited by water. Fast oils exhibit a moderately fast cooling rate in the nucleate boiling range. C-stage cooling rates are usually about the same as provided by conventional quenching oils but substantially slower than those provided by water (see Fig. 50). However, some fast quenching oils contain special additives that provide faster C-stage cooling rates that result in slightly better through-hardening effects, as illustrated by the curves in Fig. 50(c). The cooling characteristics of quenching oils, particularly fast quenching oils, are critically dependent on the concentration of some of the additives. Therefore, it is essential that the quality of quench oil be monitored over time if consistent quench severity is to be maintained.

Fig. 50 Effect of oil type and oil temperature on center cooling curves for type 304 stainless steel specimens still quenched in a conventional oil and in two fast oils. Thermocouples were placed at geometric centers of specimens, which were 13 mm (0.5 in.) in diameter and 100 mm (4 in.) long. See text for discussion of significance of these data.

The data summarized in Fig. 51 show that the quench rates of a fast oil may decrease over time. This is due to selective drag-out of the quench accelerating additives. Thus, the residual oil becomes more like an unaccelerated conventional or slow oil.

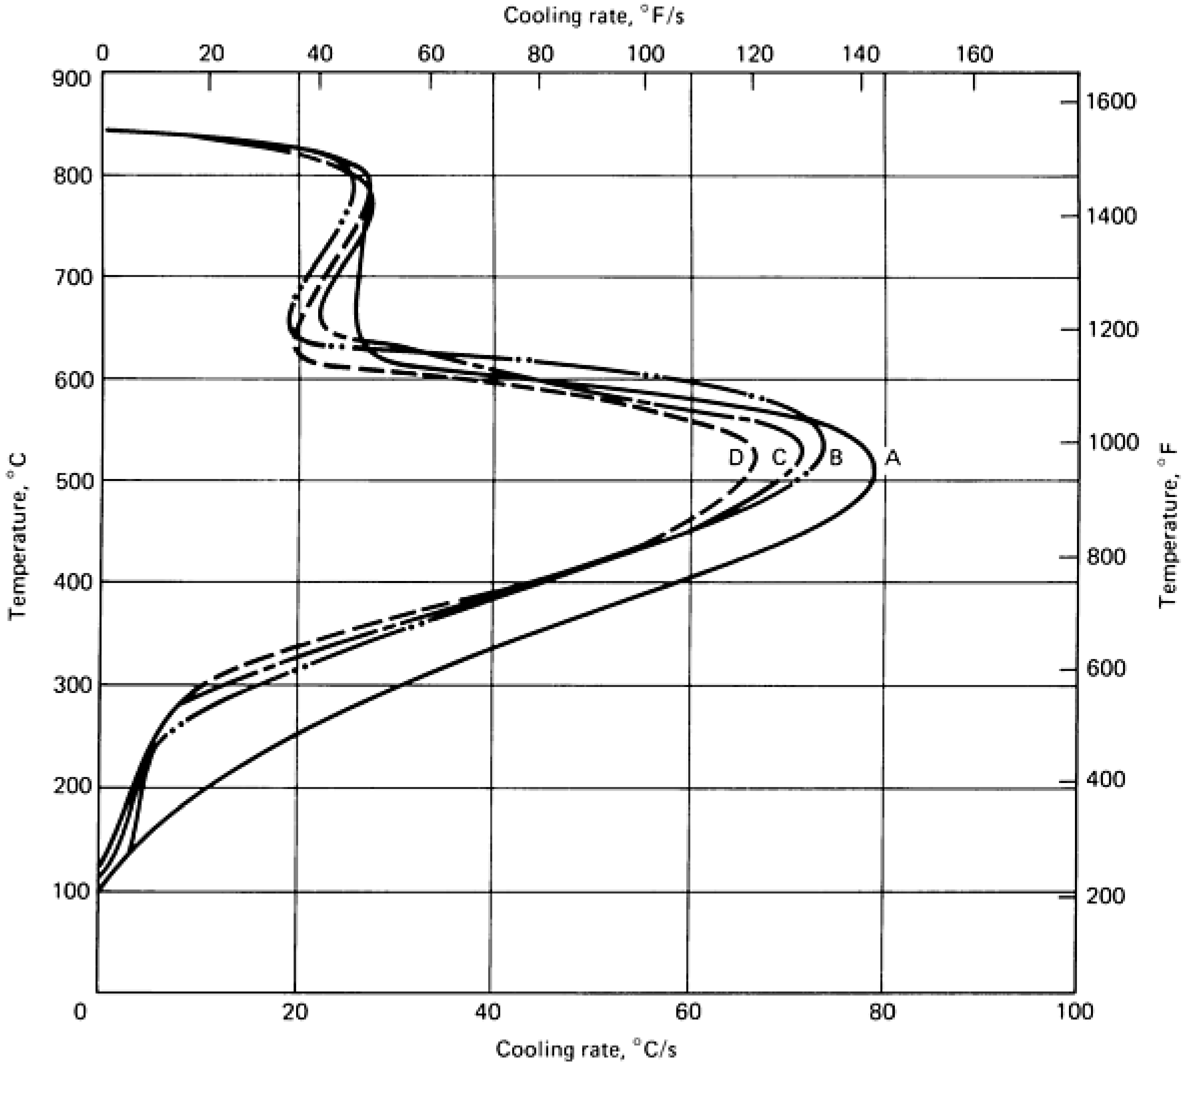

Fig. 51 Variation in cooling rate of a fast quench oil as a function of time used. A, new oil; B, 3-month old oil; C, 6-month old oil; D, 9-month old oil. Data are for oil having a bath temperature of 40 °C (105 °F).

However, oils do not always react in this manner. In some systems, the conditions cause the quench oil to shear, thus causing the oil to increase its quenching severity. In almost all systems, the oil initially speeds up due to the initial contamination with solids which, in suspension, act as a speed-improving additive. As contamination increases and the oil begins to degrade, the quenching severity begins to decrease. The makeup oil added to replace the dragout and evaporated oil usually stabilizes the quenching severity.

If quenching oils are reclaimed from wash systems and returned to the quench system, care must be taken that other fluids and solids are not carried back into the tank.

The variation in quench severity of eight compounded (speed-improving additive-containing) fast quenching oils is shown in Fig. 52 as a shaded band with a reference curve for a conventional additive-free 100 SUS at 40 °C (100 °F) mineral quenching oil. These cooling curves show the difference in quench severity that may be exhibited by conventional and fast quenching oils. These curves were obtained without agitation using a cylindrical austenitic stainless steel test probe with a diameter of 13 mm (0.5 in.) and a length of 64 mm (2.5 in.) containing a thermocouple in its geometric center. The oil temperature was 50 °C (125 °F)

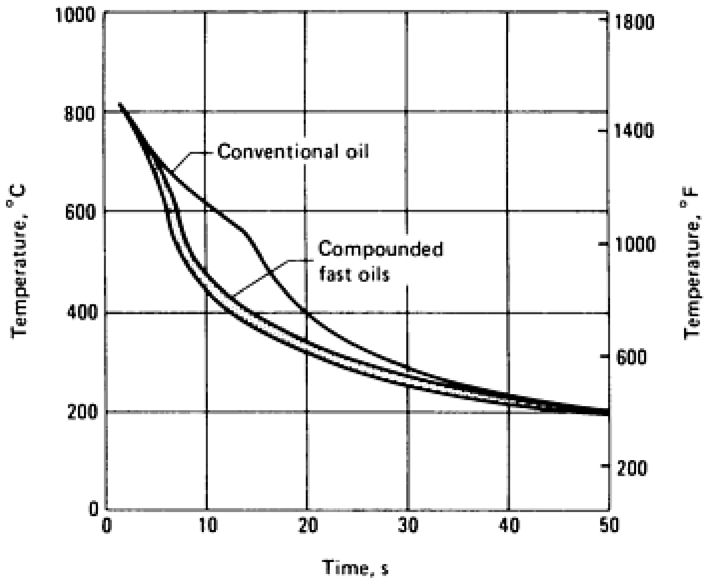

Fig. 52 Center cooling curves for austenitic stainless steel quenched in conventional oil and compounded oils with fast quenching capacities. All oils at 52 °C (125 °F). Specimens were 13 mm (0.5 in.) in diam by 64 mm (2.5 in.) long.

Test results from magnetic quenchometer test methods were presented in Table 5 and show the difference in quenching effect between conventional and fast quenching oils at Various temperatures. Table 5 also shows that martempering oils with speed improvers have, at 120 °C (250 °F), quenching effects close to the upper range of fast oils. The martempering oils quench as fast as conventional 100 SUS quenching oils when used at about 175 °C (350 °F). Thus, the martempering oils permit modified or actual martempering of steel parts that are either thicker or lower in hardenability than previously permissible when using martempering oils without speed-improving additives.

Temperature Effects. The typical ranges for the magnetic quenchometer speeds of the different quenching oil groups are listed in Table 6 as a function of their actual use temperature. Table 6 clearly illustrates that the quenching effect of quenching oils does not change with moderate changes in oil temperature. Significant decreases in quench severity only occur for temperatures over about 150 °C (300 °F) where martempering oils are preferred.

The cooling curves in Fig. 50 also show that the cooling characteristics of quenching oils are not substantially changed over a modest range of operating temperatures. The only differences are found in the last stage of cooling when the temperature of the quenched part approaches the oil temperature. During this stage, the cooling rate decreases with higher quenching oil temperatures. Slower cooling rates reduce temperature gradients between surface and core and result in lower internal stresses. This is especially beneficial while the steel part is passing through the temperature range of martensite formation, below about 260 °C (500 °F).

The cooling curves presented in Fig. 53 show that emulsions of water and soluble oil combine the poorest features of water and oil quenchants. The center-cooling curves of an oil-water emulsion, consisting of 10% soluble oil and 90% water at 25 °C (75 °F) and 50 °C (125 °F), show that stable vapor envelopes are formed at the beginning of the quenching cycle. Thus, at the higher bath temperature, the initial quench severity is below that of a conventional oil. As the cooling process continues, the quench severities approach those for water.

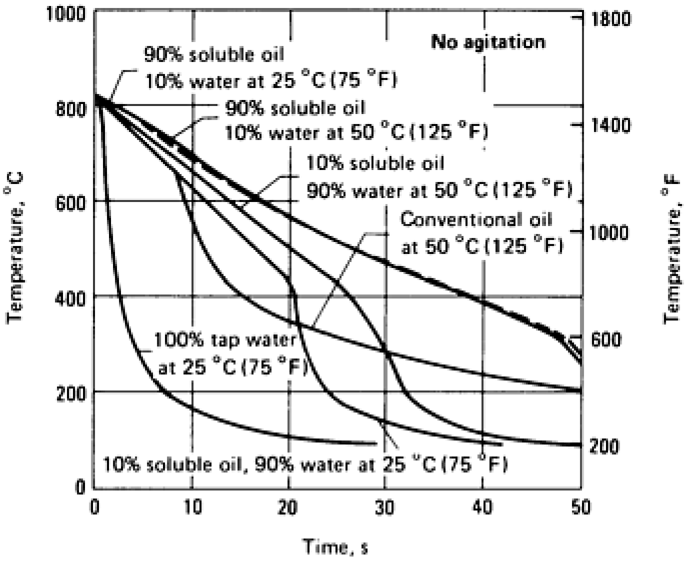

Fig. 53 Comparison of center cooling curves for still-quenched 18-8 stainless steel treated in water, oil, and emulsions of water and soluble oil at temperatures of 25 and 50 °C (75 and 125 °F). Specimen dimensions were 13 mm (0.5 in.) in diameter by 64 mm (2.5 in.) long.

Water-in-oil emulsions containing 90% soluble oil and 10% water have much lower cooling rates than conventional oil. For these reasons, oil and water emulsions are generally inferior to other quenchants, but they are sometimes used for spray quenching of induction or flame-heated parts. Even in these instances, aqueous polymer quenchants would be more desirable.

Oil-in-water emulsions are effective as a final coolant for tempered parts to provide a black surface and rust protection. Such emulsions commonly contain about 3 to 10% soluble oil and are used at temperatures between about 30 and 80 °C (85 and 175 °F) However, in the application, the primary purpose is to produce the desired black color and not to alter the metallurgical properties.

The quenching effects of conventional and fast oils are only slightly affected by their use temperatures under normal quenching conditions. For practical reasons, these oils are generally maintained at temperatures between 40 and 95 °C (100 and 200 °F), most often at 50 to 70 °C (120 to 160 °F) Higher or lower oil temperatures are possible without any substantial change in the as-quenched hardness but are rarely utilized. Higher temperatures will cause faster aging of the oil and can lead to increased fuming. For safety purposes, the maximum oil use temperature should be at least 50 °C (120 °F) below the flash point of the oil. Lower oil temperatures may increase the fire hazard because the higher viscosity of cold oil leads to localized heating above the oil flash point.

The advantage of a lower viscosity quenching oil is illustrated in Fig. 54. The viscosity of an oil will decrease with increasing temperature. However, when a hot part is immersed into a low-viscosity oil, the fire hazard may be lower even if the oil's flash point is lower. This effect occurs because heat extracted from the part is distributed rapidly by the thermosyphon effect (convective currents in the oil). Thus, oil contacting the hot metal at the air interface does not exceed its flash point. The depth of a quenched part or load must be sufficient to allow the heated oil above the hot work to distribute the heat to the bath before the oil reaches its auto ignition temperature.

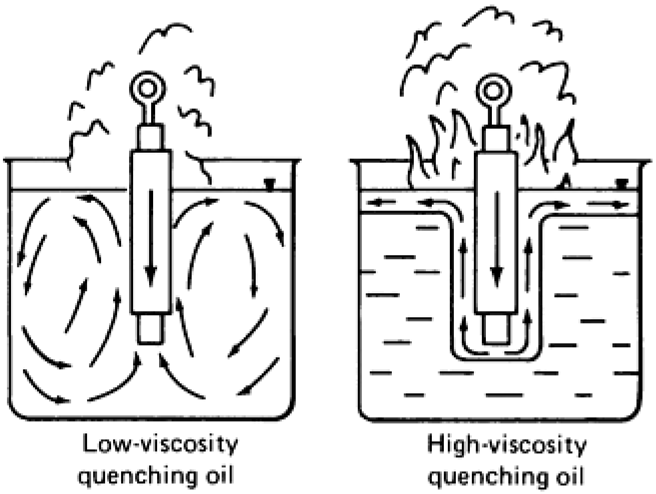

Fig. 54 Advantage of low-viscosity quenching oil over high-viscosity oil. See text for discussion.

Quenching oils with comparatively high viscosities (for example, cold oils) do not distribute heat as rapidly. Instead, a comparatively thin layer of oil is heated at the part surface, and the oil gets hotter as it rises through the load. The oil can reach the air-oil interface at a temperature in excess of its auto ignition temperature and cause an immediate fire.

In one test, two similar parts, each weighing 80 kg (175 lb) and at a temperature of about 870 °C (1600 °F), were partially immersed in separate baths containing 180 kg (395 lb) of oil at 20 °C (70 °F) with no circulation. One oil had a flash point of 205 °C (400 °F) with a viscosity of 120 SUS at 50 °C (120 °F), and the oil ignited immediately. The second tank contained oil with a lower flash point of 120 °C (250 °F), but the oil had a lower viscosity of 46 SUS at 50 °C (120 °F) and it took 20 s to ignite.

Two precepts are apparent from these test results. First, cold viscous oils should be preheated to decrease their viscosities, and second, higher-flash-point oils are preferred. Typical conventional or fast quenching oils have minimum flash points of 125 °C (260 °F) and average flash points of 175 °C (350 °F).

Martempering oils are designed for use at higher temperatures. The typical use temperature ranges for commercially available martempering oils are given in Table 16.

Table 16 Typical bath temperatures for commercially available martempering oils

Viscosity at 40 °C (100 °F), SUS[(a)]	Flash point[(b)]		Temperature range			
			In open air		Under protective atmosphere	
	°C	°F	°C	°F	°C	°F
250-550	220	430	95-150	205-300	95-175	205-345

(a) SUS. Saybolt universal seconds.

(b) Minimum

Martempering oils, when covered by an inert, neutral, or reducing atmosphere in an integral quench furnace are largely protected from oxidation by air. Thus, they may be used at higher temperatures and closer to their flash points than similar oils used in open air.

The dragout loss of a quenching oil depends mainly on its viscosity, which is dependent on its temperature. Because oils of higher viscosities are usually used at higher temperatures, the actual viscosities and dragout losses of different quenching oils do not vary significantly. Table 17 shows the viscosities of a conventional, a fast, and two martempering oils as a function of the temperature.

Table 17 Viscosity of a conventional oil, a fast oil, and two selected martempering oils as a function of temperature

Oil temperature		Oil viscosity, SUS[(a)]			
		Conventional	Fast	Martempering	
°C	°F			Oil no. 1	Oil no. 2
40	105	100	95	720	2630

95	205	40	40	85	180
120	250	35	35	55	90
150	300	30	35	45	60
175	345	. . .	. . .	40	45
205	400	. . .	. . .	35	40

(a) SUS, Saybolt universal seconds

Quench loads in relation to the oil volume determine the temperature rise in the quenching oil, but uniform hardening usually can be maintained despite moderate temperature increases. However, the danger of fire must be considered when the oil temperatures approach the flash point. Parts with high ratio of surface area to volume increase the fire hazard because they transfer heat more rapidly to the oil. As a consequence, parts with a high surface to volume ratio require

lower quenching oil temperatures, larger oil volumes, or oils of higher flash point. A commonly used rule is that the capacity of an oil quench tank (in gallons) should equal the weight of the quench load in pounds. This rule includes the weight of fixtures, trays, and so on, that are at the temperature of the parts and enter the quenchant.

For more massive parts, the oil volume can be lower since large parts transfer the heat comparatively slowly to the oil. However, it is still necessary to install coolers and provide circulation from tank to cooler in order to maintain the oil temperature at a safe value.

All quenching oils should have as little contact with air as possible to minimize oxidation. For this reason, it is recommended that the surface of open-air quench baths be kept as small as possible. Exposure to the air should be as short as possible for oil baths under controlled atmospheres.

Oil Flow. Quenching oils should be agitated to distribute heat quickly and uniformly and to maintain a uniform bath temperature, which maintains a uniform quenching effect throughout the quench cycle. Only mechanical agitation should be used (pumps or impellers). Compressed air should *never* be bubbled through oil for agitation! Heating elements used for pre-heating quenching oils should have less than 1.5×10^4 W/m^2 (10.0 W/in.^{2}) to prevent local overheating, unnecessary aging, and the formation of an insulating carbonaceous layer on the heater elements with the possible result of heating element burn-outs.

Measurements of the rate of flow from pipes into tanks or from mechanical stirrers usually have too much variation to provide quantitative information on the effects of oil flow rate. However, flow rate data such as those plotted in Fig. 55, 56, and 57 obtained in specially designed equipment, are of more general applicability. The data in Fig. 55 were obtained on scale-free bars of 9445 alloy steel (0.46C-1.05Mn-0.040P-0.040S-0.27Si-0.40Cr-0.45Ni-0.12Mo) heated in an exothermic atmosphere and quenched in a mineral oil at 50 °C (120 °F), viscosity at 40 °C (100 °F), 79 SUS. Figure 56 shows the relationship between bar diameter and equivalent locations on the end-quench hardenability specimen, both for scale-free bars and for those scaled by heating in air. The criteria listed in Table 18 were used to develop the data in Fig. 55, 56, and 57.

Table 18 Quenching temperature data used to compile plots shown in Figs. 55, 56, 57 for 9445 alloy steel

Position in quenched bar	Temperature range	
	°C	°F
Surface	730-315	1350-600
$\frac{3}{4}$-radius	730-370	1350-700
$\frac{1}{2}$-radius	730-425	1350-800

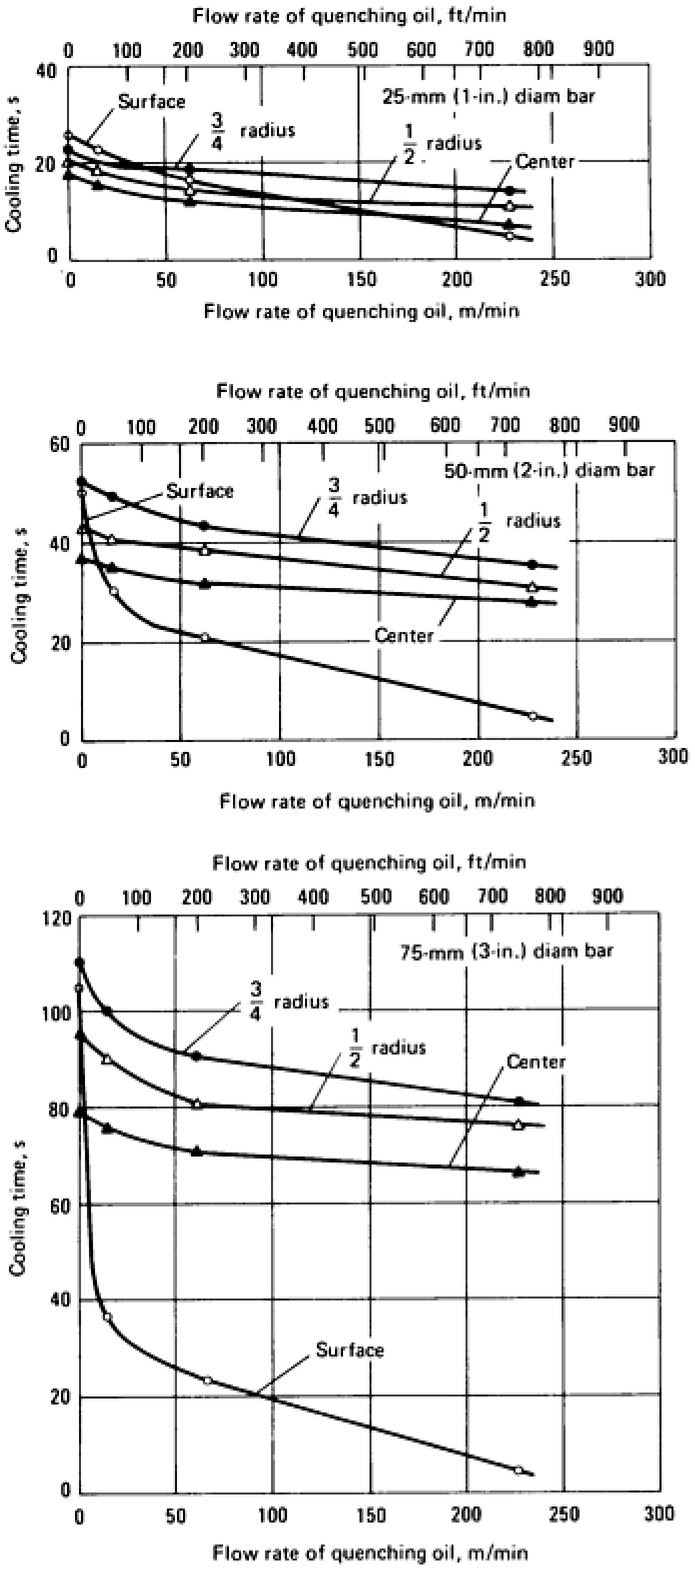

Fig. 55 Fffect of flow rate of quenching oil on cooling time of scale-free bars of 9445 alloy steel. Bars were heated in an exothermic atmosphere, and were quenched in a mineral oil at 50 °C (120 °F). Saybolt universal viscosity of the oil at 40 °C (100 °F) was 79 SUS.

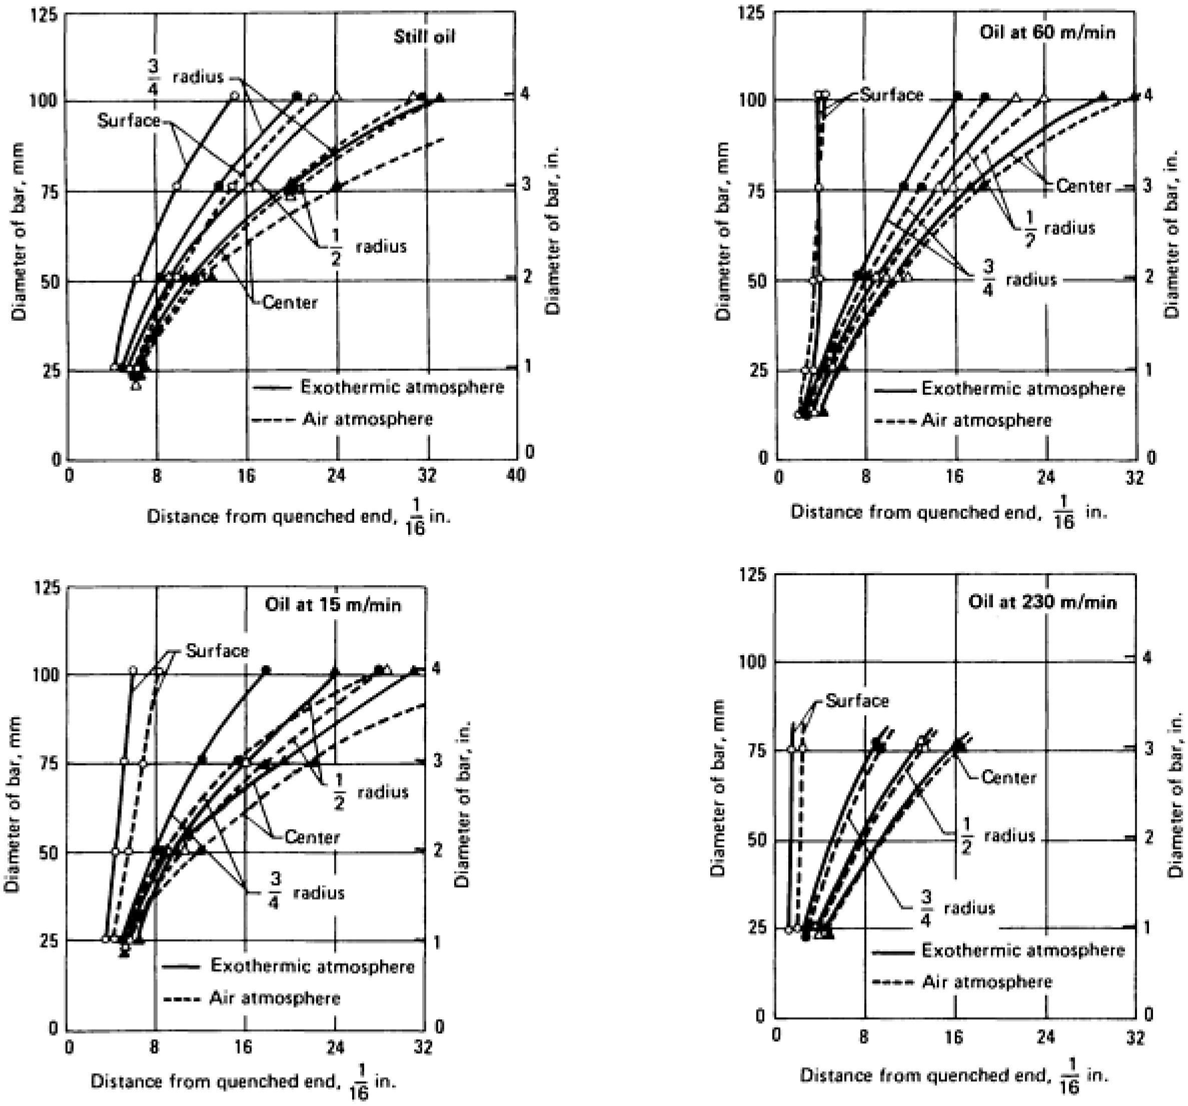

Fig. 56 Curves for identical cooling times in 9445 alloy steel end-quench hardenability specimens and round bars quenched in oil. Mineral oil used for quenching had a Saybolt universal viscosity at 40 °C (100 °F) of 79 SUS.

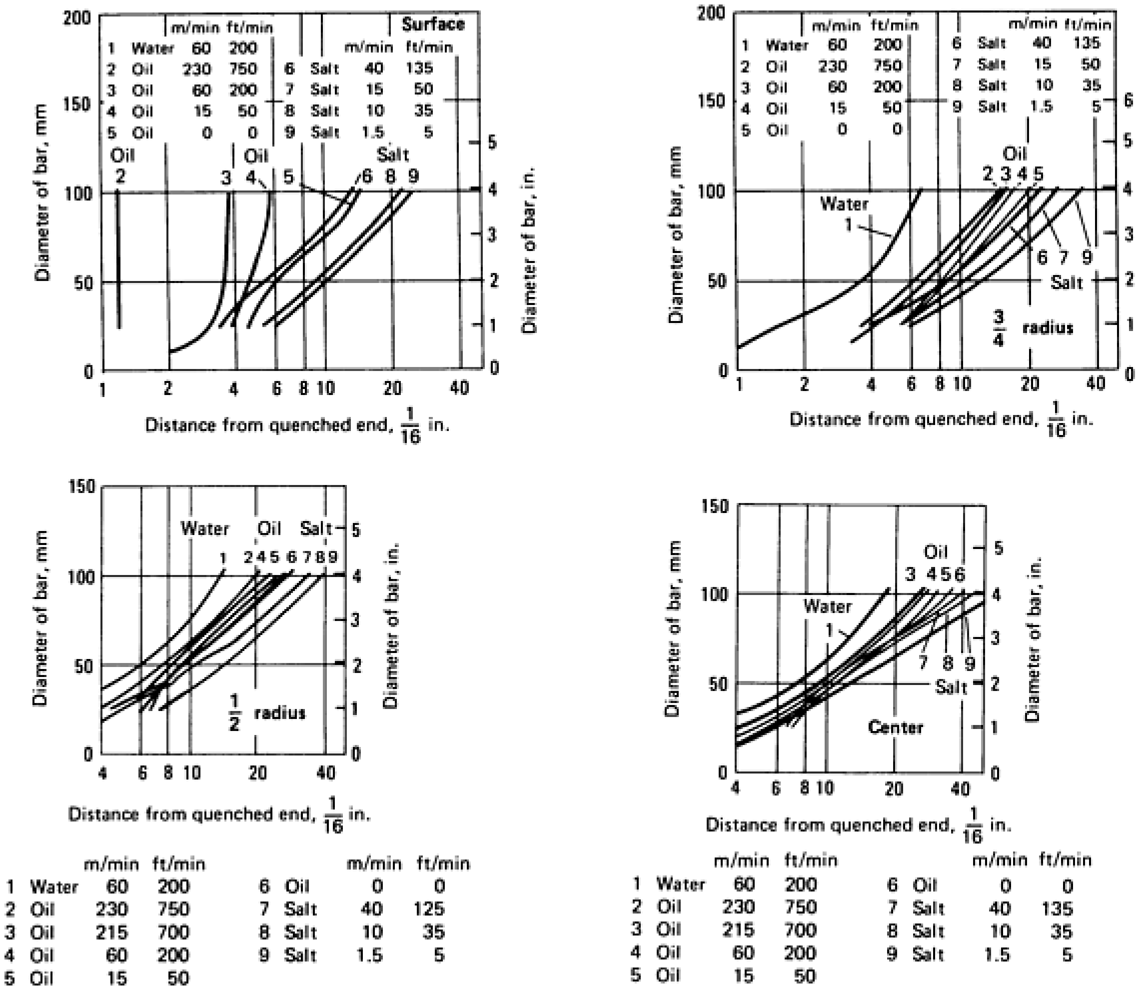

Fig. 57 Correlation curves for identical cooling times in 9445 alloy steel end-quench hardenability specimens and round bars quenched in hot salt, oil, and water. Water was at 25 °C (75 °F); mineral oil at 50 °C (120 °F), Saybolt universal viscosity at 40 °C (100 °F) was 79 SUS; molten salt, at 205 °C (400 °F)

The smaller temperature ranges used for $\frac{3}{4}$-radius, $\frac{1}{2}$-radius, and the center of the bar distort the relationships somewhat, but it is evident that increasing the rate of flow has the greatest influence on the cooling rate at the surface and that the surface of a 75 mm (3 in.) bar can be cooled almost as fast as the surface of a 25 mm (1 in.) bar when the velocity of the oil is above about 150 m/min (500 ft/min). It is evident also that the major advantage from agitation lies in the range between still oil and a velocity of 60 m/min (200 ft/min).

The oil quenching system, particularly heating elements and coolers, should not be composed of copper or copper alloys. These metals act as catalysts to accelerate the oxidation and polymerization of mineral oils. Steel, stainless steel, nickel-plated, and tin-plated materials are recommended instead. Existing copper or brass equipment should be tin plated.

Water Contamination. Contamination and oxidation may also produce critically important effects on quenchant performance. For example, the effect of increasing oil oxidation on a conventional oil may result in substantial quench rate variation (see Fig. 58).

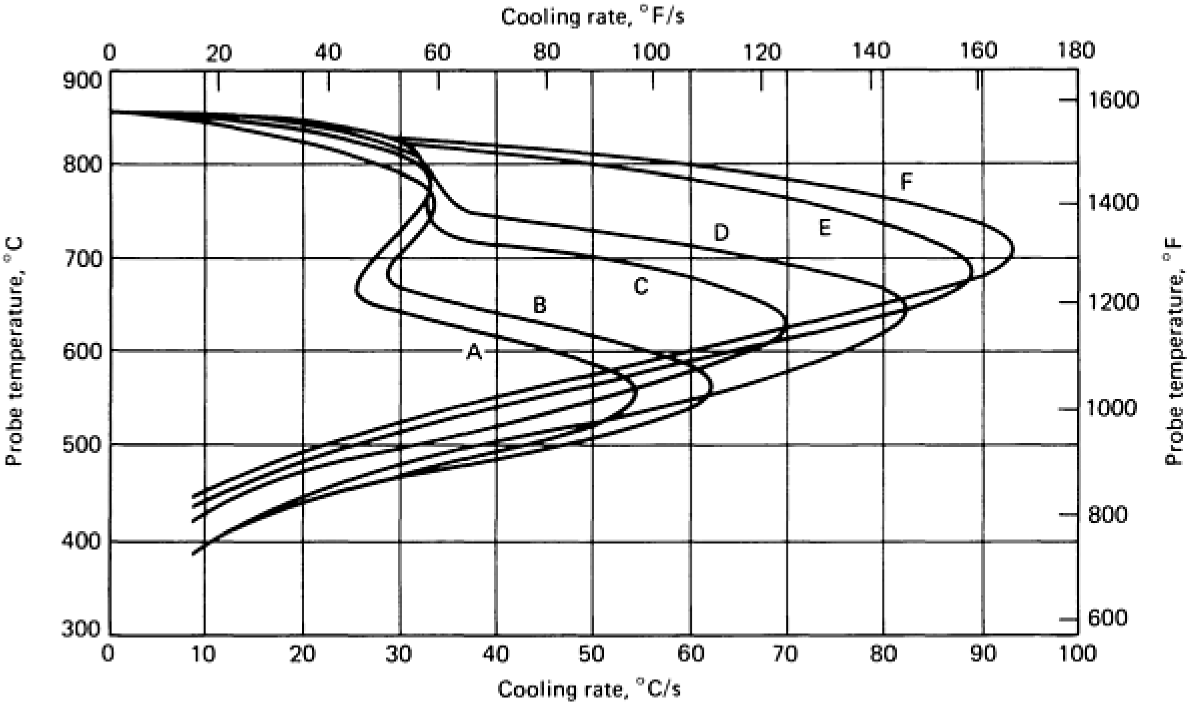

Fig. 58 Variation in cooling rate of a martempering oil as a function of time in use: A, new oil; B, 3-month old oil; C, 7-month old oil; D, 25-month old oil. Source: Ref 52

Water in quenching oils is dangerous, particularly in martempering oils used at temperatures above 100 °C (212 °F). Not only does water cause nonuniform as-quenched hardnesses, but it also causes foaming that increases the fire hazard. Oil foam that develops in an integral-quenching chamber can cause an explosion if the foam level reaches the hot furnace chamber.

The effect of water in quenching oils on cooling curves is shown in Fig. 59. These results were recorded by quenching a cylindrical stainless steel probe in a fast quenching oil free of water and after water additions of 0.06 to 2.0%. At water concentrations below 0.12%, the initial quenching speed was increased. Higher water concentrations caused a more stable vapor blanket around the probe resulting in a lower initial quenching speed.

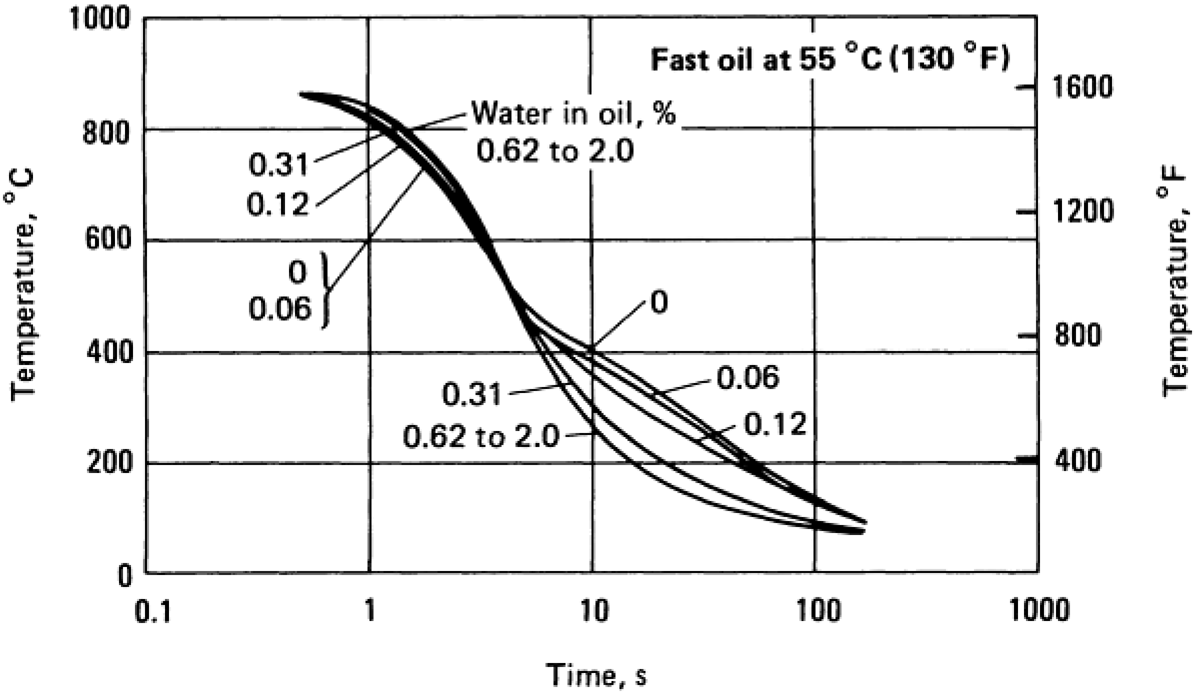

Fig. 59 Effect of water contamination on the quenching power of fast oil at 55 °C (130 °F) in quenching type 304 stainless steel. Specimens measured 13 mm (0.5 in.) in diam by 100 mm (4 in.) long. Oil was not circulated, and specimens were not agitated. Thermocouples were located at the geometric center of specimens.

All oil samples containing water quenched faster than a water-free fast oil during boiling and convection ranges. Because of the higher cooling rates in the convection range, which overlaps with the martensite formation range of most common steels, increased distortion and cracking can be expected when using water-contaminated quenching oils.

Water entrapment in an oil bath can result in an explosion from the sudden formation of large volumes of steam. Normal bath circulation dispenses the water, however, and minimizes the risk.

Water can be removed from an oil bath by several methods including: (a) raising the temperature above the water boiling point; (b) allowing the water to settle and draining it off; and (c) passing the bath through a centrifuge. However, used quenching oils may sometimes emulsify the water. Emulsions cannot be treated by using the method described in (b). The other two methods will work. The effect of boiling off the water on cooling curves is illustrated in Fig. 60.

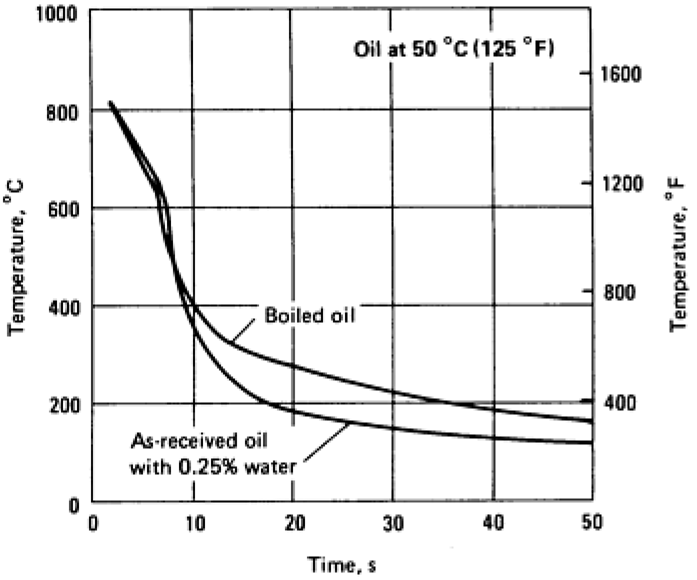

Fig. 60 Effect of boiling off water that has contaminated an oil quenchant on the center cooling curves of austenitic stainless steel. Specimens measured 13 mm (0.5 in.) in diam by 64 mm (2.5 in.) long. Plot shows the effects of quenching in as-received oil containing 0.25% water and in the same oil after it had been freed of water contamination by being boiled at 120 °C (250 °F) for 5 h. Quenching temperature of oil for both conditions was 52 °C (125 °F).

Staining. In order to attain clean quench-hardened parts, the quenching oil must retain its nonstaining features. This is best accomplished by minimizing oxidation or oil degradation.

Carbonaceous deposits (sludging) on quenched parts are symptomatic of oil breakdown. Normally, an oil does not reach this stage of degradation without detection, except in unprotected systems. Carbonaceous deposits are objectionable because they are difficult and costly to remove. However, they do not adversely affect hardening of the steel because the deposits develop at low temperatures after hardening has already occurred.

Control of Quenching Oils. Routine analyses to determine the state of a used quenching oil should be performed regularly. Used quenching oils are usually checked as follows:

- Cooling curve test
- Crackle test (water, qualitative)
- Water content (quantitative, only if above test is positive) by ASTM test method D 95
- Viscosity at 40 °C (100 °F) by ASTM test methods D 445, D 2161
- Sludge test by ASTM test method D 2273
- Magnetic quenchometer speed, using plain nickel balls, at 25 °C (80 °F) for conventional and fast quenching oils; at 120 °C (250 °F) for martempering oils
- Hot wire test

Selection of a Quenching Oil. The quenching of steel involves unsteady heat flow and solid-state transformations, both of which are difficult to handle quantitatively. As a consequence, the selection of oils for specific applications has historically been based largely on trial and error.

The most important criterion in selecting a quenching oil is that it provide a cooling rate that will harden the part without cracking it. Other considerations are degree of distortion and cost for the finished part.

If a steel has sufficient hardenability to be fully hardened by being quenched in a conventional oil, there is probably no advantage to using more costly fast oils.

For example, consider 4135 and 4140 steels that have been quenched using both conventional and fast oils. Specimens of 4140 steel having 19 mm ($\frac{3}{4}$ in.) diameter were quenched in both types of oil at 855 °C (1575 °F) and tempered at 595 °C (1100 °F). Average mechanical properties after several tests are given in Table 19. The less expensive conventional oil provided equivalent properties in this application.

Table 19 Mechanical properties of 4140 steel quenched in selected quenching oils

Property	Oil type	
	Conventional	Fast

Reduction in area, %	59.1	59.4
Charpy impact, J (ft · lb)	43 (32)	46 (34)

Tubular sections of 4135 steel, 120 mm (4.75 in.) OD, 70 mm (2.75 in.) ID, were also quenched in the conventional and fast oils. A comparison of hardness traverses through the 25 mm (1 in.) wall sections showed uniform values of 46 to 47 HRC in both cases.

In other applications, a steel may have such low hardenability that full hardening is difficult to obtain even in a water quench. Under these conditions, it is unlikely that a fast oil will provide adequate hardening. However, there are many applications where it is advantageous to make discriminating selections between competing oil types.

In many instances, oil selection is based entirely on practical results and plant experience with various quenching oils. Factors that affect oil selection are detailed in Examples 1, 2, 3.

Example 1: Elimination of Hardness Nonuniformity in 1050 Steel Transmission Shifter Shafts by Replacing Conventional Oil with Cost-Effective Fast Oil.

Transmission shifter shafts, 14.3 mm (0.562 in.) diameter by 91 mm (3.6 in.) long, made of 1050 steel were carbonitrided at 815 °C (1500 °F) and quenched in conventional oil (86 to 110 SUS) at 40 °C (100 °F), and tempered at 250 °C (480 °F) They were loaded vertically in baskets (1800 pieces per load), using a stabilizing screen. A minimum hardness of 50 HRC was required. Nonuniform hardness (within individual parts and from part to part) was encountered and caused excessive rejection.

Replacing the conventional oil with a fast oil eliminated the nonuniformity in hardness. Although the initial cost for the fast oil was higher than the conventional oil, the net cost of the heat-treated parts was lower because rejects were eliminated.

Example 2: Switching from Conventional to Fast Oil Results in Uniform Hardness of 1064 Steel Spring Clips and Fasteners.

Nonuniform hardness values ranging from 50 to 60 HRC were experienced while heat treating spring clips and fasteners made of 1064 steel having section thicknesses ranging from 0.25 to 1.55 mm (0.010 to 0.062 in.). The parts were heated in a shaker-hearth furnace at 870 °C (1600 °F) and continuously dropped at a rate of 90 kg/h (200 lb/h) into an 1890 L (500 gal) quenching tank. The temperature of the conventional quenching oil was maintained at 49 to 52 °C (120 to 125 °F) and circulation was 570 L/min (150 gal/min). Changing from the conventional oil to a fast oil resulted in consistent hardness values of 60 to 64 HRC.

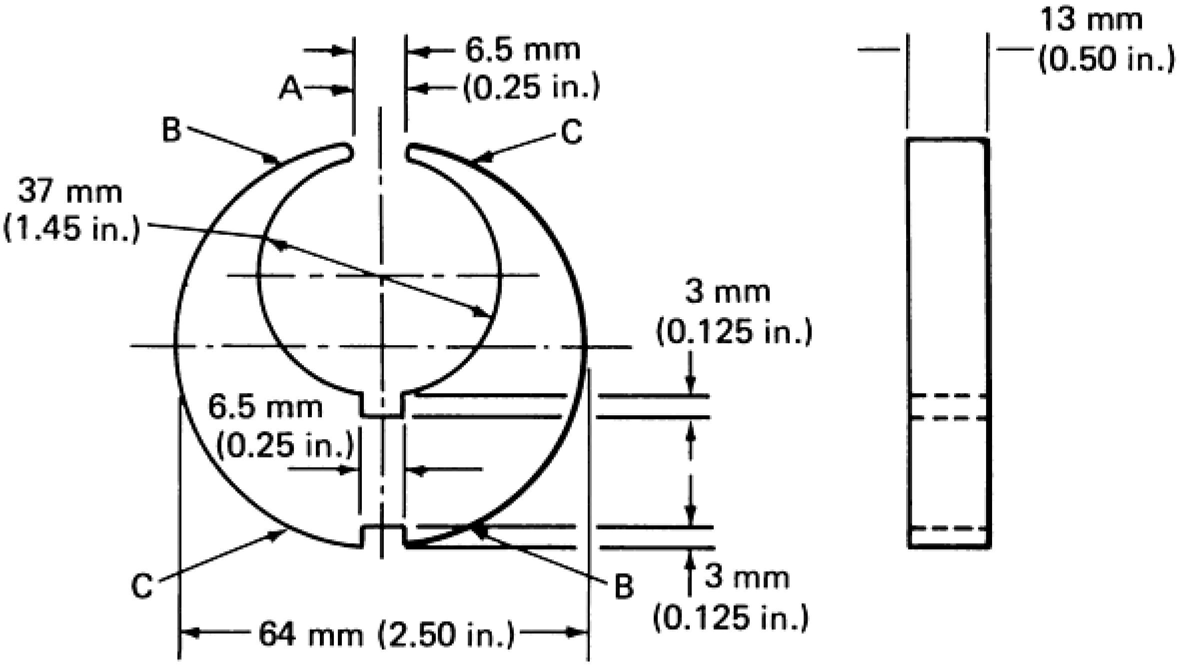
Example 3: Changing from Conventional to Fast Oil Results in 15 HRC Hardness Increase in 52100 Bearing Steel.

A minimum hardness of 62 HRC was needed on 100 mm (4 in.) diameter by 815 mm (32 in.) long steel-mill rolls, made of 52100 steel. Water quenching developed sufficient hardness, but resulted in cracking of the 50 mm (2 in.) diameter, 100 mm (4 in.) long bearing areas at the ends of the rolls. Quenching in a conventional oil resulted in hardness values of only 48 to 52 HRC. By using a fast oil, it was possible to develop hardness values of 64 to 65 HRC without cracking.

Effect of Fast Oils on Distortion. Greater distortion is sometimes associated with the use of fast oils, as indicated by these contrasting examples.

Example 4: Use of Fast Oil Minimizes Distortion in a 1085 Steel C-Section Component.

One laboratory used a modified Navy C test specimen made of 1085 steel to compare the distortion resulting from quenching it in water, conventional oil, and fast oil. The average distortion and hardness results tabulated in Fig. 61 indicate that the fast oil produced slightly less distortion than the conventional oil while providing hardness values comparable to those obtained in water quenching.



Quenching medium	Hardness, HRC		
	Maximum	Minimum	Variation
Water	67.0	63.0	4.0
Fast oil	66.0	63.0	3.0
Conventional oil	65.5	43.0	22.5

Fig. 61 Hardness values and changes in dimensions of a 1085 plain carbon steel test specimen after quenching in water, fast oil, and conventional oil

Example 5: Quenching Carburized 8620 Steel Transmission Gears in Straight Mineral Oil Yields Less Distortion than Quenching in Fast Oil.

Figure 62 shows that significantly greater distortion occurred in carburized 8620 steel transmission gears when quenched in a fast oil than when quenched in a straight mineral oil. The temperature of both oils was 65 °C (150 °F). The results represent 60 tests for each type of oil.

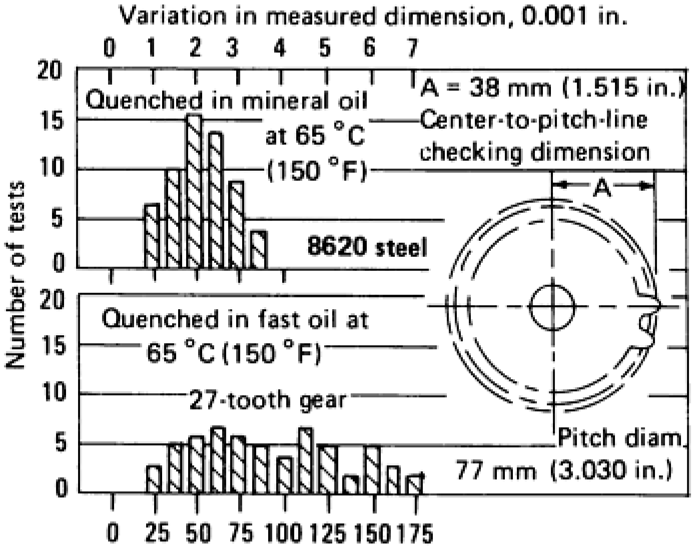

Fig. 62 Effect of type of quenching oil on variations in center-to-pitch-line dimension. For transmission counter gears of 8620 steel, paraffin-base mineral oil had viscosity at 40 °C (100 °F) of 86 to 110 SUS. Gears, carburized and direct quenched from 870 °C (1600 °F), were tempered at 155 °C 1310 °F) after quenching and had a hardness of 59 to 63 HRC.

Quenching Oil Selection Determines Steel Grade Used. In selecting a quenching oil, its contribution to the cost of the finished part must be considered. Aside from the initial cost (and the cost of replacing dragout), quenching oils can influence overall cost by:

- Limiting the type of steel from which parts can be made
- Determining the percentage of rejected parts that will require reworking
- Determining the extent of cleaning after quenching

Although it is more common to fit the oil to the steel being treated than to fit the steel to the oil, there have been instances in which fast quenching oils permitted changing to steels of lower hardenability, with accompanying reductions in cost. One such situation is described in the following example.

Example 6: Switching from Conventional Oil to Fast Oil Allows Use of Simple Steel Grade instead of Two Steels in Gear Drive Components.

Truck ring gears were being made from 3310 steel and pinion gears from 4815 steel. It was found that by using a fast quenching oil in place of conventional oil, 4718 steel could be used for both parts without sacrifice of properties. This resulted in a saving of about 15%, on a per-kilogram (per-pound) basis, in metal costs.

Fast Oil More Cost-Effective than Conventional Oil. In the following example, a fast oil proved to be cheaper, even though its initial cost was higher than a conventional oil.

Example 7: Changing from Conventional Oil to Fast Oil Reduced Long-Term Costs by 5.3%.

In a plant employing a 3000 L (800 gal) quenching tank, 1500 L (400 gal) of conventional oil was consumed in quenching 29,500 kg (65,100 lb) of steel. This amounted to 20 kg of steel per liter (163 lb of steel per gallon) of oil. For the same system and type of work, only 1135 L (300 gal) of fast oil was consumed in treating 45,600 kg (100,500 lb) of steel. Thus, despite the higher initial cost of the fast oil, the oil cost per kilogram or pound of steel treated was reduced about 5.3%.

The lower oil consumption was mainly the result of decreased dragout. In addition, the conventional oil formed more sludge which resulted in higher maintenance cost and increased the cost of cleaning the heat-treated parts.

Mechanical conditioning of quenching oils involves the removal of the following contaminants:

- Scale
- Carbonaceous materials, which may be products of oil oxidation (sludge) or carbon fallout, encountered in protective-atmosphere installations
- Other insoluble solids, such as sand
- Water
- Soluble compounds, such as carbon dioxide

These contaminants can be removed by filtering, evaporation, or draining. The solids can best be removed by appropriate bypass filters. The choice of filtering medium for removing solids is important. The most commonly used filtering media are the waste-pack, mineral-wool, and cellulose types that must be replaced after their filtering ability has been exhausted. Clay filtering media are more expensive than the above types but can be reused after exhaustion by suitable regeneration. However, the regeneration will not remove scale or sand. Clay media should be carefully selected when fast quenching oils are to be filtered, because it is possible to remove the additive along with the undesirable carbonaceous materials.

Magnetic filters, traps, and strainers are useful in removing scale and other foreign materials. These types of filters can be easily cleaned and returned to service. They are especially helpful for preventing premature filter clogging and for protecting pumps.

Water can be removed by filtering or centrifuging, but these methods are expensive and rarely used. Usually, bulk water is removed by draining, and suspended water is removed by heating. Carbon dioxide is removed by heating.

Polymer Solutions

The technology of polymer quenching has seen dramatic growth in the past 50 years. The principal quenchants were initially water, perhaps modified by additives such as inorganic salts and naturally occurring oils. With the discovery of petroleum, hydrocarbon products became a major medium for quenching. More recently, it has been established that some water-soluble organic polymers are useful in modifying the cooling characteristics of water.

The patent literature describes several polymers, however only three types are prominent commercially in the United States. These are: polyalkylene glycol (PAG), polyvinyl pyrrolidone (PVP), and polysodium acrylate. Although polyvinyl alcohol (PVA) has been used in the past, it has only limited use in the United States at the present time. However, polyvinyl alcohol is still used in some international heat-treating markets.

In general, it has been an objective of polymer quenchant suppliers to develop products that can be used to provide quench severities ranging from those equivalent to oil to those that may be greater than water.

Polyalkylene glycol, or polyalkylene glycol ethers, were first introduced as commercial products in the early 1940s. These materials are formulated by the random copolymerization of ethylene and propylene oxides although higher alkylene oxides and/or aryl oxides may also be used. The structure of PAG is schematically illustrated in Fig. 63(a).

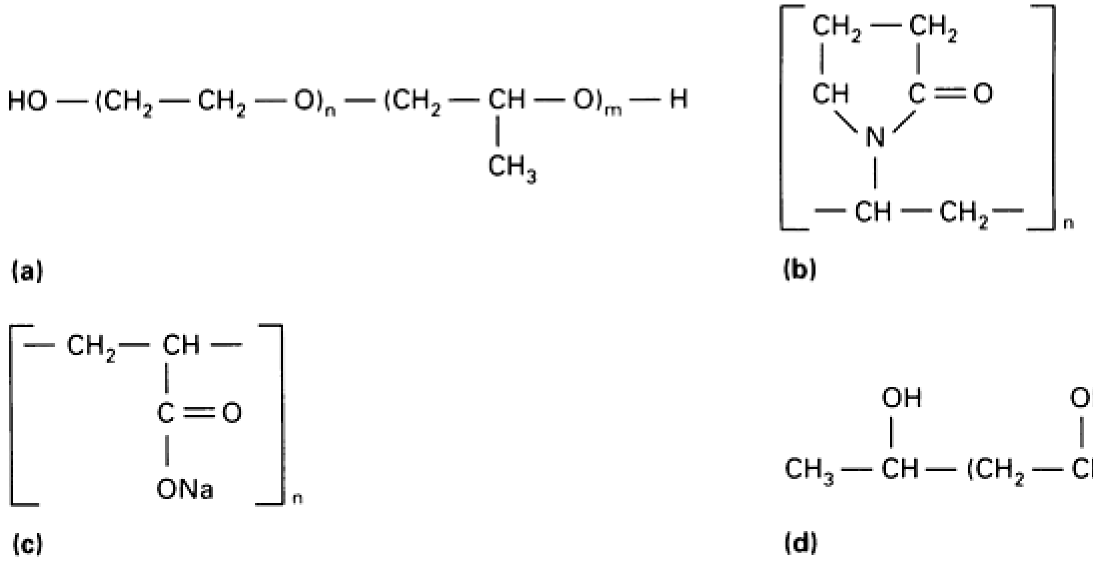

Fig. 63 Chemical structure of selected polymer quenchants. (a) Polyalkylene glycol (PAG). (b) Polyvinyl pyrrolidone (PVP). (c) Sodium polyacrylate (PA). (d) Polyvinyl alcohol (PVA)

By varying the molecular weights and the ratio of alkylene oxides used to manufacture the product, polymers having broad applicability may be produced. Some of the higher molecular weight PAG polymers have exhibited excellent metal quenchant properties when used in aqueous solutions (U.S. Patent 3,230,893).

The proper selection of the polymer and its molecular weight provides a PAG product that is soluble in water at room temperature. However, the PAG polymers typically exhibit inverse solubility--that is, they are soluble at room temperature but insoluble at elevated temperatures. This thermally reversible phenomenon provides a unique mechanism for controlling the heat transfer from hot metal by surrounding the metal piece with a polymer-rich coating.

Then, as the metal part approaches the temperature of the quenchant, the PAG polymer coating redissolves in the quenchant bath. The interfacial behavior of a representative PAG polymer at the hot metal interface at selected times during a typical quench cycle is shown in Fig. 4 (Ref 53). The application of water as a quenchant in many heat-treating processes is limited by its relatively high quench severity. The quench severity of water can be reduced by increasing the water temperature, as shown in Fig. 2, but this typically results in extended A-stage cooling times which may lead to low as-quenched hardness values.

Polyalkylene glycol quenchants have been particularly useful in view of the processing latitude they provide since quench severities from slow oil to brine may be possible by varying the bath temperature, agitation rate, and polymer concentration. Relatively dilute solutions will provide a quench severity similar to water but reduce cracking and distortion because of the slow cooling it provides at low temperatures.

The proper PAG quenchant can also provide accelerated wetting so that the cooling rates achieved are faster than water and approach those achieved by brines. Thus, brine quenching is possible without the hazards and corrosiveness attendant with the use of salts or caustic solutions.

U.S. Patent 3,475,232 teaches that the addition of water-soluble alcohols, glycols, or glycol ethers with 2 to 7 carbon atoms also can improve the wetting characteristics of PAG quenchants. However, control of a multicomponent system is considerably more complex.

Aqueous solution of PAG quenchants may be inhibited to provide corrosion protection of the quench-system components. Since corrosion inhibition of quenched parts may be of relatively short duration, specific protection should be provided following the tempering operation unless auxiliary corrosion inhibitors are used.

Cooling Characteristics. Three principal parameters are recognized as controlling the rate of cooling during polymer quenching:

- Quenchant concentration
- Quenchant temperature
- Quenchant agitation

The influence of PAG concentration on cooling rates in a 25 mm (1 in.) diameter stainless steel probe is illustrated in Fig. 64. The slower cooling rates achieved at the higher concentrations correspond to an increase in the thickness of the polymer layer that surrounds the part during quenching (see Fig. 4). PAG quenchants also are not sensitive to minor changes in polymer concentration. This problem is a recognized deficiency of polyvinyl alcohol and some other film-forming polymers used as quenchants.

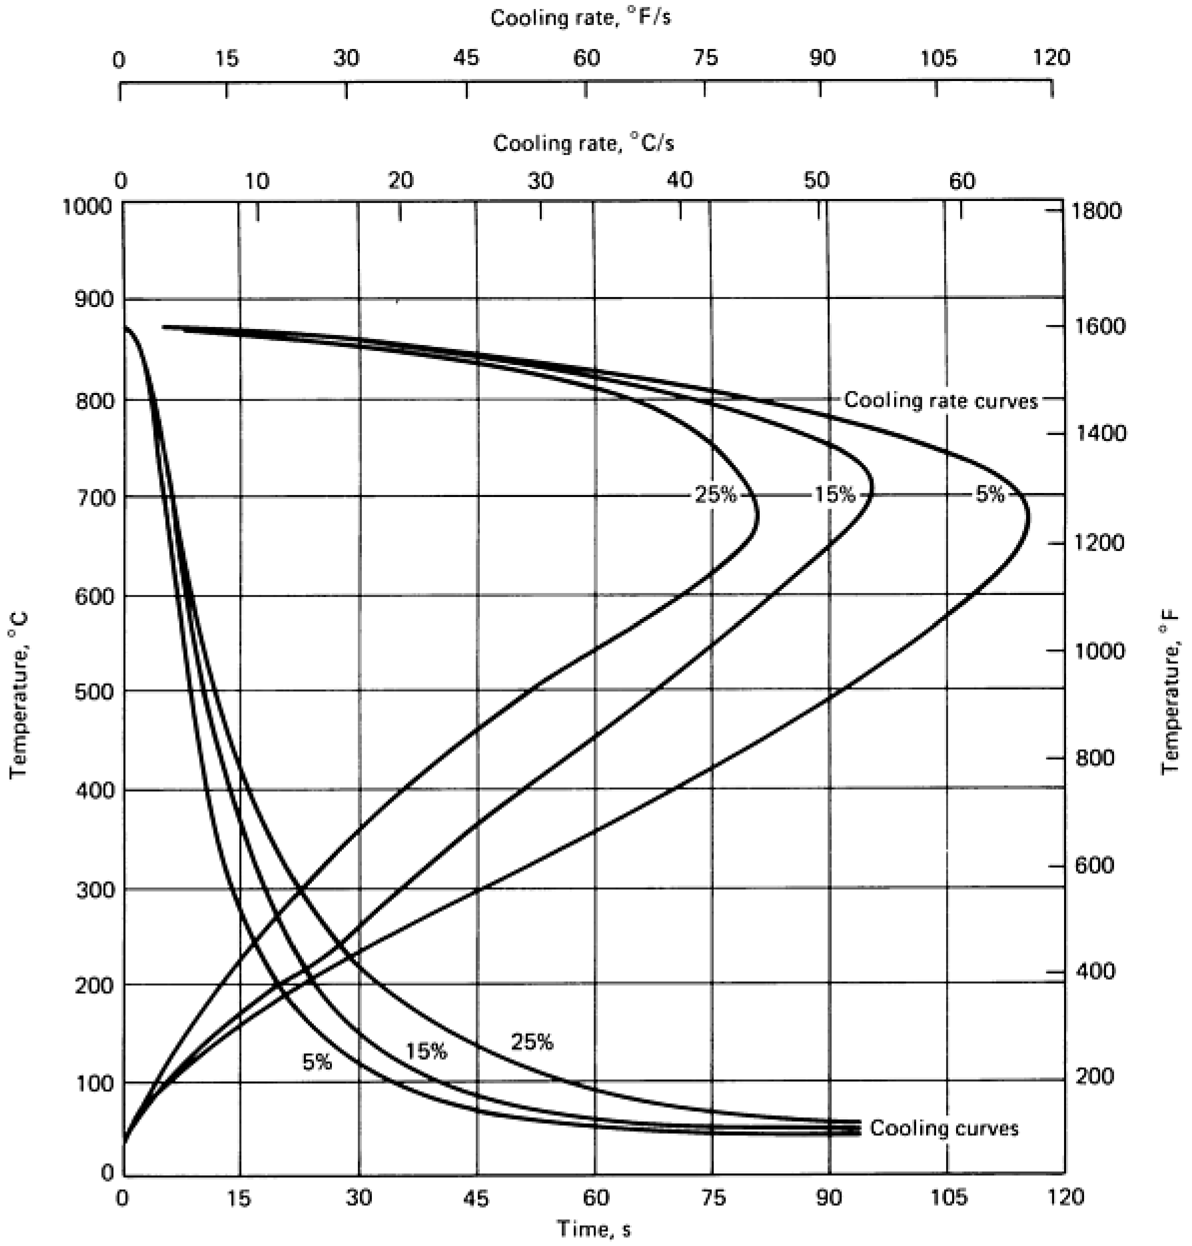

Fig. 64 Cooling curves and cooling rate curves for a 25 mm (1 in.) diameter stainless steel probe quenched in 5, 15, and 25% polyalkylene glycol at 45 °C (110 °F) that is flowing at 0.25 m/s (50 ft/min)

Additional effects of concentration on cooling rates produced by a PAG quenchant are shown in the contour plots of Fig. 65.

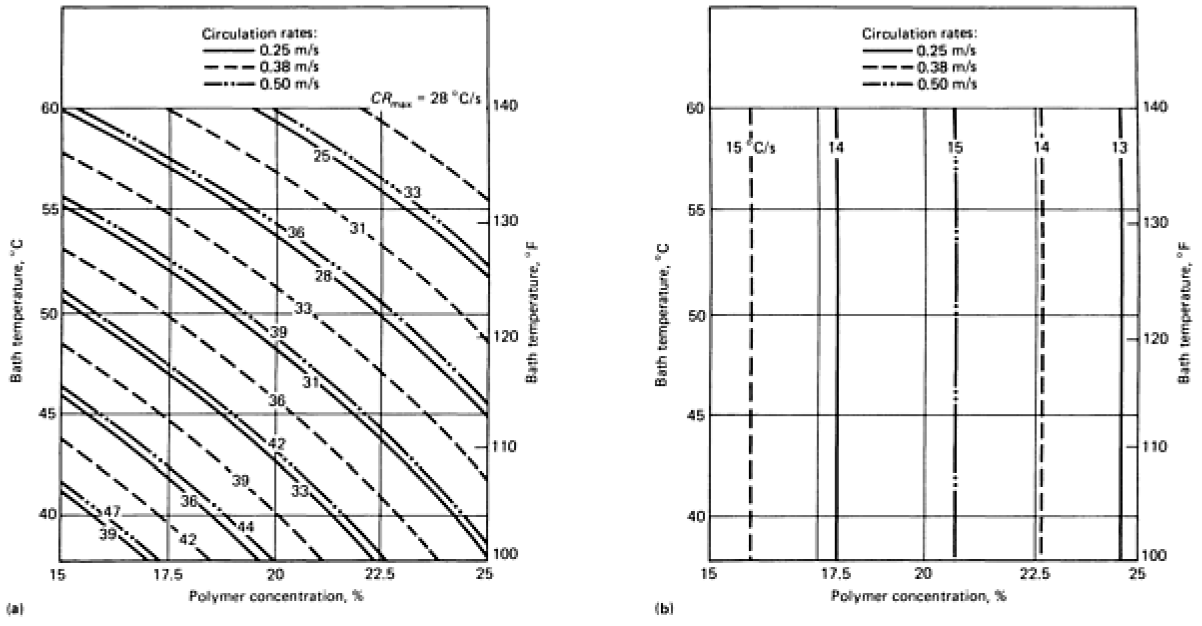

Fig. 65 Predicted properties of polyalkylene glycol quenchant at bath temperatures ranging from 38 to 60 °C (100 to 140 °F). (a) Maximum cooling rate, CR_{max}. (b) Cooling rate at 345 °C (650 °F). The plot in (b) indicates that quenching from a temperature of 345 °C (650 °F) at a predicted cooling rate of 15 °C/s (27 °F/s) will require a polymer concentration of ≈16% or ≈21%, corresponding to an agitation rate of 0.38 m/s (75 ft/min) or 0.50 m/s (100 ft/min), respectively. To determine the cooling rate at an agitation rate of 0.38 m/s (75 ft/min) between ≈16% to ≈22.5% polymer concentration, extrapolation will be required. The data show that cooling rates are independent of bath temperatures of 345 °C (650 °F) but are dependent on agitation rates.

Just as water exhibits a marked decrease in cooling capability as its temperature is elevated (see Fig. 42 and 44), this same loss is translated to the aqueous solutions of PAG quenchants. The curves shown in Fig. 66 are illustrative of the general trends that occur with changes in bath temperature. More detailed data would require specific identification of the particular PAG quenchant employed.

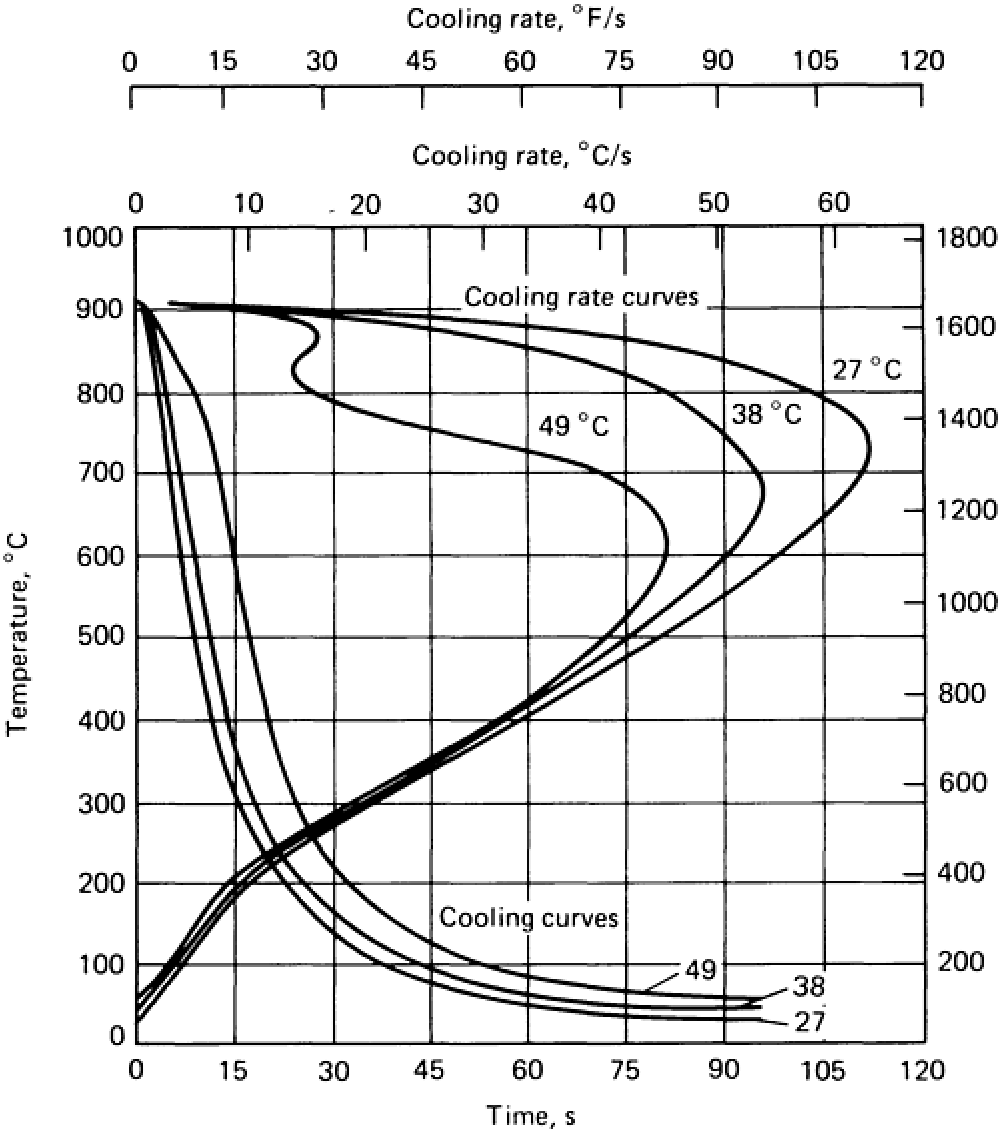

Fig. 66 Cooling curves and cooling rate curves for 25 mm (1 in.) diameter stainless steel probe quenched in 10% polyalkylene glycol at 27, 38, and 49 °C (80, 100, and 120 °F) that is flowing at 0.25 m/s (50 ft/min)

The use of polyglycol quenchants without agitation is not recommended. In general, low to moderate agitation is essential to ensure that adequate replenishment of polymer occurs at the hot metal surface and to provide uniform heat transfer from the hot part to the surrounding quenchant. Vigorous agitation may be essential to achieve a rapid rate of cooling (for example, with a low hardenability steel) to avoid undesirable transformation products. As agitation is increased, the cooling rates rapidly increase, as clearly illustrated in Fig. 67. A contour plot illustrating the variation in Grossmann *H* factor, with varying polymer concentration, bath temperature, and circulation rates of an illustrative PAG quenchant is shown in Fig. 68.

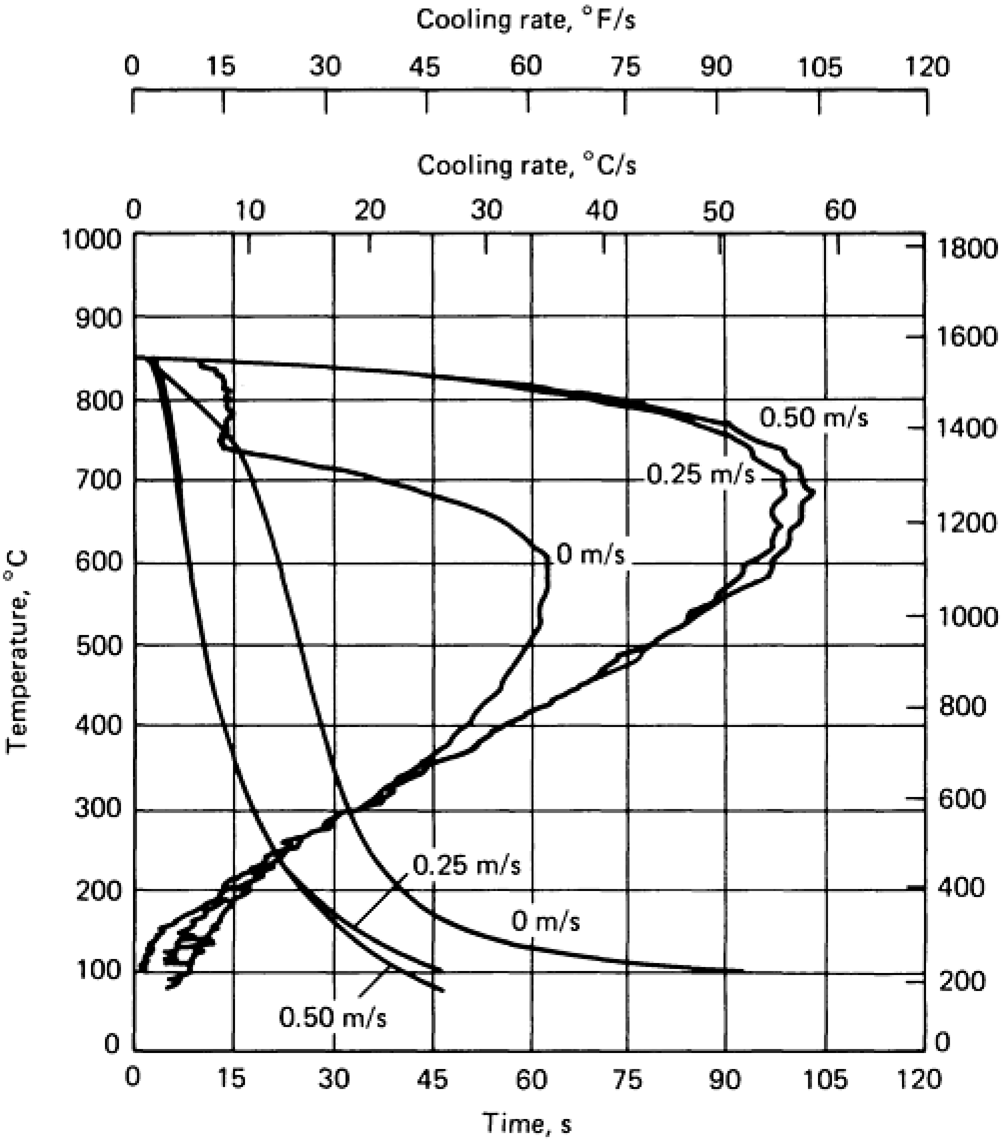

Fig. 67 Cooling curves and cooling rate curves for 25 mm (1 in.) diameter stainless steel probe quenched in 20% polyalkylene glycol at 45 °C (110 °F) that is flowing at 0, 0.25, and 0.50 m/s (0, 50, and 100 ft/min)

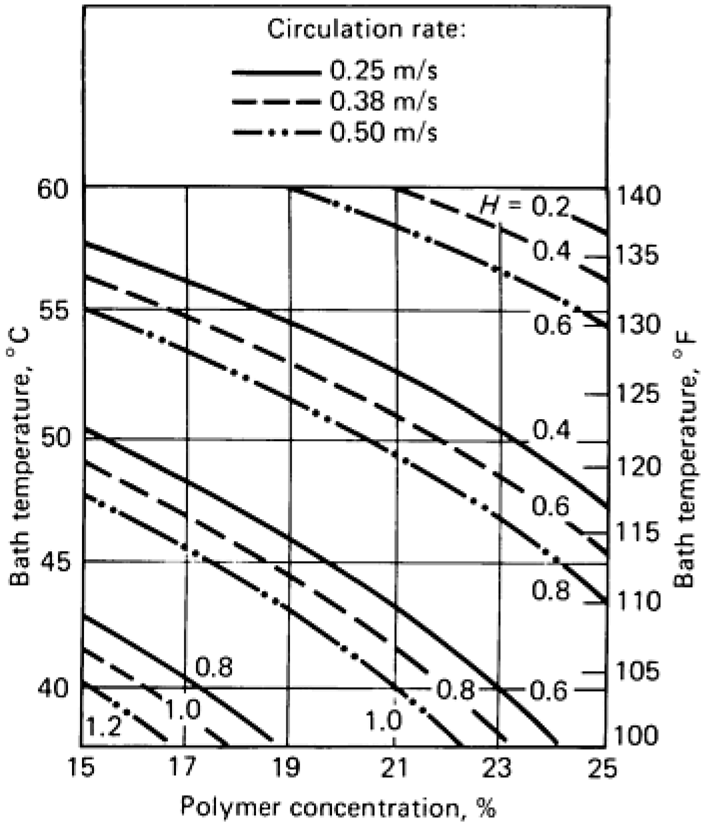

Fig. 68 Variation in the Grossmann hardenability factor, *H*, of a PAG quenchant as a function of polymer concentration, bath temperature, and circulation rate

The effect of varying polymer concentration, bath temperature, and circulation rate on a typical PAG-base polymer quenchant on the maximum cooling rate and cooling rate at 345 °C (650 °F) is illustrated by the contour plots shown in Fig. 65. The data are based on cooling curves obtained by the method described by Hines and Mueller (Ref 54).

Control Measures. The refractive index of polyalkylene glycol polymer solutions (in the range employed for quenching) is almost linear with concentration. Thus, the refractive index of a PAG quenchant solution can serve as a measure of product concentration. Refractive index versus quenchant concentration calibration plots are usually available from quenchant manufacturers. However, since this relationship is typically linear, a calibration plot can be easily constructed by the heat treater by obtaining refractive index values at 0, 10, and 20% concentrations. A best-fit line can be calculated by a linear regression analysis of the data. The resulting equation can then be used to calculate the quenchant concentration from a refractometer reading.

Industrial optical refractometers that employ an arbitrary scale may also be calibrated. Whereas such instruments prove valuable for day-to-day monitoring of the quenchant concentration, the refractometer also registers other water-soluble components such as salts in the quenchant. When the refractometer reading begins to provide erroneous numbers, another analytical test is required to define the effective quenchant concentration.

With PAG quenchants, kinematic viscosity measurements, which also correlate with concentration, have proved to be most useful as a cross-checking procedure. These plots also are available from quenchant manufacturers, and are similar to those for refractive index with one exception. The exception is that viscosity usually has a nonlinear relationship to polymer concentration. Therefore, first-order linear regression analysis should not be used as a line fitting procedure.

Additional tests for pH, inhibitor level, and conductance also are useful adjuncts to a monitoring program.

If the level of contaminants in the PAG quenchant becomes excessive, quenchant recovery can be effected thermally. The contaminants may be the same materials detrimental to water or oil quenchants. By heating the quenchant solution above the separation temperature, a more-dense polymer-rich layer is obtained (see Fig. 69). Generally, the polymer layer is the

lower layer. However, in cases where high salt contamination has been encountered, there may be a layer reversal. Where this condition is thought to exist, the quenchant manufacturer should be consulted. Much of the water-soluble contamination can be withdrawn with the supernatant water layer. Thermal separation is useful for water-soluble contaminants. The removal of solid contaminants, such as scale or carbon, requires separation by settling, filtration, or centrifugation. Membrane separators that allow water and soluble salts to escape from the PAG solution are also used to remove contaminants.

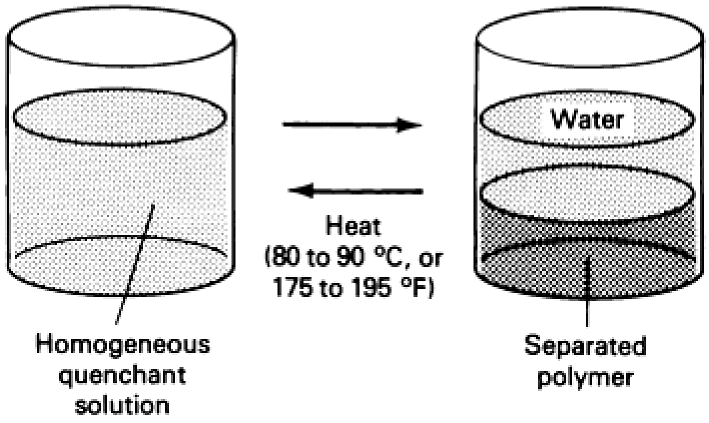

Fig. 69 Typical thermal separation procedure that utilizes inverse solubility. The water concentration in the bottom polymer layer at a separation temperature of 80 °C (175 °F) is 70%, while at 90 °C (195 °F) it is 46%. Source: Ref 55

Because PAG quenchants are bioresistant, the addition of a bactericide to the as-supplied quenchant is not generally required. Biochemical activity in use is traceable not to the PAG polymer itself, but to the introduction of nutrient contaminants. Microbiological treatment, such as is employed with other aqueous metal-working fluids, generally will keep this foreign biological activity under control.

Polyvinyl pyrrolidone is derived from the polymerization of N-vinyl-2-pyrrolidone. Polyvinyl pyrrolidone is a water-soluble polymer characterized by its complexing and colloidal properties and by its physiological inertness. Polyvinyl pyrrolidone is available in the United States as a white, free-flowing powder, manufactured in four molecular-weight grades. Its structure is shown in Fig. 63(b).

Solutions of polyvinyl pyrrolidone in water were first introduced as quenchants in 1975, coinciding with the issuance of U.S. Patent 3,902,929. The patent defines the molecular weight range for the pyrrolidone polymer, the quantity of polymer recommended for a solution concentrate (generally about 10% polymer solids) and the preferred use of a rust inhibitor and a bactericidal preservative.

Quenchant Variables. As with other polymer-type quenchants, concentration, bath temperature, and agitation play a role in establishing the cooling characteristics. The quenching rates tend to be faster with polyvinyl pyrrolidone quenchants during the stable film and nucleate and boiling stages, but slower during the convection stage. Contour plot relationships illustrating the effect of quenchant concentration, agitation, and bath temperature on Grossmann H factor, the maximum cooling rate (CR_{max}), and cooling rate at 365 °C (650 °F), under laboratory quenching conditions is shown in Fig. 70. Since polyvinyl pyrrolidone is soluble up to the boiling point of water, a broader working range of temperatures for quenching can be employed.

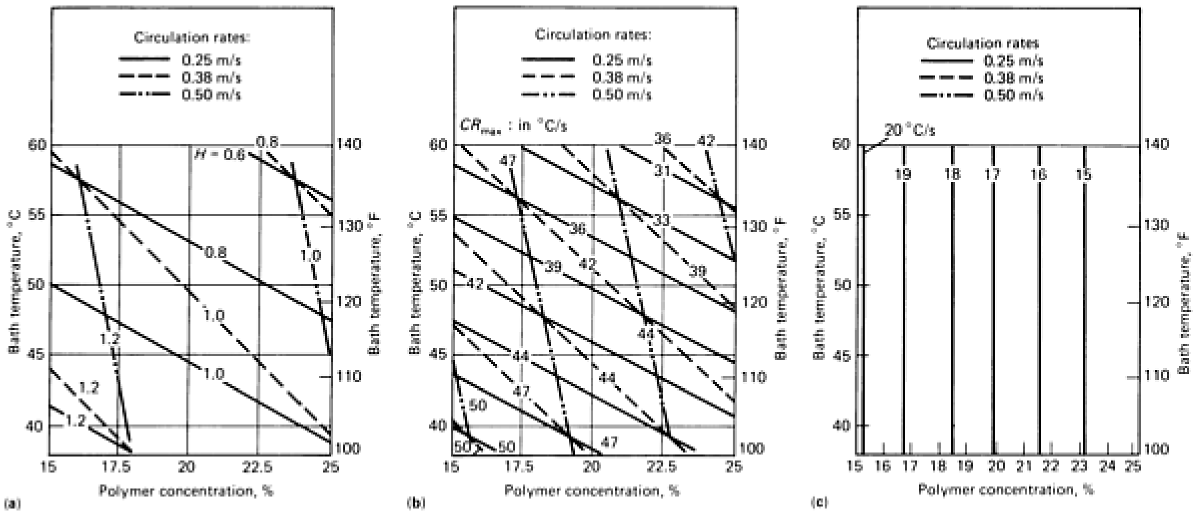

Fig. 70 Predicted quenching characteristics of polyvinyl pyrrolidone quenchant at bath temperatures ranging from 38 to 60 °C (100 to 140 °F) (a) *H* factor. (b) Maximum cooling rate (CR_{max}). (c) Cooling rates at 345 °C (650 °F) The data in (C) apply to all circulation rates.

Optical refractometer readings will provide initial control of concentration, but backup with viscosity measurements is strongly recommended. A means for removal of impurities by ultrafiltration was recently patented (U.S. Patent 4,251,292). This can be done without interrupting the quenching process.

Polyacrylates. Another class of polymers that is used to formulate aqueous polymer quenchants is the sodium polyacrylates (PA) class. The PA polymer can be produced by the homopolymerization of sodium acrylate, or the alkaline hydrolysis of a polyacrylate ester. The material has the structure illustrated in Fig. 63(c).

Like polyvinyl pyrrolidone, aqueous sodium polyacrylate solutions are soluble up to the boiling point of water. Their ability to reduce the rate of heat removal is proportional to the molecular weight of the polymer and its effect on solution viscosity. By varying the polymer molecular weights, a whole family of quenchants can be designed to cover applications ranging from water to oils.

The effect of polymer concentration and temperature for one of the commercially available sodium polyacrylate quenchants is shown in Fig. 71. The cooling curves obtained with polyacrylate solutions can be almost linear with time, which is a result of the extended A-stage cooling and reduced cooling rates during nucleate boiling. This property of the polyacrylate quenchants allows their use in hardening crack-prone parts made of high hardenability steels. A comparison of cooling curves of a sodium polyacrylate quenchant with those of water, conventional oil, and a few typical polymer quenchants is shown in Fig. 72. The cooling rates produced by the sodium polyacrylate solutions are distinctly slower than those of other polymer quenchants. This is an advantage in applications requiring slow quenching.

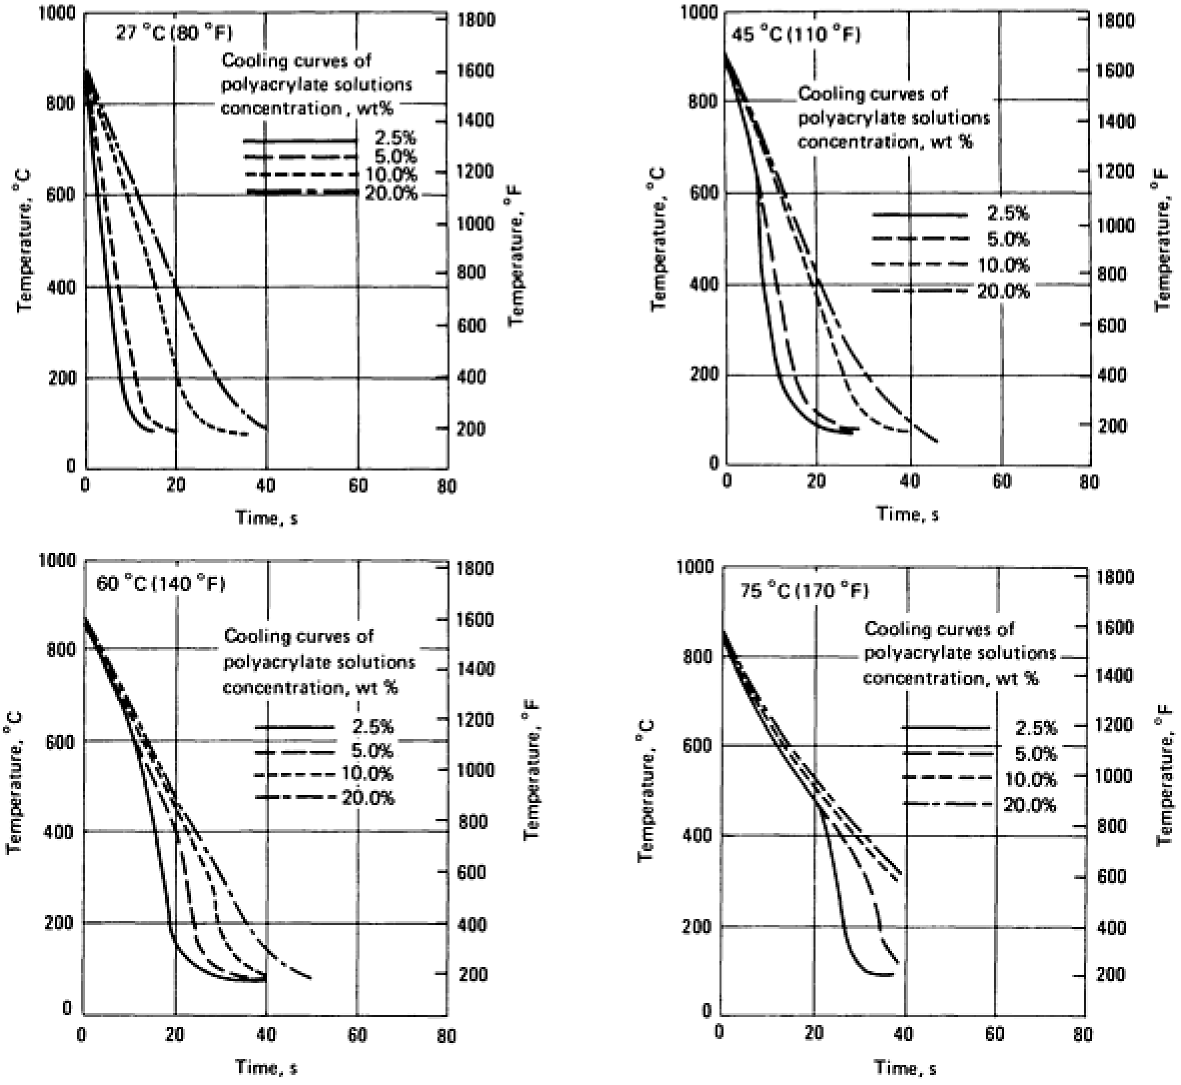

Fig. 71 Cooling rate of an agitated sodium polyacrylate quenchant as a function of concentration and temperature that was used to treat an austenitic steel. Test specimen dimensions were 10 mm (0.4 in.) diam by 60 mm (2.4 in.).

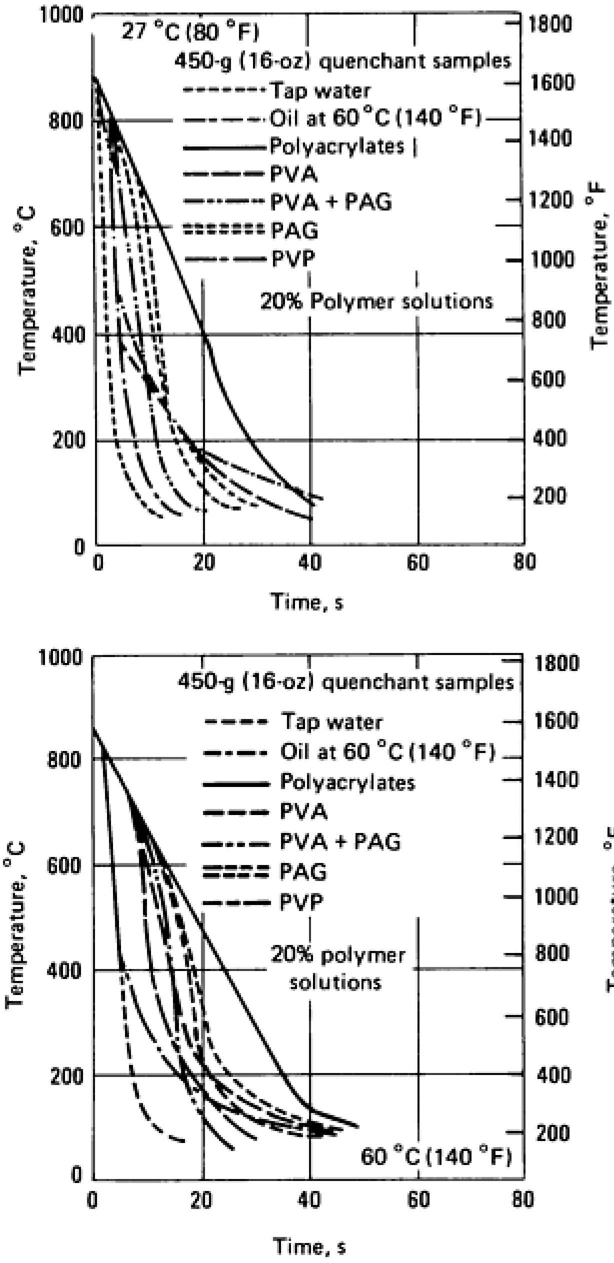

Fig. 72 Cooling rates of selected polymer quenchants at 20% concentration and bath temperatures of 25 and 60 °C (80 and 140 °F). Test specimen type and dimensions: 10 mm (0.4 in.) diam by 60 mm (2.4 in.) scaleproof austenitic steel, medium agitation

With increasing PA concentration and bath temperature, the cooling rate can be reduced to such an extent that many ferrous metals do not transform to martensite at all, but form bainite or fine pearlite. This nonmartensitic quenching can be utilized for achieving lower hardness values.

Some applications of the sodium polyacrylate solutions for nonmartensitic quenching are as follows:

- Deep carburized parts, such as bearing races, balls, and rollers, which are often double quenched in oil to obtain grain refinement. The first quenching can be done in a polyacrylate solution
- Direct quenching of plain carbon steel with a high carbon concentration to obtain similar mechanical properties as obtained by quench and temper or austempering, such as automotive sway bars or railroad rails made of SAF 1070 to 1090
- Rod or wire patenting in sodium polyacrylate solutions, instead of lead or salt baths at 510 to 565 °C

(950 to 1050 °F)

- Direct quenching of hot formed parts to obtain good machinability without having to temper after quenching of steels of low hardenability such as carburizing steels
- Cooling of hot formed parts in sodium polyacrylate solutions to prevent scaling and decarburization such as might occur during slow cooling in air, while achieving practically the same microstructure
- Large continuously cast steel slabs may be water quenched to shorten cooling duration, thus permitting inspection shortly after casting

This is possible only for slabs of plain carbon steel containing up to about 0.2% C. Alloy steels and steels with higher carbon concentrations cannot be water quenched because of their cracking tendency but may be quenched in polyacrylate solutions.

As with all polymer quenchants, sodium polyacrylate solutions require agitation, the degree of which depends on the specific application. As a general rule, a high degree of agitation is recommended for hardening operations.

The concentration control of the sodium polyacrylate quenchants is based on kinematic viscosity. To take into account the influence of contaminations, they also should be periodically checked with other laboratory methods including cooling curve analysis. This service is usually provided by a quenchant supplier.

Polyvinyl Alcohol. The use of aqueous solutions of polyvinyl alcohol (PVA) as quenching media was first described in U.S. Patent 2,600,290, issued in 1952. The chemical formula for polyvinyl alcohol is schematically illustrated in Fig. 63(d).

Although polyvinyl alcohol can be regarded as a polymer of vinyl alcohol, in reality all PVA resins are made by the hydrolysis of polyvinyl acetate. The extent of hydrolysis, which can govern commercial applications, may vary from partial (87 to 89%) through fully hydrolyzed (95%) to superhydrolyzed (99.7%). The water solubility and quenching characteristics of PVA resins vary with the molecular weight of the polymer.

Cooling Characteristics. Slight variations in solution concentration are needed to produce changes in cooling characteristics of PVA solutions, as illustrated in Fig. 73. Concentrations as low as 0.10% have significant effects. Since small concentration variations have substantial effects, close control of PVA solutions is necessary. Control is complicated by the fact that quenched parts can become coated with an insoluble layer of resin, thus reducing the bath concentration. Maintaining an effective concentration requires specific control measures. Very little polyvinyl alcohol is used in quenching at the present time, largely because of the difficulty of maintaining the correct bath concentration.

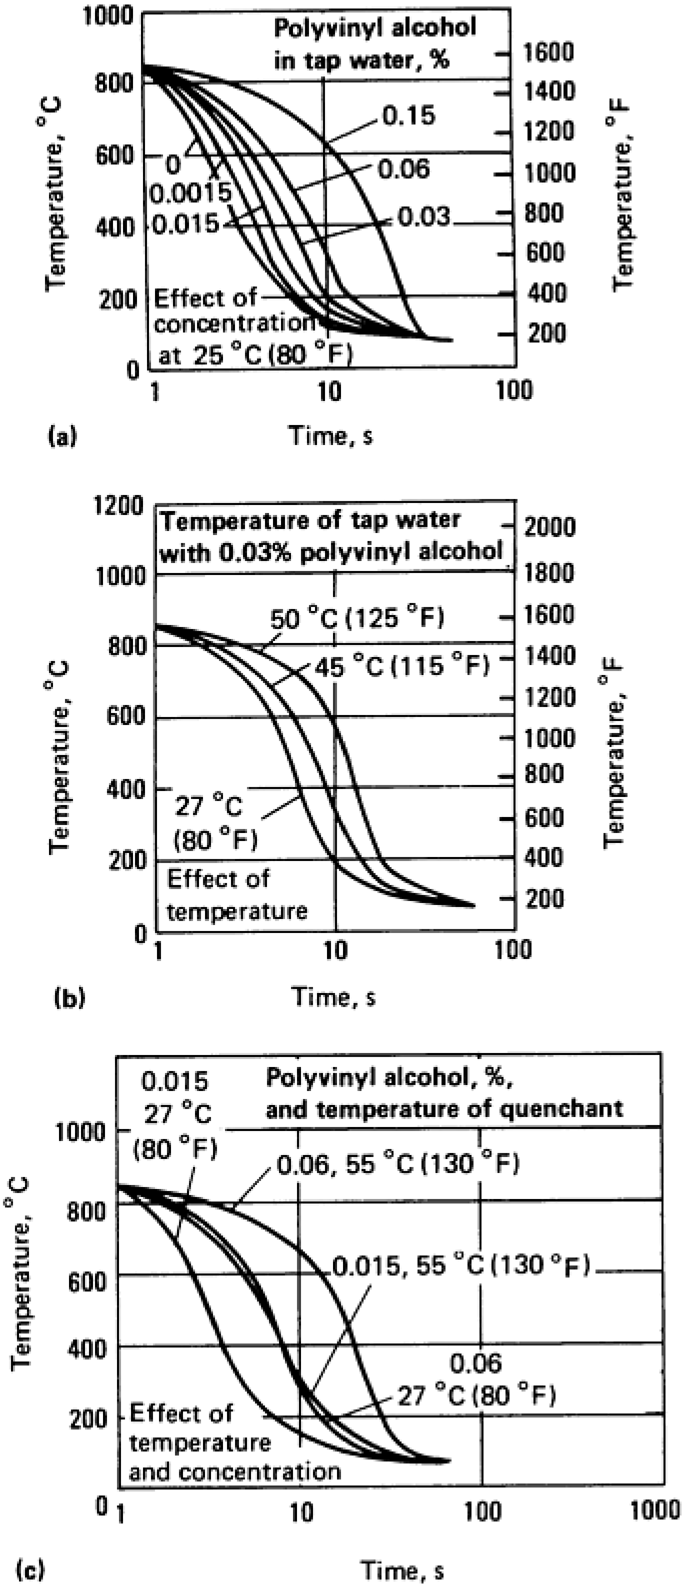

Fig. 73 Effect of temperature and concentration on polyvinyl alcohol solutions. Center cooling curves for type 304 stainless steel specimens 13 mm ($\frac{1}{2}$ in.) diam by 100 mm (4 in.) long quenched in still tap water at 25 °C (80 °F) (or at other temperatures shown) containing various concentrations of polyvinyl alcohol. Thermocouple was placed in geometric center of each specimen. Water hardness, 130 ppm

Molten Salts

The relation between molten salt flow and the cooling rates in bars quenched in a marquenching salt at 205 °C (400 °F) is shown in Fig. 57. Also shown in Fig. 57 are similar curves obtained from water and oil quenching, thus providing comparisons among three media that provide a wide range of cooling rates. The data are plotted to allow correlations between cooling times in quenched round bars and standard end-quench hardenability specimens. The bars were of medium-carbon 9400 steels, heated in an exothermic atmosphere.

The small-diameter bars (and the surface of all bar sizes shown) may be cooled faster in rapidly flowing salt at 205 °C (400 °F) than in still or mildly agitated oil at 50 °C (120 °F) However, as the bar size increases, subsurface regions of salt quenched parts cool more slowly than those quenched in still oil. This limits the section size or steel composition that can develop a fully martensitic structure by quenching in hot salt.

Gas Quenching

Gas quenching is used to provide a cooling rate that is faster than that obtained in still air and slower than that obtained in oil.

In gas quenching, the austenitized work-piece is placed directly in the quenching zone and heat is extracted by a fast-moving stream of gas. The cooling rate of the metal is related to the surface area and mass of the part and to the type, pressure, and velocity of the cooling gas. The cooling rate can be adjusted and controlled by altering the type, pressure, and velocity of the gas, thus providing a degree of flexibility that can be obtained with very few other quenching media.

Recirculation. During the quench period, large volumes of gas are directed through nozzles or vanes to achieve impingement on the surface of the work load. After absorbing heat from the material being processed, the gas is cooled by being passed through water-cooled or refrigerated coils. Recirculating fans return the gas to the nozzles, through which they are again directed at the work load.

Gas quenching units are designed for either batch or continuous processing, but batch processing is more common. Atmospheres containing some hydrogen or helium are commonly used, not only to produce bright work but also to increase the heat transfer rate between the gas and the work.

Applications. In some applications, quenching in a still gas is too slow and oil quenching is undesirable because of distortion, cost factors, handling problems, or the final hardness obtained. In these applications, gas quenching constitutes a useful compromise between two extremes.

Gas quenching is used to advantage in hardening aircraft tubing made of low-alloy steel. Tubing with up to 3.2 mm ($\frac{1}{8}$ in.) wall thickness can be satisfactorily quenched in a continuous process. A comparison of the cooling curves obtained in quenching 4130 steel tubing 31.8 mm (1.25 in.) OD by 1.7 mm (0.065 in.) wall in gas, oil, and still air (normalizing) is presented in Fig. 74.

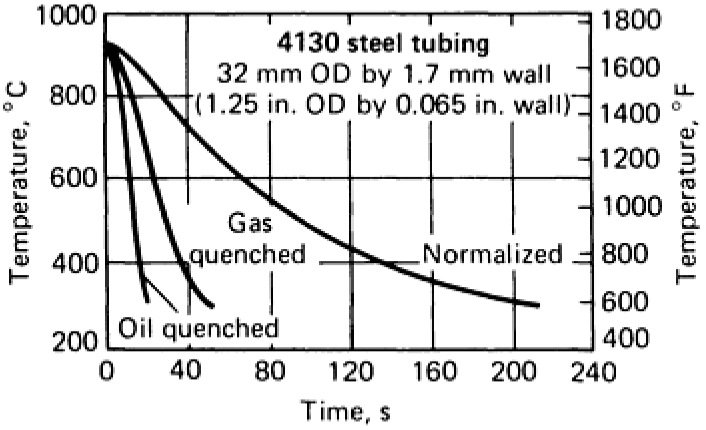

Fig. 74 Cooling curves obtained in quenching 4130 steel tubing in gas, oil, and still air (normalizing)

When a steel that is not air hardenable because of its chemical composition or section size, or both, is quenched in oil, gas, or still air, considerable differences in hardness are obtained. Brinell hardnesses, surface to center, obtained by quenching 100 mm (4 in.) thick disks forged from 1095 steel in each of the three different media, are shown in Fig. 75.

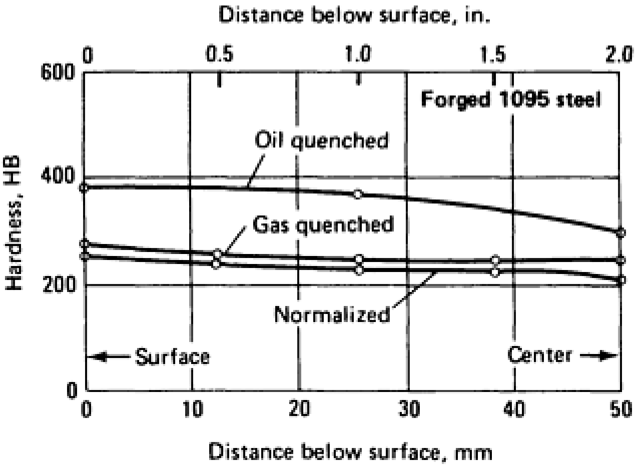

Fig. 75 Differences in Brinell hardness of forged 1095 steel disks, 100 mm (4 in.) thick, after oil quenching, gas quenching (forced air), and cooling in still air (normalizing)

Tool steels of types A2 and T1, in the form of solid blocks 50 by 100 by 100 mm (2 by 4 by 4 in.), were successfully austenitized and gas quenched with cylinder nitrogen in a vacuum furnace. A sealed fan in the roof of the furnace chamber chilled the nitrogen by forcing it over the water-cooled walls of the chamber; the cooled gas was then admitted to the chamber at 69 kPa (10 psig) and directed at the steel. As indicated in Fig. 76, the A2 steel cooled from 1010 to 345 °C (1850 to 650 °F) in 8 min, and the T1 steel from 1290 to 345 °C (2350 to 650 °F) in 13 min. These rates were sufficient for maximum hardness.

Fluidized Bed Quenching

Quench severities intermediate between those for still air and slow oil quenchants are now possible with fluidized bed quenching (Ref 56, 57). Some of the variables that affect heat transfer in fluidized bed quenching include:

- Compaction, particle size, and distribution of the bed material
- Velocity, composition, and heat capacity of the gas or gas mixture flowing through the bed
- Dimensions of the fluidized bed relative to the size and mass of the parts being quenched
- Position of the part in the bed

Some of the advantages of fluidized bed quenching include its flexibility, improved process control, and cleanliness. One of the disadvantages of fluidized bed quenching that inhibits its use is the cost of the fluidizing gas. Fluidized bed quenching processes are being used increasingly as safer and more ecologically sound alternatives to molten metal and salt bath quenching (Ref 56, 57).

Cooling curves comparing fluidized bed quenching to quenching in selected aqueous solutions are shown in Fig. 77.

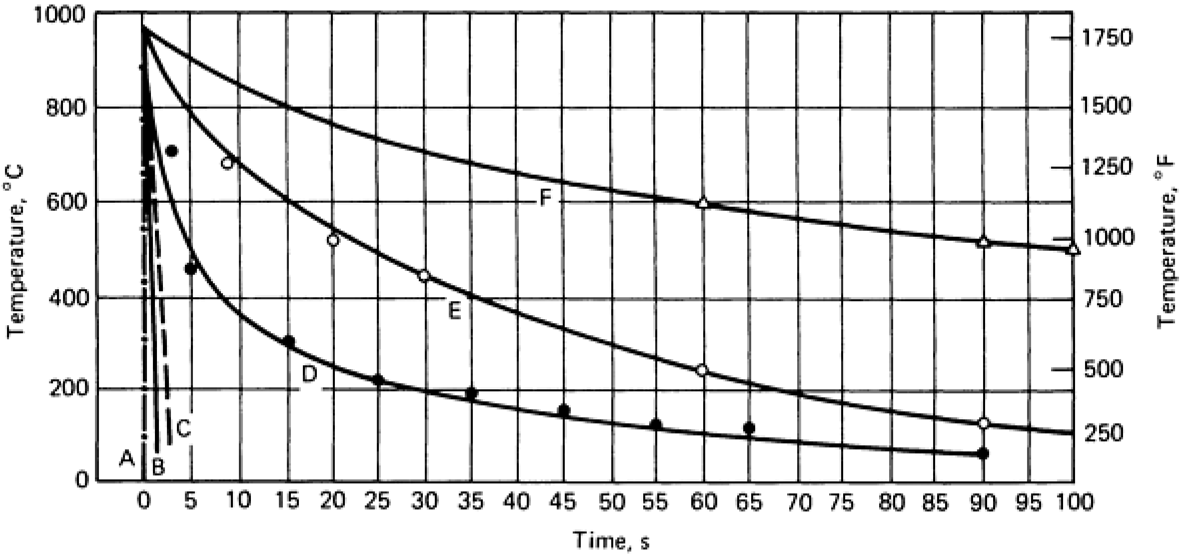

Fig. 77 Comparison of fluidized bed quenching to selected liquid quenchants and normalizing based on relative heat transfer (cooling) rates: A, salt solution; B, agitated water; C, still water; D, oil; E, fluidized bed; F, normalized. Test specimens were 12.6 mm (0.50 in.) diameter bars.

Fog Quenching

In fog quenching, heat is rapidly extracted from the metal by a fast-moving stream of gas that contains water droplets. The cooling capacity of the fog is derived from both the absorption of heat by the gas and the heat of vaporization of the water. The addition of water droplets (or fog) to an air stream can increase its cooling capacity by a factor of $4\frac{1}{2}$. Fog quenching is most effective in the lower temperature ranges.

An outgrowth of gas quenching, fog quenching normally is substituted for liquid quenching in an effort to minimize distortion. Although less severe than a liquid quench, fog quenching is more severe than a plain gas quench of equivalent velocity. In general, the types of parts that are fog quenched are similar to those that are considered suitable for gas quenching.

Cold Die Quenching

Thin disks, long slender rods, and other delicate parts that distort excessively when they are quenched in conventional liquid media can often be quenched between cold dies with virtually no distortion.

One means of solving such problems is to utilize various forms of cold, flat, or shaped dies, depending on the shape of the part being quenched. If only a few parts are involved, the dies will not require special cooling, provided they are allowed

to cool before another part is quenched. The dies usually are used in some sort of press located close to the austenitizing operation.

Large thin thrust washers that were blanked from cold rolled steel and contained machined oil grooves distorted as a result of blanking and machining stresses. A dimensional variation of 1.3 mm (0.050 in.) was common, and even larger variations sometimes occurred. Nevertheless, these washers had to be flat to within 0.13 mm (0.005 in.) after hardening. To ensure the required flatness, the washers were squeezed between a pair of water-cooled die blocks immediately after they left the hardening furnace. The die blocks provided the necessary quenching action while maintaining flatness. When water-cooled beryllium copper die blocks were used in this application, the rate of cooling approached that obtained in water quenching.

Cold die quenching is limited to parts with a large surface area and a relatively small mass, such as washers, rods of small diameter, and thin blades.

Press Quenching

Commercial quenching presses are designed for controlled quenching of ring gears and other round, flat, or cylindrical parts to permit heat treating with minimum distortion.

Probably the most widely used special technique is press quenching. To realize the maximum advantages of controlled quenching and to minimize distortion caused by the heating cycle, press quenching dies must be made to provide the proper oil flow and hold critical dimensions of the part being quenched. In press quenching, the die contacts the heated part, and the pressure of the press aligns the part mechanically. This occurs before quenching begins, while the part is hot and plastic. The machine and dies then force the quenching medium into contact with the part in a controlled manner (see Fig. 78).

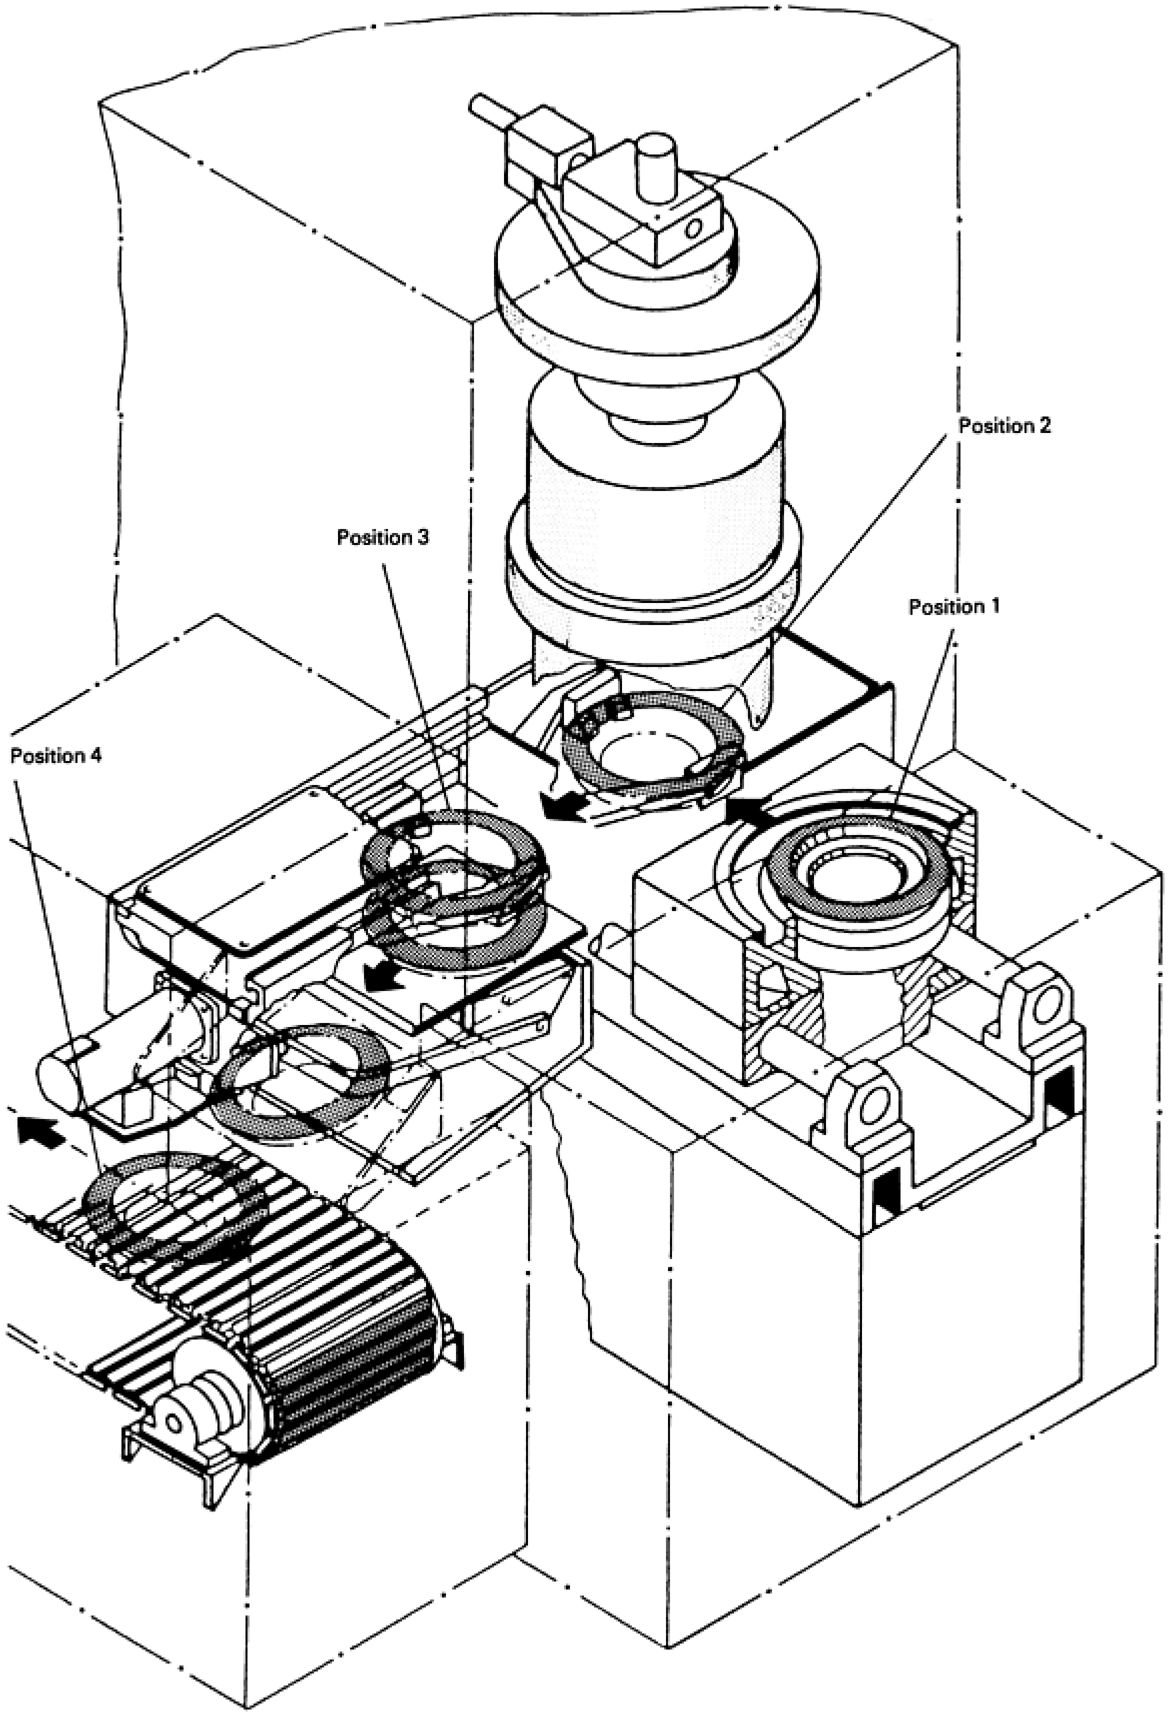

Fig. 78 Cutaway view of a four-position, automatic gear-quenching press using the pulsing principle. Hot gear placed in extended lower die (position 1) is transferred to the center of the quench chamber containing the upper die, the chamber is sealed, and the workpiece subjected to the intermittent pressure of flowing oil for 20 s (position 2). Quench chamber door opens as die is raised and workpiece is moved into an auxiliary quench chamber (position 3) that is subsequently also sealed to provide further cooling while submerged in oil.

Workpiece is then ejected into conveyor tank (position 4) for final cooling.

The quantity of quenchant and its rate of flow are controlled by the press. The distribution of the flow is controlled by the dies. The speed of the quench depends on the quenching medium and the rate of oil flow. The rate of cooling can be controlled by adjusting the rate of flow of oil through the die.

Although some basic types of dies are available for certain workpiece shapes, additional dies are usually required to accommodate specific parts.

Quenching to a tolerance of 0.025 to 0.050 mm (0.001 to 0.002 in.) for roundness and flatness is common practice for ring gears when the proper equipment and correctly designed dies are used.

Quenching of Flame and Induction Hardened Parts

A great many flame and induction hardening applications employ water as the quenching medium. Other media, such as oil, soluble oil, compressed air, aqueous polymer solutions, or brine are occasionally used. Because water provides the greatest ease in handling, and the greatest safety, it is used unless metallurgical considerations indicate the necessity for a less severe quenching media.

Although numerous agitation designs may be used in induction quenching applications, two of the most common are open and submerged spray. The spray orifice for water quenching is often relatively small to maximize cooling rates. However, the orifice diameter must be sized differently when aqueous polymers are used since high pressure and fine spray result in premature rupture of the polymer film that attenuates the cooling rate at the hot metal surface. Suggested types of sprays, pressures, and orifice sizes for quenchants from open and submerged spray systems are shown in Table 20.

Table 20 Recommended orifice size and fluid pressure for induction spray systems used to quench steels from an austenitizing temperature of 845 °C (1550 °F) with a PAG polymer quenchant

Type of spray[(a)]	Pressure[(b)]		Orifice diameter	
	kPa	psi	mm	in.
Open	<140	<20	3.2	$\frac{1}{8}$
Submerged	>275	>40	6.4	$\frac{1}{4}$

(a) All of the cooling curves for the quench factor correlation were determined using AISI type 304 stainless steel probes.

(b) Data for UCON (Union Carbide Chemicals and Plastics Company. Inc.) Quenchant B.

In order to minimize foaming, the quenchant reservoir volume should be at least five times the volume rate of flow. For example, if the flow rate is 25 L/min (6 gal/min), then the reservoir volume should be at least 110 L (30 gal).

Testing and Evaluation of Quenching Media

The testing of quenching media can be classified into two broad categories:

- Tests of hardening power (metallurgical response)
- Tests of heat removal ability of the quenchant

The results of hardening tests are related to the size, microstructure, and composition of the steel being quenched as well as to the heat removal characteristics of the quenchant. Traditionally, steel hardening power tests have been determined experimentally by quenching test specimens and performing cross-sectional hardness (U-curves) and Jominy end-quench surveys (ASTM A 255).

Reproducibility problems are occasionally encountered due to procedural and lot-to-lot variations in the steel chemistry. Therefore, there has been a continuing interest in alternative tests that would relate metallurgical properties of steel, such as hardness, to the heat removal characteristics of the quenchant media.

Hardening-Power Tests

The final criterion for selecting a quenching medium is its hardening power, that is, its ability to develop a specified microstructure and hardness in a given material-section size combination under specified conditions of quenchant, agitation, and temperature. The major factors influencing the hardness obtained on quenching can be summarized as follows:

- Nature and concentration (if applicable) of the quenchant
- Quenchant temperature
- Quenchant agitation and mass flow
- Material composition, structure, and thermal history of the metal component
- Section size, geometry, and surface condition of the metal component

Jominy End-Quench Test (ASTM A 255). This test is widely used to determine hardenability of steels. It consists of heating a specimen 25 mm (1 in.) round by 100 mm (4 in.) long to the desired hardening temperature, and then withdrawing heat from one end of the bar by the use of a water jet quench. The bar is then ground along its length to 0.38 mm (0.015 in.) below the surface, and hardness readings of the specimen are taken 1.6 mm ($\frac{1}{16}$ in.) apart. Hardenability is expressed in terms of the distance from the quenched end to a given hardness. Detailed information is available in the article "Hardenability of Carbon and Low-Alloy Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

The standard end-quench procedure employs 25 °C (80 °F) water, but some investigators employ oils or polymers to perform the end quench and then compare the results obtained with the alternate quenchant with the results produced by water.

Immersion Quench Test. The standard Jominy end-quench test does not readily permit adequate modeling of agitation effects encountered in many commercial quench practices. Also, the Jominy end-quench test is not a generally acceptable method for use with aqueous polymer quenchants since the pressure of the flood quench at the end of the test specimen often disrupts film-forming properties of the polymer at the hot metal interface.

In view of limitations of the Jominy end-quench test, a cross sectional hardness survey, or U-curve, is often determined on a standard test piece under actual quenching conditions. The hardenability indicated by the U-curve may be related to the hardness of an end-quench test by use of the Lamont transformation as shown in Fig. 41 (Ref 59).

Cooling Power Tests

Because hardening power tests are time consuming and relatively difficult to perform, cooling power tests have been developed for the evaluation of quenching media. The three tests most commonly used today are:

- Cooling curve tests
- The magnetic test
- The hot wire test

Cooling Curve Tests. The most useful method to determine the cooling power of a quenchant is the cooling curve test, wherein cooling rates are established throughout the complete quenching process. The test is performed by quenching test specimens, containing one or more thermocouples, and following the cooling process by using a temperature measuring device. Test specimens can be made of stainless steel, silver, nickel, or carbon steel. Although cylindrical shapes are most common, other shapes may be used, including balls, plates, tubes, or production parts. A test specimen of relatively small mass may be desired for slow quenching fluids, whereas faster quenching fluids may require larger mass or a recorder having a very high response rate. Silver probes are used by some investigators because they are free from transformation effects and resistant to corrosion. The relatively high conductivity of silver averages out localized surface thermal variations while retaining high sensitivity to the quenchant properties.

The characteristic temperature (the lowest temperature at which a vapor envelope can be maintained) and the boiling point are unaffected by the temperature, the thermal conductivity, or the mass of the test piece when the cooling curve is taken at the surface of the test piece. This is not true when the curve is taken at any point below the surface. Overall, the cooling curve test is an excellent research and quality control tool and provides for a great degree of comparative accuracy. Standardization of the test would facilitate the comparison of results from different sources.

In conducting cooling curve analysis, it is critical that data acquisition rates be sufficient to provide enough data points to precisely determine cooling rates in the regions of highest heat transfer. Higher thermal conductivity or smaller probes require faster data acquisition rates.

A surface thermocouple is sometimes used to detect surface events that would be obscured in the center thermocouple output.

High data acquisition rates are usually required for surface thermocouples because of the high cooling rates encountered. For example, if a surface thermocouple is used with a 10 mm (0.4 in.) diameter silver test piece, the recorder must be capable of accurately registering rates of temperature change of at least 540 °C (1000 °F) in 0.1 s throughout the temperature range being explored.

It is generally recognized that surface temperature readings are important in calculating heat transfer coefficients and the surface heat flux during the quenching process. However, oxidation of the probe during the heating prior to quenching often makes it difficult to obtain reproducible surface cooling curves. However, surface temperatures during the quenching process can be calculated by finite-element method (FEM) or finite-difference method (FDM) analyses using commercially available computer programs (Ref 53).

As discussed earlier, Liščić has described the construction of a stainless steel probe that permits measuring cooling curves and temperature profiles across an instrumented specimen (see Fig. 10). This type of probe permits the calculation of heat transfer rates occurring during the quench process and may be related to the hardness properties of the steel being quenched (Ref 17).

Heat treaters are usually reluctant to measure the surface cooling behavior because they are more interested in the core hardness. Consequently, they have been more interested in centerline cooling curves in iron- or nickel-base alloys with thermal characteristics similar to the metals being heat treated.

When analyzing cooling curves obtained from probes of different construction, analysts should recognize that the ability of metals to diffuse heat from the core is reflected by the expression:

$$a = \frac{K}{rC_p} \quad \textbf{(Eq 19)}$$

where α is the thermal diffusivity; *k* is the conductivity; ρ is the density; and C_P is the specific heat of the metal.

The value of α is 0.25 cm^2/s for silver, 0.175 cm^2/s for nickel, and 0.11 cm^2/s for carbon steel. The temperature gradients in probes made of steel are higher than in nickel and both are higher than the temperature gradient in silver.

If cooling curves from different sources are to be compared, it is essential that they be obtained under the same conditions. This includes standardized test specimen (probe) alloys, probe size, thermocouple type and position, initial probe temperature, quenchant temperature, size and geometry of quenchant bath, volume of the quenchant, data acquisition rate, and so on. Currently, an International Organization for Standardization (ISO) specification is being developed for a standardized testing procedure. The procedure is based on work originally conducted by Wolfson Heat Treating Institute. A similar specification is being drafted by American Society for Testing and Materials in the United States.

Magnetic Quenchometer Test (ASTM D 3520). This test makes use of the properties of metals that lose their magnetism when heated above a Curie point, and regain their magnetism when cooled below this temperature. The quenchometer test was devised to provide a means of comparing the heat extraction rates of oil, molten salt, water, and other quenching media. The test method involves heating a 22 mm ($\frac{7}{8}$ in.) diameter nickel or chromized nickel sphere, weighing approximately 50 g (1.8 oz) to 885 °C (1625 °F) in either air or a controlled atmosphere. After temperature uniformity is attained, the sphere is quenched in a 200 mL (0.055 gal) sample of liquid located in a magnetic field. As the nickel sphere cools through its Curie temperature, it is attracted by the magnetic field to the side of the container. The time required for the nickel sphere to cool from 885 °C (1625 °F) to the Curie temperature 355 °C (670 °F) is a measure of the cooling power of the quenching medium. The higher the cooling power of the quenchant medium, the shorter the time required for the nickel to regain its magnetism.

Other alloys with different Curie points can be used to establish additional points on a cooling curve. A modification of the magnetic quench test can be used to study the influence of circulation and heat on the cooling power of quenching oils.

Magnetic quenchometer test results presented in Table 5 are reported in seconds. The time reflects the time required to cool a 48 to 52 g (1.7 to 1.8 oz), 22 mm ($\frac{7}{8}$ in.) diameter nickel ball from 885 °C (1625 °F) to 355 °C (670 °F) These results are listed for some commercially available conventional and fast quenching oils as well as for martempering oils with and without quench rate accelerators. Conventional and fast oils are usually tested at 25 °C (80 °F) Martempering oils, which are used at higher temperatures, are commonly tested at 120 °C (250 °F).

The test balls are made of either pure nickel or chromized pure nickel. The latter type was developed to approach the conditions and results obtained with pure nickel balls heated to 885 °C (1625 °F) under reducing atmospheres. This magnetic test, using the chromized nickel balls, is specified in ASTM D 3520, but it is so cumber-some that the much simpler plain nickel ball test usually is preferred.

The Hot Wire Test. This method of quenchant evaluation consists of heating a nichrome wire (of standard gage and electrical resistance) by means of an electrical current in 100 to 200 mL (0.025 to 0.055 gal) of quenchant. The wire is supported by two copper or brass electrodes and the quenchant is usually at its use temperature. The wire is heated by steadily increasing the current by means of a rheostat. The cooling power of the quenchant is indicated by the current flow at which the wire is melted or burned into. Quenchants capable of extracting heat more rapidly permit the passage of

higher currents through the wire. This test resembles the interval test in that it compares the heat removal capability of quenchants only in the higher temperature ranges.

Interval Test. This method, also known as the interval or 5-s test, is a method of comparing the cooling power of oil quenchants. In this test, a 2 L (0.5 gal) sample of an oil is placed in an insulated container and the oil temperature is determined. A bar of metal (usually, stainless steel) weighing about 250 g (8.8 oz) is heated to 815 °C (1500 °F), quenched for 5 s and then removed. The oil sample is then stirred to ensure temperature equalization throughout the bath, and the temperature rise is determined to the nearest tenth of a degree Celsius. This process may be repeated for several test bars.

Finally, a bar is fully quenched in a second sample of oil, and the rise in temperature is noted. The heat removal ability of the oil is computed using the following equation:

$$\%quench\ \text{speed}=100\frac{A}{B} \quad \textbf{(Eq 20)}$$

where *A* is the average rise in oil temperature for the 5-s quench bars; and *B* is the temperature rise in the oil sample after fully quenching. The interval test reflects the proportion of heat removed by the quenchant in a fixed 5-s interval compared to the total heat content of the specimen. A 5-s duration, however, only reflects heat removal in the higher temperature region of the quench and may be misleading because it encompasses only a portion of the cooling curve, namely, the vapor blanket and vapor transport stages.

Quenching Systems

Equipment requirements for quenching vary widely. A small plant making machine parts might require the hardening of only a few simple carbon steel parts each day. For such an application, the quenching system might be comprised of a container of water with a supply line and a drain. Handling equipment might consist of a pair of tongs. As the quantity of work and complexity of workpieces increase, however, various other items of equipment and equipment modifications must be added.

For a complete quenching system, the following functional parts are usually required and installed:

- Furnaces
- Quench tank
- Facilities for handling the quenched parts
- Quenching medium
- Equipment for agitation
- Coolers
- Heaters
- Pumps with strainers or filters
- Quenchant supply tank
- Equipment for ventilation and for protecting against hazards
- Equipment for removal of scale from tanks

Quenching Process Variables

The primary function of the quenchant is to mediate heat transfer rates from the hot metal to the cooler quenchant during the quenching process. At least three factors must be considered in understanding the cooling process:

- Nature and thermal properties of the metal
- Film forming characteristics of the quenchant at the hot metal interface
- Bulk properties quenchant itself

The heat transfer properties of the hot metal/quenchant interface can be described using Grossmann's relationship for quench severity (*H*), in Eq 2:

$$H = \frac{h}{2k}$$

where *h* is the film coefficient; and *k* is the thermal conductivity of the metal.

The Grossmann value is largely controlled by the quenchant medium. The conductivity, *k*, is a property of the metal and *h* defines the heat transfer rate from the metal to the quenchant solution. The thermal conductivity varies with the metal and is temperature dependent.

The heat transfer from the surface of a hot metal into a liquid quenchant solution is (Ref 12):

$$q = h \cdot \mathrm{A} \cdot (T_1 - T_2) \qquad \textbf{(Eq 21)}$$

where *q* is the amount of heat transferred; *h* is the heat transfer coefficient; *A* is the surface area; T_1 is the initial temperature of the hot metal; and T_2 is the bath temperature.

From Eq 21, it is evident that heat flow, *q*, increases as the (T_1 - T_2) value increases. Therefore, faster heat transfer rates are to be expected as the temperature of the quenchant bath decreases or as the initial temperature of the hot metal increases.

The amount of heat extracted, *Q*, from a part during quenching from the austenitizing temperature to the bath may be estimated from the equation:

$$Q = C_P \cdot W_m \cdot (T_1 - T_2) \qquad \textbf{(Eq 22)}$$

where C_P is the specific heat of the metal, for example, 0.166 Btu/lb · °F for steel; W_m is the metal weight (lb) being quenched including the quench trays; T_1 is the initial temperature of the load in °F; T_2 is the final temperature of the load in °F; and *Q* is the total amount of heat (Btu) given up by the load to the quenchant.

Although the specific heat of metal is actually a temperature dependent function, this simplified equation (Eq 22) permits a reasonable estimate of the amount of heat evolved from the metal being quenched. In making this calculation, it is assumed that no heat is lost to the environment during the process. A similar equation permits the temperature rise, T_r, in a quenchant bath during the quench cycle to be estimated:

$$T_r = (T_2 - T_1) = Q \cdot W_q \cdot C_{P(quench)} \qquad \textbf{(Eq 23)}$$

where T_r is the bath temperature rise; T_2 is the final bath temperature; T_1 is the initial bath temperature; W_q is the weight of the quenchant; $C_{P(quench)}$ is the heat capacity of the quenchant; and *Q* is the amount of heat given up by the metal as defined above.

From Eq 21, 22, 23, it is clear that the temperature rise, (T_2 - T_1), can be affected by the initial temperature of the metal, the mass of the load, volume, and temperature of the quenchant, and heat capacity of the metal.

It is important to remember that the heat transfer rate from the metal at the metal interface may be affected by oxidation. Typically, very small amounts of oxidation increase the heat transfer rate, but larger amounts reduce heat transfer rates.

Therefore, it is essential that surface oxidation be considered when attempting a detailed understanding of heat transfer behavior in a quenchant system.

Sometimes heat treaters closely pack trays of parts to be quenched. It is important to remember that this causes localized quenchant overheating which reduces the heat transfer rates. This may result in uneven quenching and low hardness values on interior parts in a tray in spite of the fact that the quenchant is satisfactory.

It is also important to remember that each quenchant has different film-forming properties during the three heat transfer regimes. Film thickness, stability, and strength are quite important. These properties can be significantly affected by agitation, bath temperature, and concentration.

Concentration, in this context, refers to several factors, including additive concentration in accelerated quench oils, polymer concentration in aqueous solutions, and the presence of oxides or contaminants in the bath. These factors, and others, can impact the quenchant performance.

Mass and Section Size Effects

The cooling curves in Fig. 79 and 80 illustrate the effect of mass and section size on the cooling curves of carbon steel in water and oil. Figure 81 summarizes data in Fig. 79 and 80, including data on still air at the center of bars of various diameters. The combined effects of mass and quenching medium for cooling small sections of selected steels are shown in Fig. 82, 83, and 84.

Continuous Quenching

A tank, such as schematically illustrated in Fig. 85, is commonly used for continuous quenching of parts that can be dropped into the quenching liquid. The parts fall from the furnace belt through a chute into the quenching medium and onto a second belt that conveys them out of the quenchant. Agitation can be provided by an impeller directed at the lower end of the quench chute. If the mass of work entering the tank is large, a means of controlling the quenchant temperature is required. This type of quench system is usually limited to symmetric and simple shapes because free fall from the furnace belt can result in distortion and nonuniform quenching. Gravity fall of the hot workpiece through the quenchant usually is employed for quenching small parts that have a high ratio of area to weight.

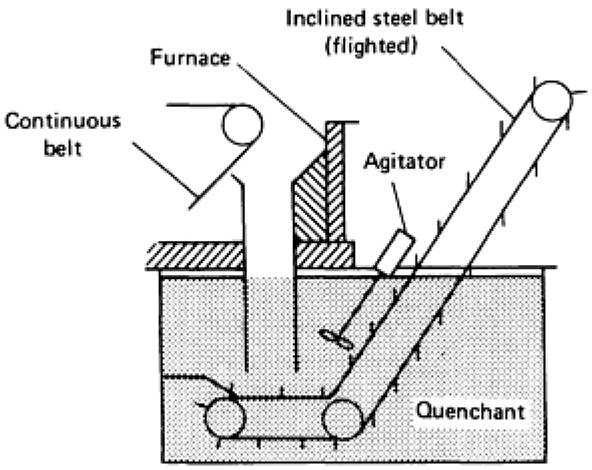

Fig. 85 Schematic of typical tank used for continuous quenching applications. The tank is designed for quenching parts of similar shape from a continuous hardening furnace. Parts fall from the furnace belt through the quenchant and onto a conveyor belt that transports them from the quenching tank. Quenchant may be water or oil.

Water Quenching System

A simple arrangement for water quenching, incorporating a method for controlling water temperature, is shown in Fig. 86. A supply of fresh water is continuously introduced and overflows to a drain. Temperature control of the water is provided by a regulator that opens and closes at predetermined temperatures.

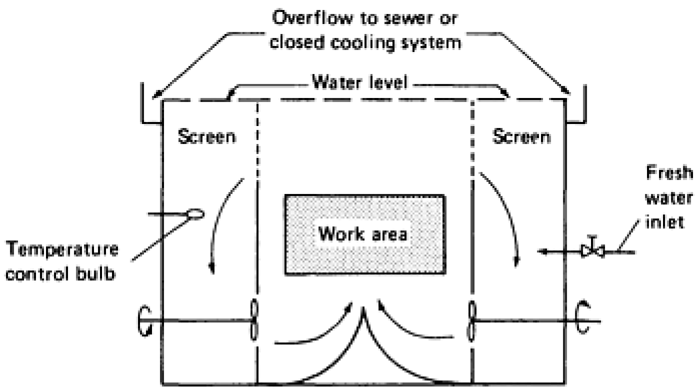

Fig. 86 Temperature-controlled overflow tank used for water quenching applications

This system can also be connected to a closed water-cooling system to minimize water consumption and control the bath temperature.

Oil Quenching Systems for Continuous Carburizers

Additional controls of the quenching operation are required for mass production of parts through a continuous carburizer. Plants involved in heat treating rear and front axle assemblies, gears, stem pinions, and differential side gears require loading fixtures for batch-quenched parts and quenching presses for ring gears. Because low unit cost must be maintained, quenching was integrated with heating and handling facilities were arranged accordingly. Machined gears were charged into a continuous pusher-type gas carburizer. Work-pieces were loaded on alloy trays with fixtures that permitted direct quenching.

Figure 87 shows a schematic arrangement of a system such as that described above. The principal elements are:

- Quenchant storage-supply tanks and pumps of sufficient capacity to maintain efficient quenchant transfer
- Coolers and heaters to maintain the quenchant temperature
- Filters to minimize free carbon and other foreign materials that may affect the rate of heat transfer or interfere with the operation of quenching presses
- Quenchant agitators
- Alloy fixtures and handling facilities to transfer workpieces
- Quenching oil
- Quenching presses

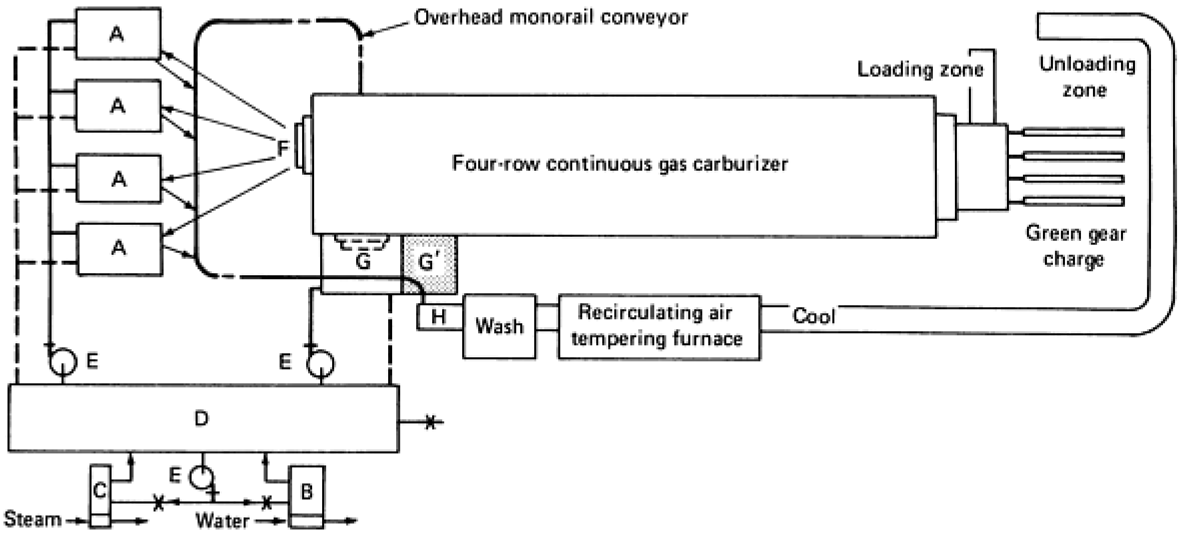

Fig. 87 Layout showing the elements of a quenching system used with a four-row continuous gas carburizing furnace. A, press quenches; B, cooler; C, heater; D, storage tank; E, pumps, strainers; F, slot door; G, atmosphere-hooded quench; G', open portion of G; and H, washer loading platform

A batch-quenching tank that can be used for high-volume production of work on trays is schematically illustrated in Fig. 88. Atmosphere protection, quenchant agitation, temperature control, and other features are included in this arrangement. The internal gas pressure must be greater than that of the outside air to prevent air entry into the chain-drive unit opposite the agitator motors. The revolving chain may otherwise carry air into the oil and cause oxidation.

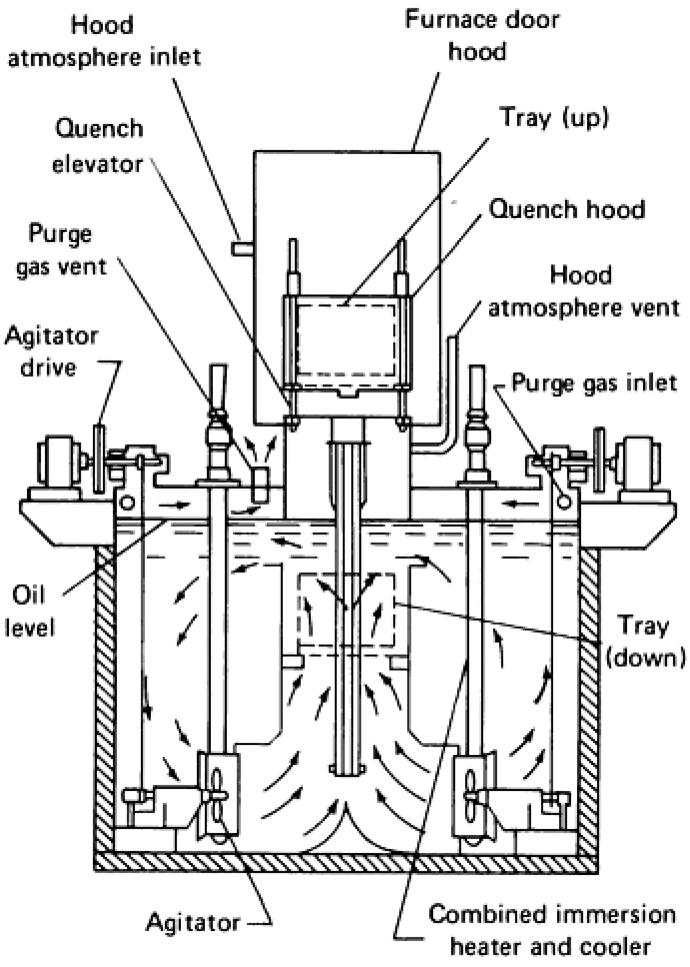

Fig. 88 Schematic of a typical installation for high-volume batch quenching of carburized or hardened parts on trays. Directional vanes in the oil stream distribute the oil flow uniformly. Unit contains combined heating and cooling elements and provision for blanketing the surface of the oil with an inert gas atmosphere. Radiant tube is used for heating and cooling.

Quenchant Agitation

The agitation of a quenchant can be obtained in several ways. In conventional quench tanks, circulation of the quenching medium is usually provided by:

- Pumps
- Passage of the workpiece through the quenching medium
- Manual or mechanical movement of the workpiece
- Mechanical propellers

The selection of the agitation method is dependent on the tank design, type of quenchant, volume of quenchant, the part design, and the severity of quench required.

Pumps are commonly employed because they provide a controllable means for directing the quenchant. The quenchant flow can be diverted to provide circulation to more than one location in the tank. When the quenching medium is oil and a cooling system is employed, the pump is used to recirculate oil to the cooling system and provide agitation. Recirculating pumps with directed outlets may be preferred for use in a floating fountain quench that is capable of removing heat quickly from an internal cavity of a workpiece.

Movement of the Workpiece. On small, low-production items, agitation can be accomplished by moving the part or a small basket or tray of parts through the quenchant by hand. Workpieces may also be driven mechanically with respect to the quenching medium. For example, shafts are sometimes rotated in the quenching medium to produce the effect of agitation. Propeller or pump agitation is more desirable, however, because it is more controllable and less dependent on the operator.

Propellers are compact, require no piping, and can be easily removed for maintenance. Propellers must, however, be properly located in the quench tank to function effectively.

Propellers are usually placed near the bottom of the tank. A liquid accelerated by a propeller flows in a helical motion in the same direction as the rotation of the propeller blades. This high-velocity stream moves across the bottom of the tank and spreads as it moves from the propeller. Upon striking the opposite wall, the stream is diverted in the direction of propeller rotation. This produces a general rotation of the liquid in the tank, which is partially disrupted by the return of the liquid to the propeller.

Propeller agitators may be either top-entry or side-entry units, as indicated in Fig. 89 and 90. Side-entry units are usually placed below the floor level to conserve floor space. Top-entry units require more floor space but less excavation for installation.

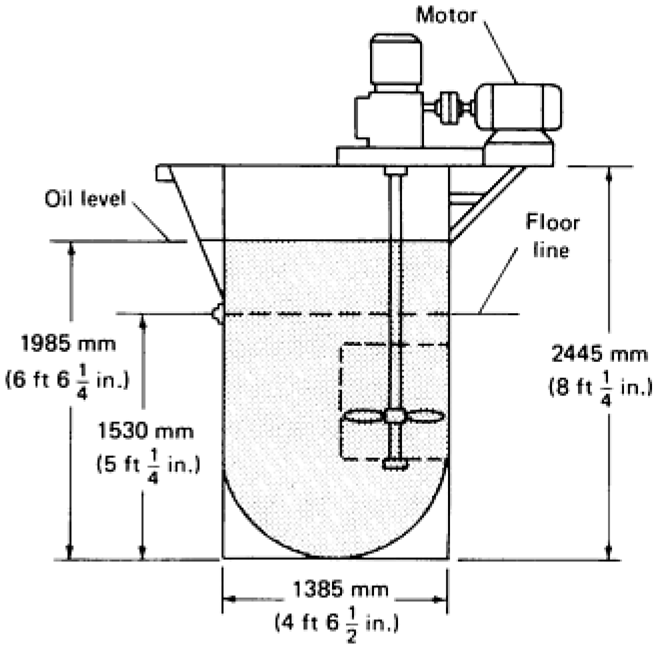

Fig. 89 Oil quenching tank with four top-entry propeller-type agitators used for quenching bar stock

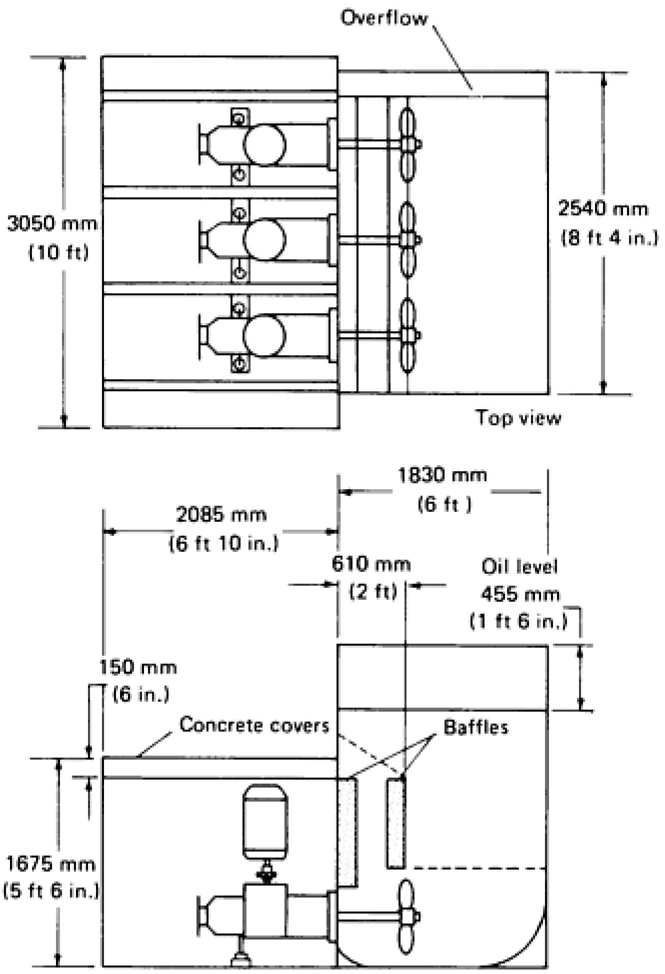

Fig. 90 Quench tank of 10 000-L (2600-gal) capacity with three propeller-type agitators entering from the side

The propeller horsepower is usually in the range of 0.6 to 1.0 kW/100 L (3 to 5 hp/100 gal) of quenchant. Horsepower estimates can be made from the data in Table 21. The volume of quenchant is typically about 8.3 L/kg (1 gal/lb) of steel. The power requirements in Table 21 are recommended minimums to produce a velocity of about 15 m/min (50 ft/min). Higher horsepower is required for higher quenchant flow velocities.

Table 21 Power requirements for propeller agitation of quenching liquids

		Power required for velocity of ≈15 m/min (≈50 ft/min)			
		Conventional oil		Water or brine	
L	gal	W/L	hp/gal	W/L	hp/gal
190-3000	50-800	0.985	0.005	0.788	0.004
3000-7600	800-2000	1.182	0.006	0.788	0.004

7600-11400	2000-3000	1.182	0.006	0.985	0.005
>11400	>3000	1.380	0.007	0.985	0.005

Once the horsepower of the motor used to drive the agitator is determined, the propeller diameter can then be determined from Table 22.

Table 22 Recommended propeller size as a function of motor power consumption

Power consumption[(a)]		**Minimum propeller diameter**[(b)]	
kW	**hp**	**mm**	**in.**
0.7	1	330	13
1.5	2	380	15
2.2	3	405	16
3.7	5	455	18
7.5	10	535	21
11	15	585	23

19	25	635	25

Source: Ref 59

(a) Motor speed, 1750 rev/min.

(b) Propeller speed, 420 rev/min.

Variables affecting agitation include oil velocity, agitator quantity, and relation of tank design to agitation sources.

Velocity. Tests have shown that quenching oil moving at a velocity of 23 m/min (75 ft/min) will increase the depth of hardening over that obtained at lesser velocities in sections up to 100 mm (4 in.) in diameter. In heavier sections, it is possible that no advantage can be gained by increasing agitation, because the rate of heat transfer from the core through the workpiece becomes the limiting factor. However, a practical upper limit on agitation is that which produces foaming on the surface of the quenchant. Foaming indicates that air is being entrapped and is undesirable.

Number of Agitators. The number of units required depends on the total horsepower required and the horsepower of available units. The sizing of the propellers for a system using multiple agitators is obtained by first determining the total horsepower required for the volume of the quenchant using Table 21. The horsepower per agitator is then (Ref 58):

$$hp_{agitator} = \frac{hp_{total}}{number \text{ of agotators}} \qquad \textbf{(Eq 24)}$$

The size of the propeller for each agitator is determined from Table 22.

Two or more smaller units provide more uniform agitation and more versatility than one large unit. The velocity of the quenchant can be varied by using two-speed motors or variable-pitch propellers or a combination of both devices.

Relation of Tank Design to Agitation. A properly designed tank and two or more propellers usually provide more uniform agitation throughout the working area. Sometimes baffles are required to direct the quenchant flow throughout the tank. On top-entry units, guide vanes are usually installed in the draft tube to prevent the quenchant from vortexing.

An oil quench tank used primarily for quenching bar stock is shown in Fig. 89. The four agitators develop a total of 75 kW (100 hp). Power consumption per unit volume of quenchant is 0.008 kW/L (0.04 hp/gal). The velocity is 60 m/min (200 ft/min), and the turnover is 113 500 L/min (30,000 gal/min). A similar tank holds 13 600 L (3600 gal) and has two 37 kW (50 hp) motors driving the propellers. The quenchant velocity is 110 m/min (360 ft/min) and the turnover of the quenchant is 196,000 L/min (51 800 gal/min); power consumption per unit volume of quenchant is 0.0055 kW/L (0.028 hp/gal).

A 10,100 L (2660 gal) oil quenching tank with three 19 kW (25 hp) side-entry agitators is shown in Fig. 90. This amounts to 0.00556 kW/L (0.0282 hp/gal) and produces a velocity of 20 m/min (66 ft/min), with a turnover of 51 100 L/min (13 500 gal/min).

The tanks illustrated in Fig. 89 and 90 are designed with baffles and curved bottoms to obtain uniform and smooth flow of oil. Baffles are used in the return path to direct the flow oil to the input side of the propeller with a minimum of turbulence.

With these design features, a higher-velocity flow or more general circulation can be obtained with a given input horsepower. Without these features, high agitation can spill the quenchant from the tank.

Factors Controlling Agitation. In all agitated quenching baths, the degree and character of the agitation varies from point to point within the bath. Although accurate measurements of velocity are difficult, the principal factors affecting velocity agitation are known. These include the shape of the bath, location of the work, direction of flow currents, type of agitator, flow rate, and power consumed. In spray or jet quenching, additional factors are encountered, such as the shape, arrangement, and placement of the spray head in relation to the work; the pressure, velocity, and size of the jets; and the total volume of quenching fluid used per unit of time.

Quenching velocities depend primarily on the mode of agitation. Very low velocities, not exceeding 0.9 m/s (3 ft/s), are encountered in immersion by gravity. Intermediate velocities, ranging from 1.1 to 1.8 m/s (3.5 to 6.0 ft/s), are achieved in hand quenching with an up-and-down, circular, or figure eight movement over 510 mm (20 in.) of travel. Spray quench rings are usually operated between 4.6 and 30 m/s (15 and 100 ft/s), but special applications sometimes use velocities as high as 150 m/s (500 ft/s).

Measurement of Quenchant Velocity

The Pitot tube is useful for measuring unidirectional velocity, such as that of a lamellar or jet stream, although it is not suitable for measuring turbulent (multi-directional) flow.

The tube can be constructed by drawing 6.4 mm ($\frac{1}{4}$ in.) glass tubing to an inside diameter of approximately 0.4 mm ($\frac{1}{64}$ in.) and grinding the drawn end flat and square with the tube axis. It may also be made of metal, provided the tube opening is knife-sharp and square with the axis of the tube. A suitable Bourdon gage or a manometer is connected by

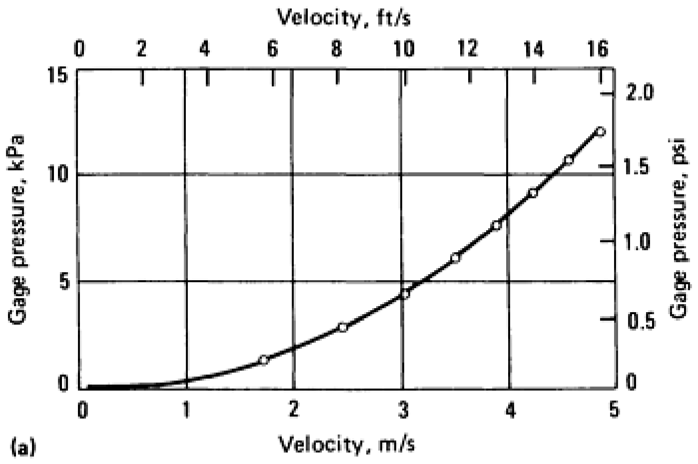
rubber or transparent plastic hose to the tube. If precise measurements are required, a correction must be made for the quenchant column height in excess of the level of the upper opening of the Pitot tube.

The axis of the Pitot tube must be accurately aligned parallel to, and in the center of, the stream being measured. Alignment is obtained by exploring the stream with the tube, and searching for the highest pressure reading. The velocity of the fluid as it strikes the tube is converted to a pressure head that is measured by the pressure gage. The pressure head, *h*, in feet of water, is converted into velocity, *v*, in feet per second, by the equation:

$$u = K.(2gh)^{\frac{1}{2}} \qquad \textbf{(Eq 25)}$$

where *K* is the Pitot tube constant (most often 1.0, or approximately unity); and *g* is the acceleration of gravity (980 cm/s^2 (32.2 ft/s^2).

The relationships are shown in the Pitot tube calibration charts in Fig. 91. Commercial instruments using immersible impellers with a magnetic pick up unit to provide direct readings of quenchant velocity are also available. These must also be rotated to find the maximum localized velocity similar to Pitot tubes.



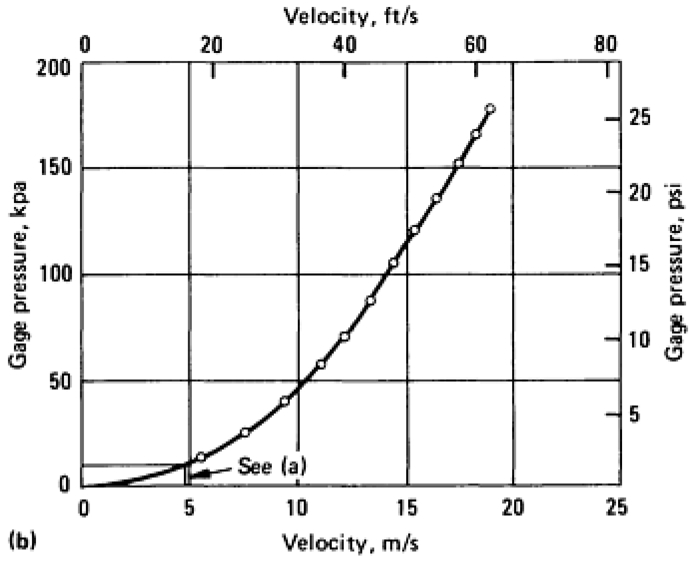


Fig. 91 Pitot tube calibration chart assuming a Pitot tube factor, *K*, of 1.0. Velocity equals *K* where *h* is the pressure head, in feet of water. (a) Low-velocity. (b) Full range

Turbulent agitation in a quenching bath takes the form of a multitude of swirling eddy currents. Turbulent agitation is desirable for uniform cooling of shapes that do not lend themselves to a complete washing of all surfaces with a lamellar or streamlined flow. A multitude of eddy currents will often cause sufficiently uniform average quenchant flow over irregular parts to produce adequate quenching.

Design of Quench Tanks

Quenching systems are integrated into heat-treating lines, and the automated lines are normally used to process many types of parts. It is seldom economically feasible to design a quench tank for only one type of part. One of the major goals of any design is to obtain as much flexibility in the quenching system as possible without appreciably affecting the cost of the unit.

The quench tank design is based primarily on such factors as the weight of steel to be quenched per hour, size of the part, part shape, weight, section thickness, grade of steel, and properties needed. A design based solely on the weight of metal treated per hour may produce unacceptable results.

Some practical suggestions for the design of quench tanks are as follows:

- The time required to quench out parts should be measured, and the desired part throughput per hour should be determined. From this information, the size of the quench tank and enclosure can be determined. The volume of quench medium and throughput is then used to select the size of the cooler and to determine whether a storage tank is necessary
- Adequate space should be provided around the workpiece to obtain quenchant circulation and maximum heat removal rate from quenched parts
- Hot and plastic workpieces should not be allowed to impact on a chute or conveyor until they have fallen through sufficient quenchant to produce a high-strength surface on the part
- The work tank should be accessible for maintenance and cleaning
- Provision for scale removal from the tank must be made for parts heated in air. The use of a controlled atmosphere furnace can be used to eliminate scaling
- Adequate ventilation should be provided to protect workmen from fumes
- Protection against fires should be provided when using oil quenchants
- Clean-out plates below the quenchant level in tank should be avoided because gaskets are prone to leakage and are difficult to maintain
- Special materials of construction are required for systems using brine or caustic solutions that usually result in a higher maintenance cost
- Alloy trays and fixtures of the 25Cr-12Ni or 35Ni-15Cr type can be quenched in oil quite satisfactorily, but not in water, caustic, or brine
- Wherever possible, the design of the work tank should provide for flexibility and control of such conditions as time cycle of quench, volume of circulation, and uniformity of bath conditions
- Excessive agitation can blow light parts off of conveyors
- A quenching bath should not be agitated so violently that foaming occurs on the bath surface. This entrained air reduces the heat transfer rate and the foaming of oils could lead to fires

Fixtures are widely used to minimize distortion during quenching. Fixtures vary in design from simple trays or racks to complex compartmented baskets and special holders. Distortion of shafts is minimized if they are hung or supported vertically during heating and quenching. Circular parts, such as rings, may be supported on flat surfaces during heating but quenching on the flat surface may result in nonuniform hardness, because quenchant flow may be restricted by the support surface. A preferred practice is to support such members on fixtures with ribs to permit flow of the quenchant around the part.

Distortion of thin-wall circular members is sometimes corrected by inserting pins inside the ring to force concentricity during tempering. The pins may be a part of an adjustable turnbuckle assembly.

Restraint fixtures are costly. Examples of parts requiring restraint during heating and quenching include rocket and missile casings and other large components with thin-wall sections. For such components, two or more external restraining bands may be used along with an articulated internal fixture. The internal fixture may be built up of cast or stamped pieces pinned to provide points of support and a free flow of quenchant to the inner surface of the workpiece. Articulated fixtures can accommodate workpieces of various diameters and lengths. The whole assembly is usually hung in the furnace and lowered into the quench tank.

Cooling Systems. As quenching proceeds, heat is removed from the workpieces and the temperature of the quenching medium rises. Uniform results in the hardening operation depend in part on the control of quenchant temperature. Accordingly, coolers (and sometimes heaters) are required to achieve temperature control. A typical oil-cooling system is shown schematically in Fig. 92.

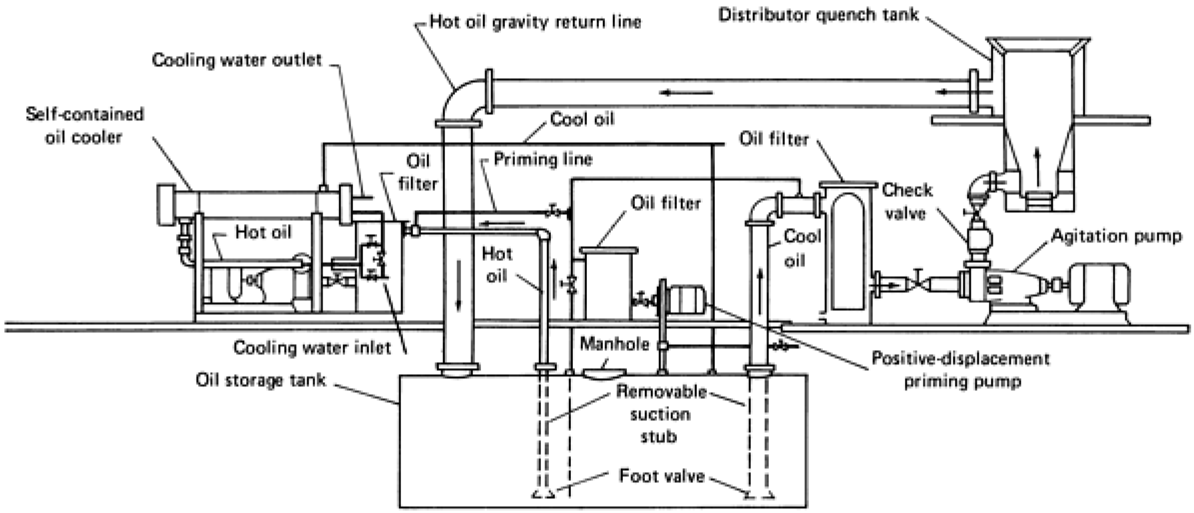

Fig. 92 Typical oil-cooling system employing an underground storage tank

Many types of heat exchangers are used for cooling quenching liquids, and each offers certain advantages. The rate of heat transfer through the cooling unit depends on the velocity of the cooling medium passing through it. As the velocity of the cooling medium increases, the rate of heat transfer increases up to the maximum flow rate capacity of the exchanger. Therefore, the efficiency of the cooling unit depends on an adequate pumping facility.

The maintenance of cooling equipment is also related to its design. If the cooling unit is capable of maintaining a uniform quenchant temperature, the possibility of fouling is minimized. To facilitate maintenance, cooling equipment should be designed for easy cleaning.

The shell-and-tube heat exchangers consist of a series of copper or steel tubes enclosed in a steel shell. The quenching liquid is circulated through either the tube section or the shell section, with the remaining section reserved for the coolant. Water is a commonly used coolant. With larger heat loads, an evaporative water-cooling unit may be employed to conserve water.

In general, disposable water is used when the total quenching load is less than about 910 kg/h (2000 lb/h). However, the use of disposable water depends on the water-consumption costs compared to the initial and operating costs of the evaporative unit. Usually, evaporative units do not provide water at as low a temperature as can be expected from well water or city water.

The shell-and-tube heat exchanger requires little maintenance, but when properly designed, the tubes can be removed for cleaning if necessary.

Maintenance costs are related to the number of mechanical units involved. Pumps are essential for quenchant circulation, and in some types of towers, motor-driven fans are required for air circulation.

Selection of Cooling System. To select a cooling system for the quenching circuit, the maximum heat load demand must be determined from the following data:

- Weight of steel quenched during a specified period
- Specific heat of steel and quench trays or fixtures
- Temperature of steel entering the quench
- Temperature of steel leaving the quench
- Temperature of quenching liquid entering the work tank
- Temperature of quenching liquid leaving the work tank
- Characteristics of the quenching medium such as specific heat, specific gravity, viscosity, flash point,

boiling point, and point of vaporization of toxic solutions

The proper cooling equipment can be selected for the quenching system from the above data and associated cost information.

Storage and Supply Tanks. Experience has indicated that the rise in temperature of the quenchant should be maintained within as narrow a range as possible--preferably within 5 °C (10 °F) during quenching. This requires a substantial volume of quenchant to limit the temperature rise in the quench tank. The volume can be supplied by an auxiliary storage tank. In addition to providing sufficient quenching liquid, the storage tank is an economical means of linking equipment such as pumps, coolers, heaters, and filters.

The storage tank design depends on individual requirements and conditions. The tank should be of the closed type and sufficiently large to supply the necessary quench capacity when about three-quarters full. The tank should be equipped with one or more manhole covers and appropriate openings for connections with quench tanks. The ends of the tank should have capped valve outlets, a sight gage, and a drain valve.

There are advantages in having tanks above the floor in a ventilated basement room with sufficient space to house pumps, coolers, filters, and other required equipment. This permits gravity feed of the quenchant to the pumps, eliminates the possibility of loss of pump prime, and allows insulation of the storage tank to minimize heat loss where temperature control is desirable. However, underground storage tanks require less space. The oil-cooling system illustrated in Fig. 92 employs an underground storage tank.

Heaters. Storage tanks containing water or brine may be heated economically by steam, hot water pipes, or radiant tubes in the tanks. The optimum storage temperature range for water or brine is 13 to 25 °C (55 to 75 °F). For oil storage tanks (or quenching tanks), the preferred temperature range is about 50 to 70 °C (120 to 160 °F), depending upon the type of quenching oil. When steam or hot water is used for heating quenching oils, there is some danger of contamination that can change the quenching characteristics of the oils, cause foaming, and create danger of explosion.

When fuel-fired radiant tubes are used they should burn deep in the tube well below the height of the quenching liquid. The products of combustion must be well vented.

Immersion-type electrical heating elements also are used for heating the oil in either quenching or storage tanks. A choice between immersion electric heaters and radiant-tube burners is a matter of economics and convenience.

Pumps are installed to maintain a quenchant flow through the quenchant bath and the heat exchanger. The flow is usually continuous and of sufficient mass to maintain the bath temperature in the desired range. Additional pumps or impellers may be installed in the quench tank to achieve agitation around the parts.

Centrifugal pumps are used wherever possible, because wear is minimized and the initial cost usually is lower. However, where a storage tank is employed, it may be necessary to raise the oil from the storage tank to the quenching tank.

Because a centrifugal pump is not self-priming, a small positive-displacement pump may be installed to ensure priming. The priming pump is often a positive-displacement pump that may be used both for continuous circulation and priming.

It is usually feasible to connect the pump such that it can be used for emptying or filling quenching tanks by opening and closing appropriate valves. Valves should also be installed to simplify pump repair.

Centrifugal pumps are not designed for great suction-lift operation and should be installed as near the quenchant supply as possible. Consideration should be given to the pipe flow resistance so the pump can be properly sized. If the pipe resistance is too high the pump motor may become overloaded.

Maintenance of Quenching Installations

Because quenching baths vary widely in design, shape, size, and method of operation, it is not feasible to establish universal procedures for maintenance. However, typical schedules for maintaining large oil, water, and brine quenching installations are outlined in Table 23.

Table 23 Recommended maintenance schedules for water, brine, and oil quenching systems

Quenchant	Maintenance schedule			
	Daily	Weekly	Monthly	Semiannually
Water	Check water temperature	Drain quench tanks and remove sludge	. . .	. . .
	Check water pressure	If water is recirculated, make necessary chemical addition(s) to prevent calcium compound buildup in tubes		
	Check water circulation			
Brine	Check brine temperature	Drain tanks and remove sludge	. . .	. . .
	Check brine concentration and adjust as required	Check pumps and tank condition		
		Check quenching fixtures for signs of deterioration		
Oil	Check oil level in quench tanks	Check quenching rate of oil in production system	Drain quench tanks and remove sludge	Check heat exchanger coils. pipes, and pumps Replace oil filters when necessary Check screens ahead of oil filter
	Check oil temperature			
	Check oil filter pressure	If oil filters are not included in oil system, check for solids in oil		
	Check operation of oil pumps and oil flow	Check oil temperature controller and control setting		Check oil storage tank for sludge, water leaks, and general condition Calibrate oil-temperature gage Check oil for

Safety Precautions

Fire hazards always attend the use of quenching oils. The causes of quenching-oil fires and the methods of extinguishing them should be thoroughly understood.

One of the most common causes of fire in open quench tanks--and one of which operating personnel should be made aware--is ignition of the oil surface from a partially submerged load. Some aids to the prevention of such fires are:

- Careful design of hoists or conveyors used to lower the work load into the quench
- Periodic inspection of chains, sprockets, and other components that may fail
- Having an alternate power supply in the event a power failure occurs during a quenching cycle
- The ignition of oil overflowing from a tank can produce a most damaging type of fire

When an oil quench tank is located adjacent to a furnace or other ignition source, special precautions are required, such as:

- Providing drains inside quench tanks to prevent overfilling and providing external drains to prevent the spread of burning oil
- Providing a system for detecting water in the oil (several detectors are commercially available)
- If the oil temperature approaches 120 °C (250 °F) with water present, foaming can result in an overflow of oil that exceeds the drain capacity

A third hazard arises when oil is heated by the work load to a temperature above its flash point. An oil bath temperature less than 30 °C (50 °F) below the flash point is considered dangerous. To minimize the temperature rise, several methods may be employed, including the use of:

- Cooling coils in the tanks
- External heat exchangers
- A larger tank
- Oil with a higher flash point

Extinguishing Oil Fires. A planned program for extinguishing quenching-oil fires should include:

- A quick method of extinguishing the fire without contaminating the oil, such as by smothering it with a cover or using carbon dioxide extinguishers
- Auxiliary methods, including foam or dry chemical extinguishers, or draining the tank
- Training of personnel in fire prevention and fire extinguishing

Tank covers or lids can be used effectively to smother a fire in a small tank. These covers can be actuated by heat or, from a safe distance, manually.

Carbon Dioxide Extinguishers. There are two general types of carbon dioxide systems: high-pressure systems, where the gas is stored at room temperature; and low-pressure systems, where the gas is refrigerated to -20 °C (0 °F).

The effectiveness of carbon dioxide is primarily a result of its ability to reduce the supply of oxygen at the surface of the oil to the point where combustion is not sustained. In some systems, carbon dioxide has a cooling effect as it sublimes from a solid snow to a gas.

The advantage of carbon dioxide is that it does not contaminate the quenching oil or require cleanup. Disadvantages are the short duration of the protection afforded and the storage costs for a large installation.

Fire-fighting foams are composed of fine, heat-resisting bubbles. The foam smothers the fire by floating on the oil and setting up into a protective blanket. There are two general types of foam: chemical and mechanical (or air). Both foam types are equally effective.

An advantage of foam is that it provides protection for an extended time. When a quench load has only been partially submerged, or when the fire has heated surrounding metal, the protection must last until these sources of reignition are eliminated. Some disadvantages of mechanical foams are the costs, and the possible oil contamination.

Dry chemical extinguishers use mainly sodium bicarbonate discharged through heads with high-pressure nitrogen. The extinguishing action, advantages, and disadvantages are similar to those of mechanical foams.

Tempering of Steel

Revised by Michael Wisti and Mandar Hingwe, Atmosphere Annealing, Inc.

Introduction

TEMPERING OF STEEL is a process in which previously hardened or normalized steel is usually heated to a temperature below the lower critical temperature and cooled at a suitable rate, primarily to increase ductility and toughness, but also to increase the grain size of the matrix. Steels are tempered by reheating after hardening to obtain specific values of mechanical properties and also to relieve quenching stresses and to ensure dimensional stability. Tempering usually follows quenching from above the upper critical temperature; however, tempering is also used to relieve the stresses and reduce the hardness developed during welding and to relieve stresses induced by forming and machining.

Principal Variables

Variables associated with tempering that affect the microstructure and the mechanical properties of a tempered steel include:

- Tempering temperature
- Time at temperature
- Cooling rate from the tempering temperature
- Composition of the steel, including carbon content, alloy content, and residual elements

In a steel quenched to a microstructure consisting essentially of martensite, the iron lattice is strained by the carbon atoms, producing the high hardness of quenched steels. Upon heating, the carbon atoms diffuse and react in a series of distinct steps that eventually form Fe_3C or an alloy carbide in a ferrite matrix of gradually decreasing stress level. The properties of the tempered steel are primarily determined by the size, shape, composition, and distribution of the carbides that form, with a relatively minor contribution from solid-solution hardening of the ferrite. These changes in microstructure usually decrease hardness, tensile strength, and yield strength but increase ductility and toughness.

Under certain conditions, hardness may remain unaffected by tempering or may even be increased as a result of it. For example, tempering a hardened steel at very low tempering temperatures may cause no change in hardness but may achieve a desired increase in yield strength. Also, those alloy steels that contain one or more of the carbide-forming elements (chromium, molybdenum, vanadium, and tungsten) are capable of secondary hardening; that is, they may become somewhat harder as a result of tempering.

The tempered hardness values for several quenched steels are presented in Table 1. Temperature and time are interdependent variables in the tempering process. Within limits, lowering temperature and increasing time can usually produce the same result as raising temperature and decreasing time. However, minor temperature changes have a far greater effect than minor time changes in typical tempering operations. This is discussed in more detail in the section "Tempering Time." With few exceptions, tempering is done at temperatures between 175 and 705 °C (350 and 1300 °F) and for times from 30 min to 4 h.

Structural Changes. Based on x-ray, dilatometric, and microstructural studies, there are three distinct stages of tempering, even though the temperature ranges overlap (Ref 1, 2, 3, 4):

- Stage I: The formation of transition carbides and lowering of the carbon content of the martensite to 0.25% (100 to 250 °C, or 210 to 480 °F)
- Stage II: The transformation of retained austenite to ferrite and cementite (200 to 300 °C, or 390 to 570 °F)
- Stage III: The replacement of transition carbides and low-temperature martensite by cementite and ferrite (250 to 350 °C, or 480 to 660 °F)

An additional stage of tempering (stage IV), precipitation of finely dispersed alloy carbides, exists for high-alloy steels. It has been found that stage I of tempering is often preceded by the redistribution of carbon atoms, called autotempering or quench tempering, during quenching and/or holding at room temperature (Ref 5). Other structural changes take place because of carbon atom rearrangement preceding the classical stage I of tempering (Ref 6, 7).

Dimensional Changes. Martensite transformation is associated with an increase in volume. During tempering, martensite decomposes into a mixture of ferrite and cementite with a resultant decrease in volume as tempering temperature increases. Because a 100% martensitic structure after quenching cannot always be assumed, volume may not continuously decrease with increasing tempering temperature.

The retained austenite in plain carbon steels and low-alloy steels transforms to bainite with an increase in volume, in stage II of tempering. When certain alloy steels are tempered, a precipitation of finely distributed alloy carbides occurs, along with an increase in hardness, called secondary hardness, and an increase in volume. With the precipitation of alloy carbides, the M_s temperature (temperature at which martensite starts to form from austenite upon cooling) of the retained austenite will increase and transform to martensite during cooling from the tempering temperature.

Example 1: Effect of Hardening and Tempering on the Dimensions of O1 Tool Steel Plates.

Steel plates made from O1 tool steel were hardened from two different hardening temperatures and two different soak times. The dimensional changes, after cooling to ambient temperature, are shown in Fig. 1 for tempering temperatures up to 400 °C (750 °F). The variation of 40 °C (70 °F) and 10 min has a negligible effect on dimensional changes. Tempering up to 200 °C (390 °F) is accompanied by a slight contraction in all directions of the plate. At a higher tempering temperature, there is an increase in the dimensions, with a maximum increase at 300 °C (570 °F), after which dimensions again decrease. The increased volume at 300 °C (570 °F) is attributed to the transformation of retained austenite to bainite. At 400 °C (750 °F), the dimensions revert to values closer to the original values, prior to quenching and tempering.

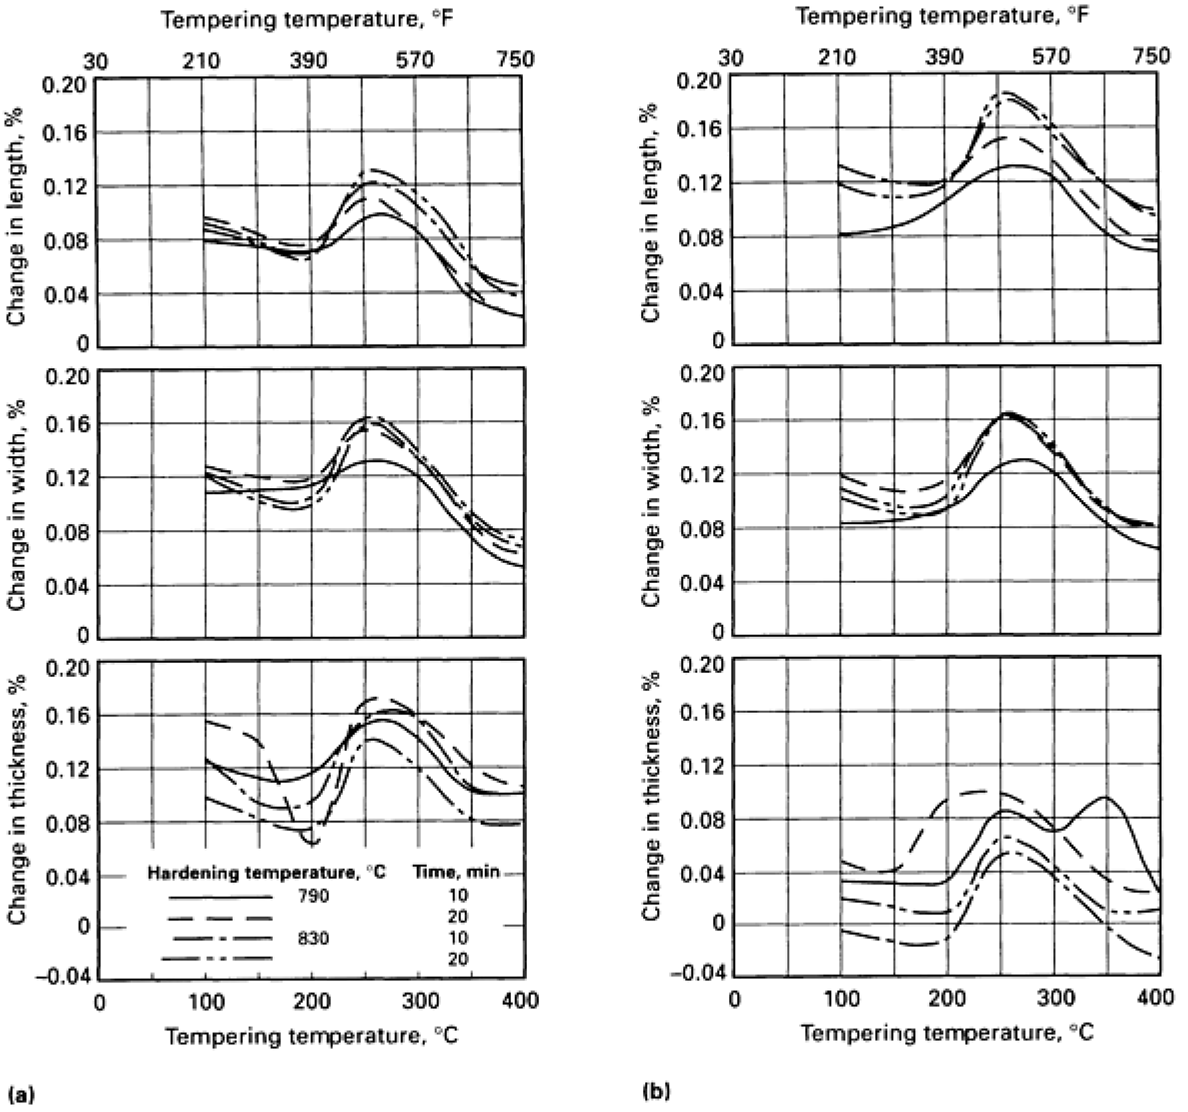

Fig. 1 Dimensional changes that occur in O1 tool steel (Bofors RT 1733) when heat treated at two hardening temperatures and two soak times using two tempering methods, (a) oil quenching, and (b) martempering. Specimen dimensions were 100 × 50 × 18 mm (4 × 2 × 0.7 in.). Steel was rolled in the longitudinal direction.

Tempering Temperature. Several empirical relationships have been made between the tensile strength and hardness of tempered steels such that the measurement of hardness is commonly used to evaluate the response of a steel to tempering. Figure 2 shows the effect of tempering temperature on hardness, tensile and yield strengths, elongation, and reduction in area of a plain carbon steel (AISI 1050) held at temperature for 1 h. It can be seen that both room-temperature hardness and strength decrease as the tempering temperature is increased. Ductility at ambient temperatures, measured by either elongation or reduction in area, increases with tempering temperature.

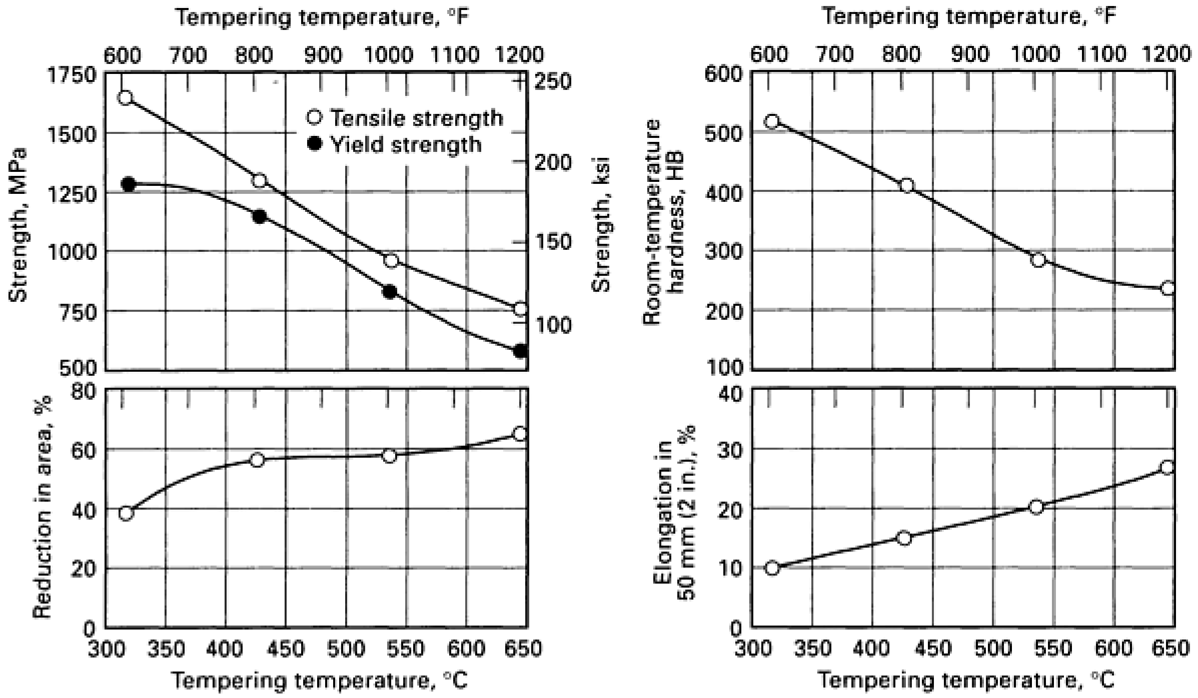

Fig. 2 Effect of tempering temperature on room-temperature mechanical properties of 1050 steel. Properties summarized are for one heat of 1050 steel that was forged to 38 mm (1.50 in.) in diameter, then water quenched and tempered at various temperatures. Composition of heat: 0.52% C, 0.93% Mn

Most medium-alloy steels exhibit a response to tempering similar to that of carbon steels. The change in mechanical properties with tempering temperature for 4340 steel is shown in Fig. 3.

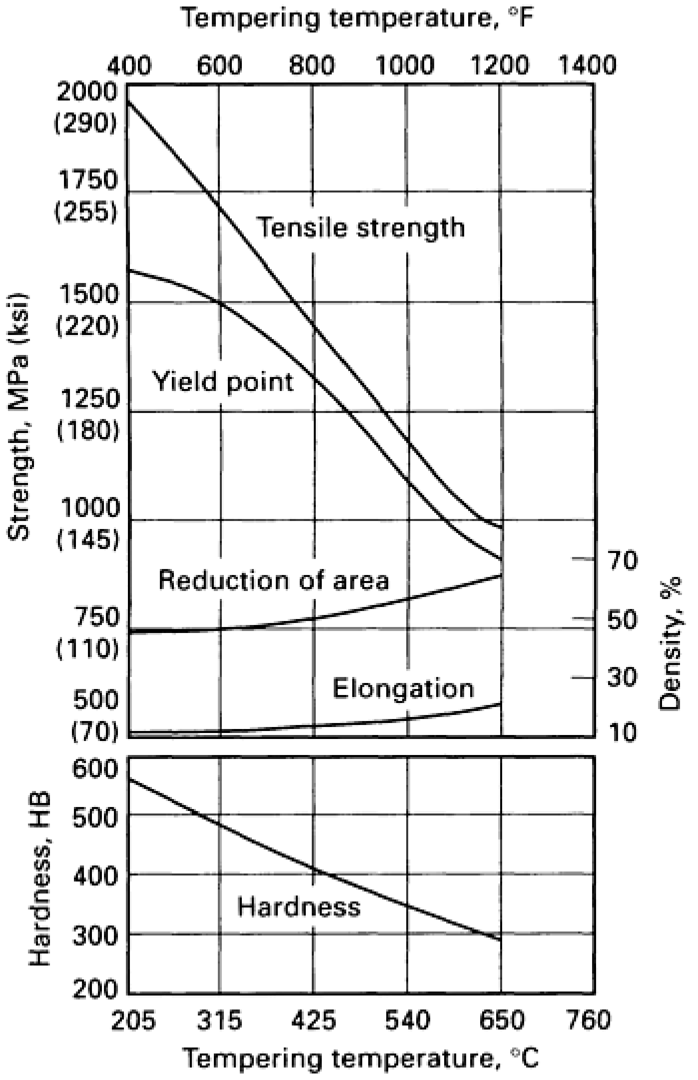

Fig. 3 Effect of tempering temperature on the mechanical properties of oil-quenched 4340 steel bar. Single-heat results: ladle composition, 0.41% C, 0.67% Mn, 0.023% P, 0.018% S, 0.26% Si, 1.77% Ni, 0.78% Cr, 0.26% Mo; grain size, ASTM 6 to 8; critical points, Ac_1, 730 °C (1350 °F); Ac_3, 770 °C (1415 °F); Ar_3, 475 °C (890 °F); Ar_1, 380 °C (720 °F); treatment, normalized at 870 °C (1600 °F), reheated to 800 °C (1475 °F), quenched in agitated oil; cross section, 13.46 mm (0.530 in.) diam; round treated, 12.83 mm (505 in.) diam; round tested; as-quenched hardness, 601 HB. Source: Ref 9

There is no decrease in ductility in the temperature range of tempered martensite embrittlement, or TME (also known as 500 °F embrittlement or one-step temper embrittlement) because the tensile tests are performed on smooth, round specimens at relatively low strain rates. However, in impact loading, catastrophic failure may result when alloy steel is tempered in the tempered martensite embrittlement range (260 to 370 °C, or 500 to 700 °F). Additional information is available in the article "Embrittlement of Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Whereas elongation and reduction in area increase continuously with tempering temperature, toughness, as measured by a notched-bar impact test, varies with tempering temperature for most steels, as shown in Fig. 4. Tempering at temperatures from 260 to 320 °C (500 to 610 °F) decreases impact energy to a value below that obtained at about 150 °C (300 °F). Above 320 °C (610 °F), impact energy again increases with increasing tempering temperature. Both plain carbon and alloy steels respond to tempering in this manner. The phenomenon of impact energy minima centered around 300 °C (570 °F) is called tempered martensite embrittlement (TME) or 500 °F embrittlement.

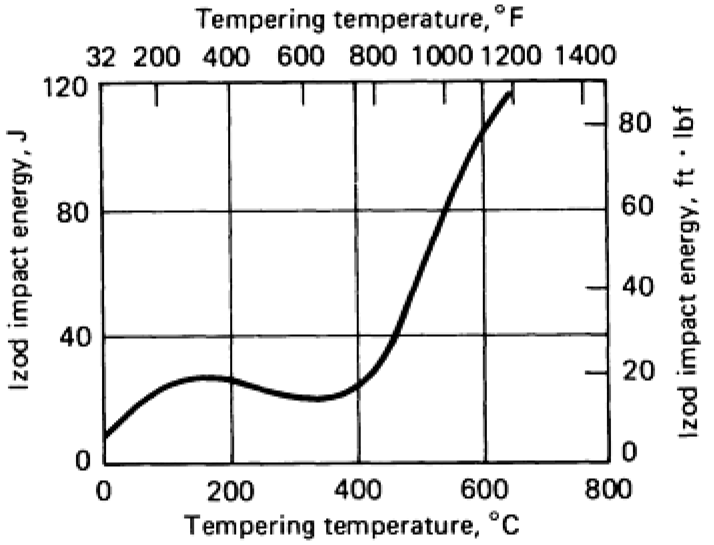

Fig. 4 Notch toughness as a function of tempering temperature for 4140 (UNS G41400) ultrahigh-strength steel tempered 1 h

Tempering Time. The diffusion of carbon and alloying elements necessary for the formation of carbides is temperature and time dependent. The effect of tempering time on the hardness of a 0.82% C steel tempered at various temperatures is shown in Fig. 5. The changes in hardness are approximately linear over a large portion of the time range when the time is presented on a logarithmic scale. Rapid changes in room-temperature hardness occur at the start of tempering in times less than 10 s. Less rapid, but still large, changes in hardness occur in times from 1 to 10 min, and smaller changes occur in times from 1 to 2 h. For consistency and less dependency on variations in time, components generally are tempered for 1 to 2 h. The levels of hardness produced by very short tempering cycles, such as in induction tempering, would be quite sensitive to both the temperature achieved and the time at temperature.

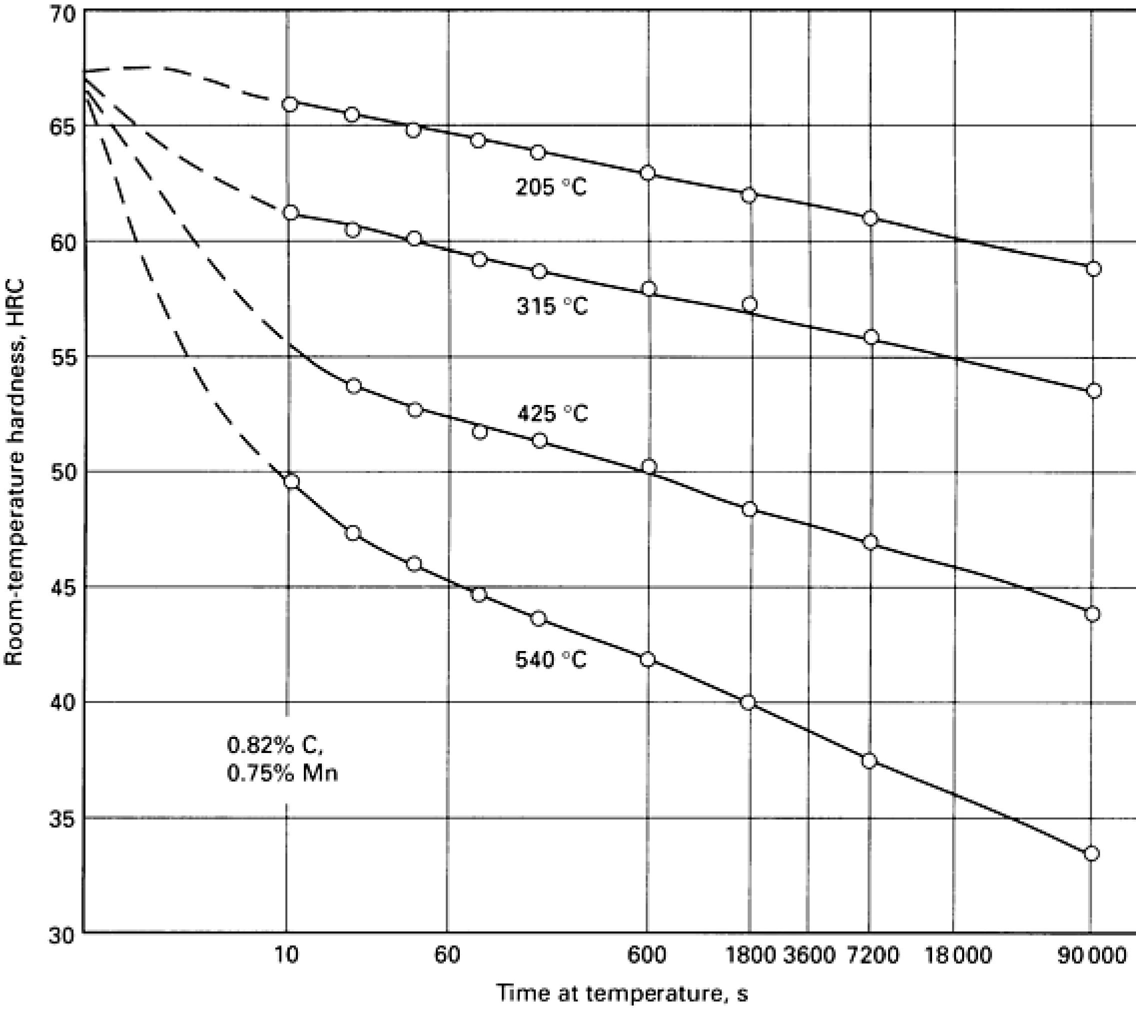

Fig. 5 Effect of time at four tempering temperatures on room-temperature hardness of quenched 0.82% C steel. Note nearly straight lines on logarithmic time scale. Source: Ref 10

By the use of an empirical tempering parameter developed by Holloman and Jaffe (Ref 11), the approximate hardnesses of quenched and tempered low- and medium-alloy steels can be predicted. The parameter is T (c + log t), where T is temperature in degrees Kelvin, t is time in seconds, and c is a constant that depends on the carbon content of the steel. Reasonably good correlations are obtained except when significant amounts of retained austenite are present.

Cooling Rate. Another factor that can affect the properties of a steel is the cooling rate from the tempering temperature. Although tensile properties are not affected by cooling rate, toughness (as measured by notched-bar impact testing) can be decreased if the steel is cooled slowly through the temperature range from 375 to 575 °C (705 to 1065 °F), especially in steels that contain carbide-forming elements. Elongation and reduction in area may be affected also. This phenomenon is called temper embrittlement and is discussed in the section "Temper Embrittlement" in this article. Additional information is available in the article "Embrittlement of Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Carbon Content

The effect of carbon content on the properties of tempered steels is shown in Fig. 6, which presents hardness data for 14 carbon steels that were tempered at temperatures ranging from 205 to 705 °C (400 to 1300 °F) and for times from 10 min to 24 h. The principal effect of carbon content is on as-quenched hardness. Figure 7 shows the relationship between carbon content and the maximum hardness that can be obtained upon quenching. The relative difference in hardness compared with as-quenched hardness is retained after tempering. Figure 8 shows the combined effect of time, temperature, and carbon content on the hardness of three carbon-molybdenum steels of different carbon contents. Figure 9 shows the hardness of these steels after tempering for 1 h, as a function of tempering temperature. The effect of carbon content is evident.

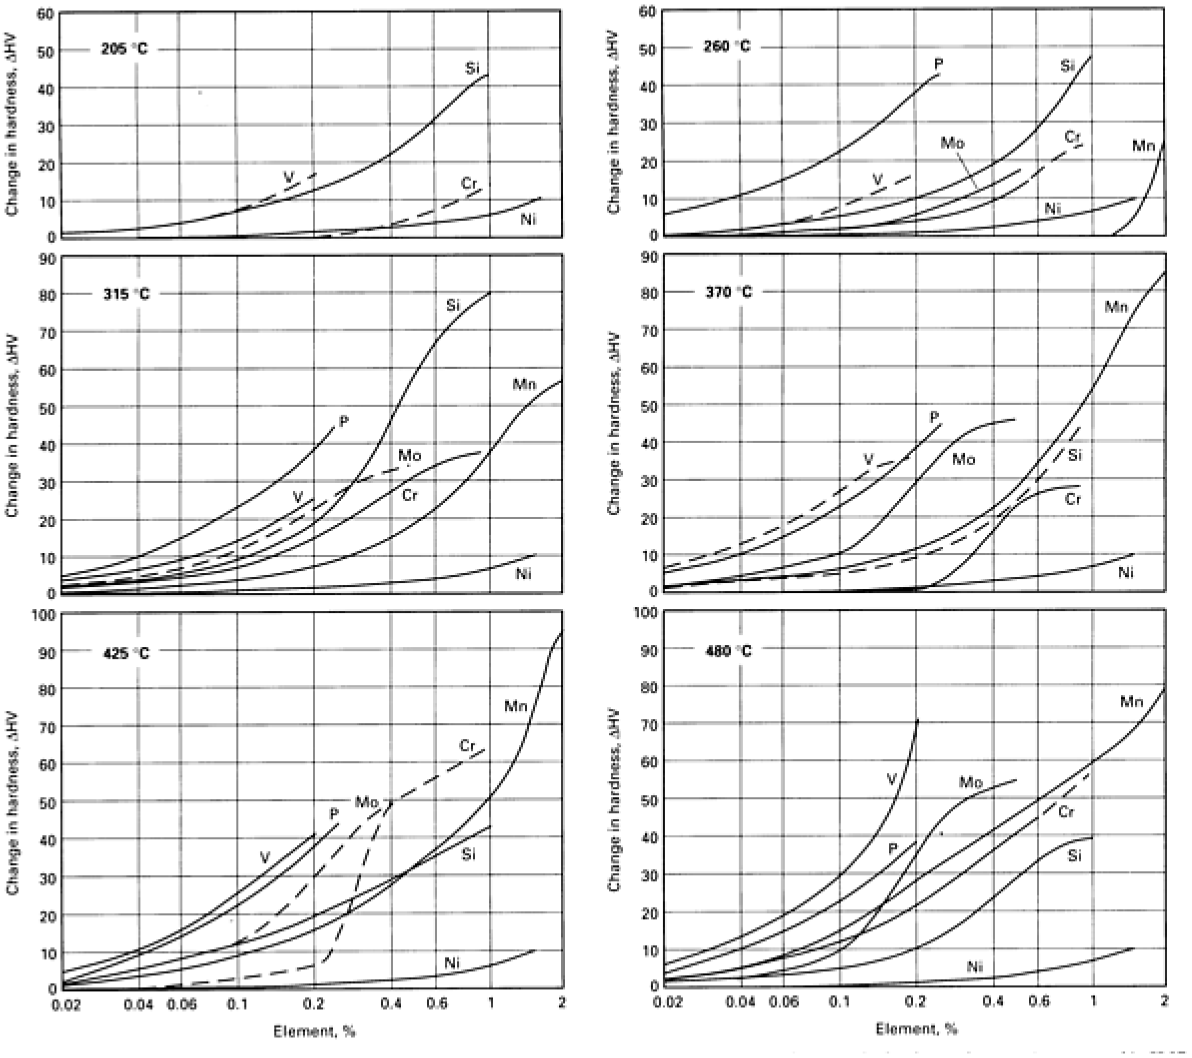
Alloy Content

The main purpose of adding alloying elements to steel is to increase the hardenability, that is, the capability of the steel to form martensite upon quenching from above its critical temperature. The general effect of alloying elements on tempering is a retardation of the rate of softening, especially at the higher tempering temperatures. Thus, to reach a given hardness in a given period of time, alloy steels require higher tempering temperatures than do carbon steels. Alloying elements can be characterized as carbide forming or non-carbide forming. Elements such as nickel, silicon, aluminum, and manganese, which have little or no tendency to occur in the carbide phase, remain essentially in solution in the ferrite and have only a minor effect on tempered hardness. Hardening due to the presence of these elements occurs mainly through solid-solution hardening of the ferrite or matrix grain size control. The carbide forming elements (chromium, molybdenum, tungsten, vanadium, tantalum, niobium, and titanium) retard the softening process by the formation of alloy carbides. The effect of the carbide-forming elements is minimal at low tempering temperatures where Fe_3C forms; however, at higher temperatures, alloy carbides are formed, and hardness decreases slowly with tempering temperature.

The increase in hardness due to the addition of alloying elements was plotted as a percent alloying element for various tempering temperatures from 205 to 705 °C (400 to 1300 °F). These graphs are shown in Fig. 10.



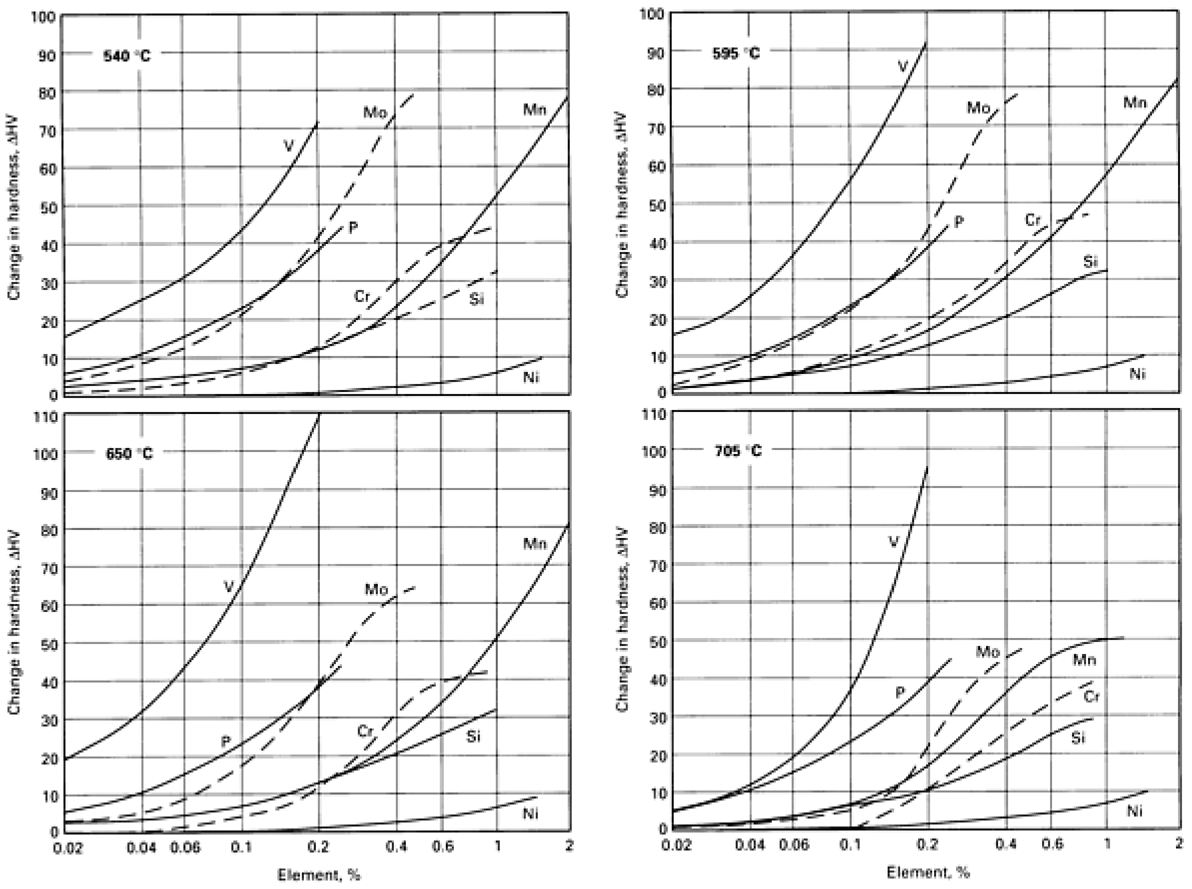


Fig. 10 Effect of seven elements (chromium, manganese, molybdenum, nickel, phosphorus, silicon, and vanadium) on the hardness of martensite tempered in 55 °C (100 °F) increments ranging from 205 to 705 °C (400 to 1300 °F), each for a 1-h duration. Note that manganese, molybdenum, and phosphorus have no effect on hardness at 205 °C (400 °F). Source: Ref 13

Strong carbide-forming elements such as chromium, molybdenum, and vanadium are most effective in increasing hardness at higher temperatures above 205 °C (400 °F). Silicon was found to be most effective in increasing hardness at 315 °C (600 °F). The increase in hardness caused by phosphorus, nickel, and silicon can be attributed to solid-solution strengthening. Manganese is more effective in increasing hardness at higher tempering temperatures. The carbide-forming elements retard coalescence of cementite during tempering and form numerous small carbide particles. Under certain conditions, such as with highly alloyed steels, hardness may actually increase. This effect, mentioned previously, is known as secondary hardening.

The effect of molybdenum content on the tempering behavior of a 0.35% C steel is shown in Fig. 11. As the alloy content increases, the magnitude of the secondary-hardening effect increases. Synergistic effects of various combinations of alloying elements can occur: Chromium tends to produce secondary hardening at a lower temperature than does molybdenum, and the combination of chromium and molybdenum produces a rather flat tempering curve, with the peak hardness occurring at a somewhat lower temperature than when only molybdenum is present. H11 steel is a widely used hot-working die steel that contains nominally 0.35% C, 5% Cr, 1.5% Mo, and 0.4% V. Figure 12 shows the room-temperature hardness of H11 as a function of tempering temperature. A very flat tempering curve results because of the specific combination of the three carbide-forming elements.

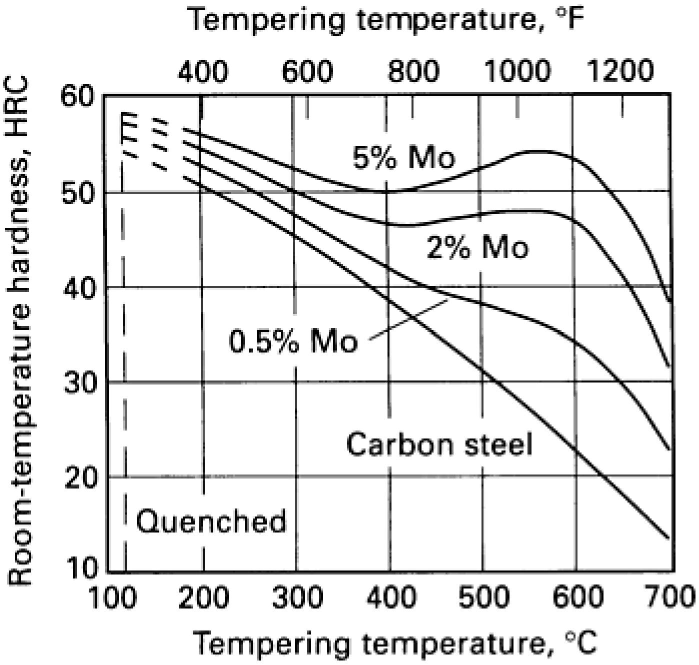

Fig. 11 Influence of molybdenum content on the softening of quenched 0.35% C steels with increasing tempering temperature. Source: Ref 10

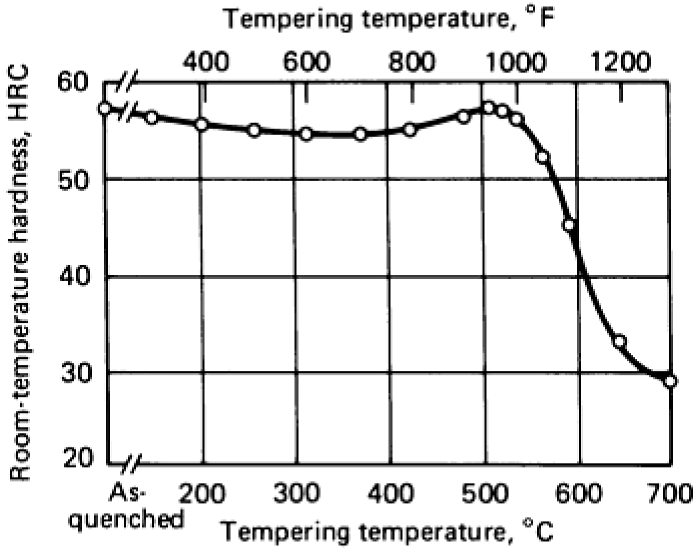

Fig. 12 Variation of room-temperature hardness with tempering temperature for H11 steel. All specimens air cooled from 1010 °C (1850 °F) and double tempered 2 h plus 2 h at temperature

Tool Steels and Stainless Steels. Extensive data on the tempering of tool steels (including H11) and martensitic stainless steels are given in the articles "Introduction to Heat Treating of Tool Steels", "Heat Treating of Specific Classes of Tool Steels", "Heat Treating of Stainless Steels", and "Heat Treating of Superalloys" in this Volume. Additional information is available in the Section "Specialty Steels and Heat-Resistant Alloys" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Other Alloying Effects. In addition to ease of hardening and secondary hardening, alloying elements produce a number of other effects. The higher tempering temperatures used for alloy steels presumably permit greater relaxation of residual stresses and improve properties. Furthermore, the hardenability of alloy steels requires use of a less drastic

quench so that quench cracking is minimized. However, higher hardenability steels are prone to quench cracking if the quenching rate is too severe. The higher hardenability of alloy steels may also permit the use of lower carbon content to achieve a given strength level but with improved ductility and toughness.

Residual Elements. Residual elements, that is, elements not intentionally added to a steel, can cause embrittlement. The elements that are known to cause embrittlement are tin, phosphorus, antimony, and arsenic. A discussion of the specific effects of these elements can be found in the section "Temper Embrittlement" in this article.

Tempering Procedures

Tempering can be accomplished by soaking entire parts in the furnace for enough time to bring the tempering mechanism to the desired point of completion or by selective heating of certain portions of the part to achieve toughness or plasticity in those areas.

Bulk processing may be done in convection furnaces or in molten salt, hot oil, or molten metal baths. The selection of furnace type depends primarily on number and size of parts and on desired temperature. Table 2 gives temperature ranges, most likely reasons for use, and fundamental problems of these four types of equipment.

Table 2 Temperature ranges and general conditions of use for four types of tempering equipment

Type or equipment	Temperature range		Service conditions
	°C	°F	
Convection furnace	50-750	120-1380	For large volumes of nearly common parts; variable loads make control of temperature more difficult
Salt bath	160-750	320-1380	Rapid, uniform heating; low to medium volume; should not be used for parts whose configurations make them hard to clean
Oil bath	≤ 250	≤ 480	Good if long exposure is desired; special ventilation and fire control are required
Molten metal	>390	>735	Very rapid heating; special fixturing is required (high density)

Selective tempering techniques are used to soften specific areas of fully hardened parts or to temper areas that were selectively hardened previously. The purpose of this treatment is to improve the machinability, the toughness, or the resistance to quench cracking in the selected zone.

Induction and flame tempering are the most commonly used selective techniques because of their controllable local heating capabilities. The immersion of selected areas in molten salt or molten metal can be accomplished, but with somewhat less control.

Special processes are employed occasionally to achieve specific properties such as those derived from steam treating or the use of protective atmospheres.

The tempering mechanism in certain steels is enhanced by cyclic heating and cooling. A particularly important procedure employs cycles between subzero temperatures and the tempering temperature to increase the transformation of retained austenite. The term used for this procedure, multiple tempering, is also applied to procedures that use intermediate thermal cycles to soften parts for straightening prior to the actual tempering operation designed to achieve the desired degree of toughness and plasticity.

Equipment for Tempering

Steel is usually tempered in either an air (convection) furnace or a salt bath (Fig. 13). Molten metal baths, oil baths, and flame or induction heating units are also used.

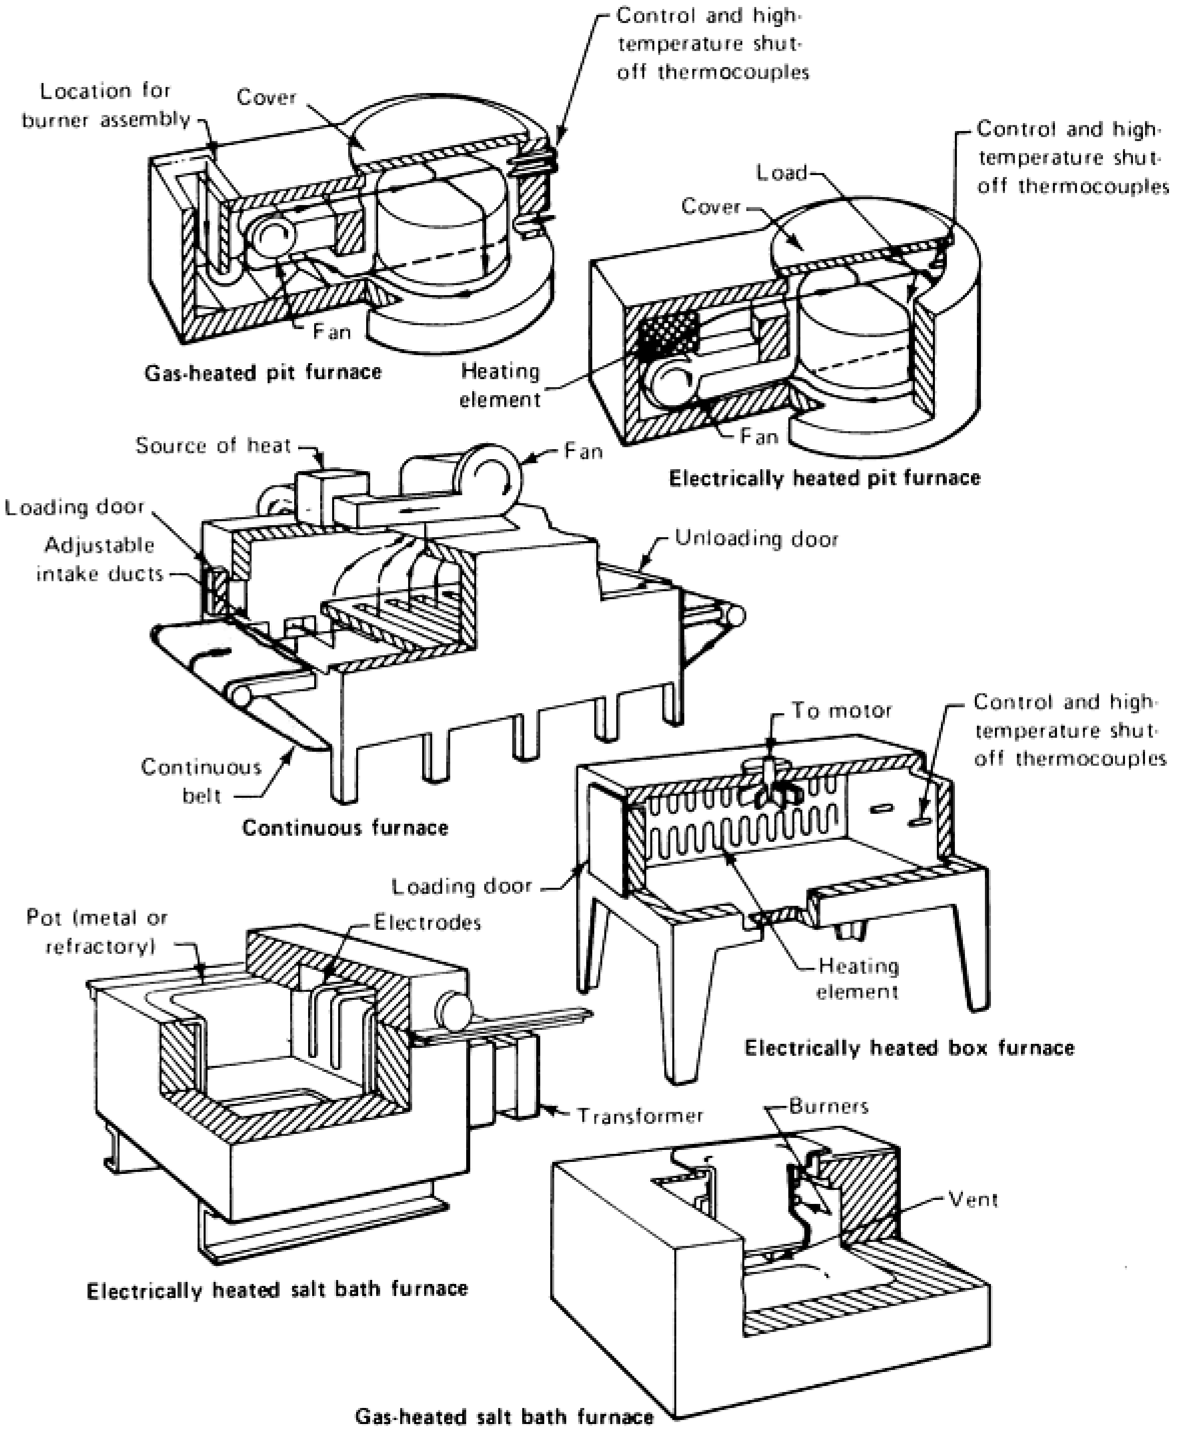

Fig. 13 Types of furnaces used for tempering of steel

Convection Furnaces. The most commonly employed tempering method utilizes the recirculating or forced-air convection furnace, and the equipment most commonly used in conjunction with convection furnaces includes continuous belt conveyor, roller rail, or dog beam pusher systems. Batch equipment such as box or pit types are also used.

Forced recirculating air is the most common and efficient method of tempering because it lends itself to a wide selection of furnace designs to accommodate a variety of products and capacities. Moreover, the metallurgical results are very good in terms of price per unit weight of yield.

Generally, convection furnaces are designed for tempering temperatures of 150 to 750 °C (300 to 1380 °F). For temperatures up to 550 °C (1020 °F), recirculated hot air is supplied to the product from a chamber separate from the work-holding area to avoid uneven heating by radiation. For temperatures of 550 to 750 °C (1020 to 1380 °F), either forced convection or radiant heating is used, depending on the metallurgical requirements of the product. To obtain closer control of metallurgical properties, recirculated forced hot air is employed; but for greater efficiency, radiant heating is used because the transfer of radiant heat is greater as the temperature approaches 750 °C (1380 °F).

The most important phase of convection furnace design is determining the proper amount of forced air. The objective of the blower is to furnish enough hot air to the complete work area so that it is efficiently used to heat the product in the shortest time thermophysically allowed. The type of product and the material being processed dictate the required forced-air supply, which is measured at the operating temperature. Consultation with fan manufacturers can help achieve maximum efficiency of heat transfer.

Heat for the furnace can be supplied by electricity, gas, or oil. In most furnace designs, a dual heat source capability can be built in, such as gas and electricity. This allows for more than one choice of utility when there is a shortage or a cost advantage of one over the other.

Temperature control is accomplished by positioning a thermocouple at the hot-air side of the recirculating system close to the product. When this technique is used, there is minimal danger of overheating, and loads of various sizes can be handled. This method also allows the duration of processing (holding time) to be varied by moving the thermocouple location, but only within the limits of the furnace size (and/or conveyor speed, for continuous-type furnaces). Temperatures generally are held within ±5 °C (±9 °F). If modern temperature controllers are used, baffle plates are positioned properly and furnace curtains are installed.

The efficient use of a continuous furnace cannot be attained when production quantities are small or when parts vary in size, shape, and mechanical requirements. A batch furnace is better suited for work of this type. When a continuous furnace is used for such applications, production time is lost when the furnace temperature is raised or lowered. Sometimes, when the process variables must be changed, a dummy load must be placed in the furnace to accelerate a desired reduction of temperature, or production must be stopped until the temperature is stabilized.

Salt bath furnaces may be used for tempering at 160 °C (320 °F) and above. Good heat transfer and natural convection in the bath promote the uniformity of workpiece temperature.

All moisture must be removed from parts before they are immersed in the molten salt because hot salt reacts violently with moisture. If dirty or oily parts are immersed in the bath, the salt will become contaminated and will require more frequent rectification. Rectification with chemical or gaseous compounds controls the soluble oxides within proper limits. A carbon rod rectification procedure is used to remove the insoluble metallics.

All parts tempered in salt must be cleaned soon after being removed from the bath because the salt that clings to them is hygroscopic and may cause severe corrosion. Parts with small or blind holes from which salt is difficult to clean should not be tempered in salt. Additional information is available in the article "Salt Bath Equipment" in this Volume.

Salt bath compositions and operating temperature ranges presented in Table 3 pertain to baths in common use for tempering and are classified according to Military Specification MIL-S-10699A (Ordnance).

Table 3 Compositions and operating temperatures for salt baths used in tempering

Class	Composition of bath, %								Operating temperature		Fuming temperature	
	$NaNO_2$	$NaNO_3$	KNO_3	Na_2CO_3	NaCl	KCl	$BaCl_2$	$CaCl_2$	°C	°F	°C	°F
1	37-50	0-10	50-60	. . .	. . .	. . .	. . .	. . .	165-595	325-1100	635	1175
2	. . .	45-57	45-57	. . .	. . .	. . .	. . .	. . .	290-595	550-1100	650	1200
3	. . .	. . .	. . .	45-55	. . .	45-55	. . .	. . .	620-925	1150-1700	935	1720
4	. . .	. . .	. . .	. . .	15-25	20-32	50-60	. . .	595-900	1100-1650	940	1725
4A	. . .	. . .	. . .	. . .	10-15	25-30	40-45	15-20	550-760	1025-1400	790	1450

Class 1 and class 2 salts are reasonably stable and seldom require rectification. If chlorides are added by carryover from a higher-temperature bath, they will cause an increase in the viscosity of the bath. Chlorides can be removed by filtering through fine screens or by cooling and settling out the insoluble chlorides as a sludge. Occasionally, carbonates become excessive. These can be removed by reaction with dilute nitric acid-base rectifiers. Upper temperature limits must not be exceeded or salt will become highly oxidizing, even toward alloy steels.

Class 3 salts seldom require rectification. However, their high melting points (about 560 °C, or 1040 °F) severely restrict their useful temperature range. Also, they are decarburizing to steels at temperatures above about 705 °C (1300 °F).

Class 4 salts, which are all-chloride neutral salts, are quite stable. They seldom require rectification but are restricted to temperatures above 595 °C (1100 °F).

Class 4A salts are close relatives of class 4 salts but contain calcium chloride, which lowers the minimum working temperature to 550 °C (1025 °F). The upper limit for these salts is more restricted than that for class 4 salts.

Commercial Availability. All of the salts for these baths are commercially available. The reader is referred to the military specification cited above for the chemical and other control procedures applicable to the various bath composition. For additional information, see the articles"Martempering of Steel", "Austempering of Steel" , "Introduction to Heat Treating of Tool Steels", and "Heat Treating of Specific Classes of Tool Steels" in this Volume.

Caution: The introduction of cyanide salts or other reducing agents into nitrite tempering baths will cause violent explosions.

Oil bath equipment for tempering may be similar in design to that used for salt baths, or a steel tank over hot plate burners will serve satisfactorily. Submerged electric heating elements may also be employed. Stirring is essential for temperature uniformity and satisfactory oil life. Simple, oven-type temperature controls may be employed but localized overheating must be avoided to prevent fire and the rapid decomposition of the oil. A standard thermometer of the proper range may be used to check the temperature of the oil.

Low-temperature tempering in a hot oil bath is a simple and inexpensive method that is especially useful for holding work at temperature for long periods of time. The practical temperature limit is about 120 °C (250 °F) without special ventilation or fire protection equipment and about 250 °C (480 °F) with such precautions, which may include extremely efficient ventilators or inert-gas blanketing systems. When a tempering temperature above 205 °C (400 °F) is required, a salt bath is usually preferable to an oil bath.

Oils for tempering must resist oxidation and have a flash point well above the operating temperature. The most commonly used oils are high-flash-point paraffinic oils with antioxidant additives. Oils used for martempering (see the article "Martempering of Steel" in this Volume) are also satisfactory for tempering.

Molten metal baths for tempering have largely been replaced by salt baths. When employed, commercially pure lead, which melts at about 327 °C (620 °F), has proved to be the most generally suitable of all metals and alloys. For special applications, however, lead-base alloys having lower melting points are used.

Lead oxidizes readily. Although lead itself will not adhere to clean steel, the adherence of lead oxide to steel surfaces is a problem, especially at higher temperatures. Within the range of temperatures usually employed, a film of molten salt will protect the surface of the lead bath, and the work will be easily cleaned. Above 480 °C (900 °F), granulated carbonaceous material, such as charcoal, may be used as a protective cover.

Because of its high thermal conductivity relative to the gaseous atmosphere, lead is useful for rapid local heating and selective tempering. A typical application is the tempering of a ball joint. The part is carburized and quenched to a minimum case hardness of 59 HRC and a core hardness of 30 to 40 HRC. The thread and taper are then tempered in lead to produce a maximum case hardness of 40 HRC.

Because of the high specific gravity of lead, parts tempered in molten lead will float unless held down by fixtures. All parts and fixtures must be dry when immersed in the bath to prevent the formation of steam in, and resultant violent expulsion of, the molten lead. Precautions also must be taken to protect personnel from industrial lead poisoning; hoods and ventilating equipment are required.

Temperature Control. For either gas or electric heat, properly adjusted potentiometers of the on-off type will control the tempering temperature within ±6 °C (±10 °F) at the thermocouple location. With proportioning controls, these instruments can maintain temperatures within ±1 °C (±2 °F) at the thermocouple location.

Selection of Tempering Equipment

The selection of equipment for tempering is based principally on the temperature requirements and the quantity and similarity of the work to be treated. Temperature requirements are dictated by prior heat treatment and by the properties to be developed by tempering.

Process Control

Variations in hardness after tempering are most frequently the result of differences in prior microstructure, as discussed previously. When prior microstructure is the same, the control of temperature is the most important factor in the control of the tempering process.

In general, the control of tempering temperature to within ±13 °C (15 °F) is adequate and is within the practical limits of most furnace and molten-bath equipment. Temperature variations are seldom permitted to exceed ±6 °C (±10 °F) unless mechanical property requirements are correspondingly broad. Examples of the range of variation in hardness obtained after tempering for a variety of wrought and cast steel parts are presented in Fig. 14, 15, and 16.

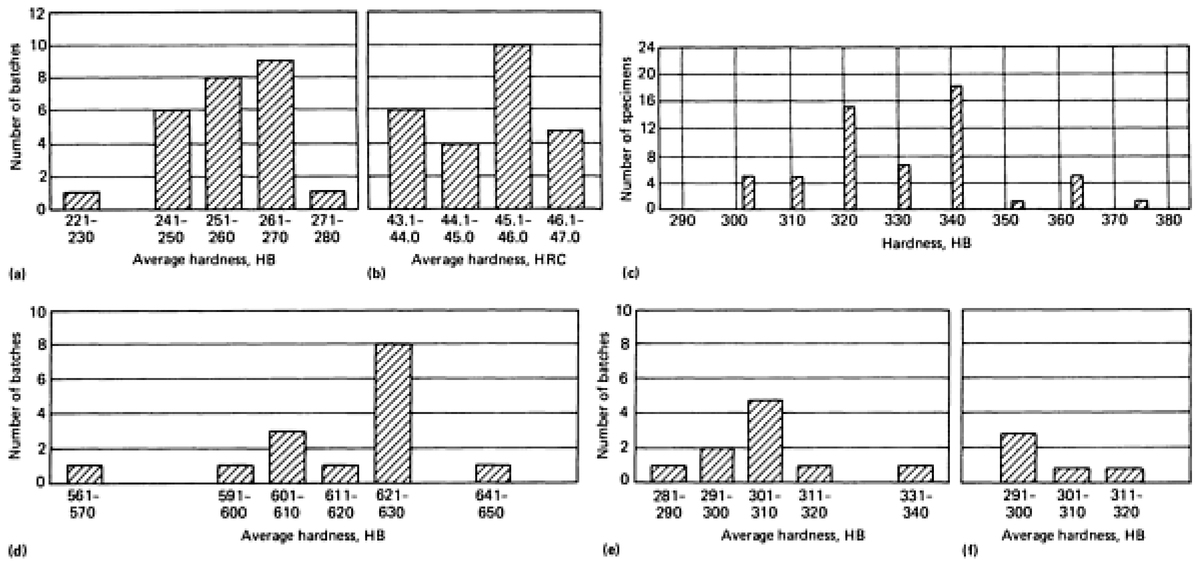

Fig. 14 Variations in room-temperature hardness of three carbon steels after production tempering. (a) Automotive steering-arm forgings made of fine-grain 1035 steel. Section thickness varied from 16 to 29 mm ($\frac{5}{8}$ to $1\frac{1}{8}$ in.). Forgings were austenitized at 825 °C (1520 °F) in oil-fired pusher conveyor furnace, held 45 min, quenched in water at 21 °C (70 °F), and tempered 45 min at 580 to 625 °C (1080 to 1160 °F) in oil-fired link-belt furnace to required hardness range of 217 to 285 HB. Hardness was checked hourly with a 5% sample; readings were taken on polished flash line of 29 mm ($1\frac{1}{8}$ in.) section. Survey of furnace revealed temperature variation at 605 °C (1120 °F) of 8, -4 °C (15, -7 °F). Data represent forgings from four mill heats of steel and cover a 6-week period. (b)Woodworking cutting tools forged from 1045 steel. Section of cutting lip was hardened locally by gas burners that heated the steel to 815 °C (1500 °F). Tools were oil quenched and tempered at 305 to 325 °C (585 to 615 °F) for 10 min in electrically heated recirculating-air furnace to a desired hardness range of 42 to 48 HRC. Data were recorded during a 6-month period and represent forgings from 12 mill heats. (c) Plate sections, 19 to 22 mm ($\frac{3}{4}$ to $\frac{7}{8}$ in.) thick, of 1045 steel were water quenched to a hardness range of 534 to 653 HRB and tempered 1 h at 475 °C (890 °F) in continuous roller-hearth furnaces. Data represent a 2-month production period. (d) Forged 1046 steel heated to 830 °C (1525 °F), and quenched in caustic. Forgings were heated in a continuous belt-type furnace and individually dump quenched in agitated caustic. Forgings weighed 9 toll kg (20 to 24 lb) each; maximum section, 38 mm ($1\frac{1}{2}$ in.). (e) As-quenched forged 1046 steel shown in (d), tempered at 510 °C (950 °F) for 1 h. (f) As-quenched forged 1046 steel shown in (d), tempered at 525 °C (975 °F) for 1 h. Average hardness data for all but (C) obtained by calculating average of high and low extremes of hardness specification range for each batch.

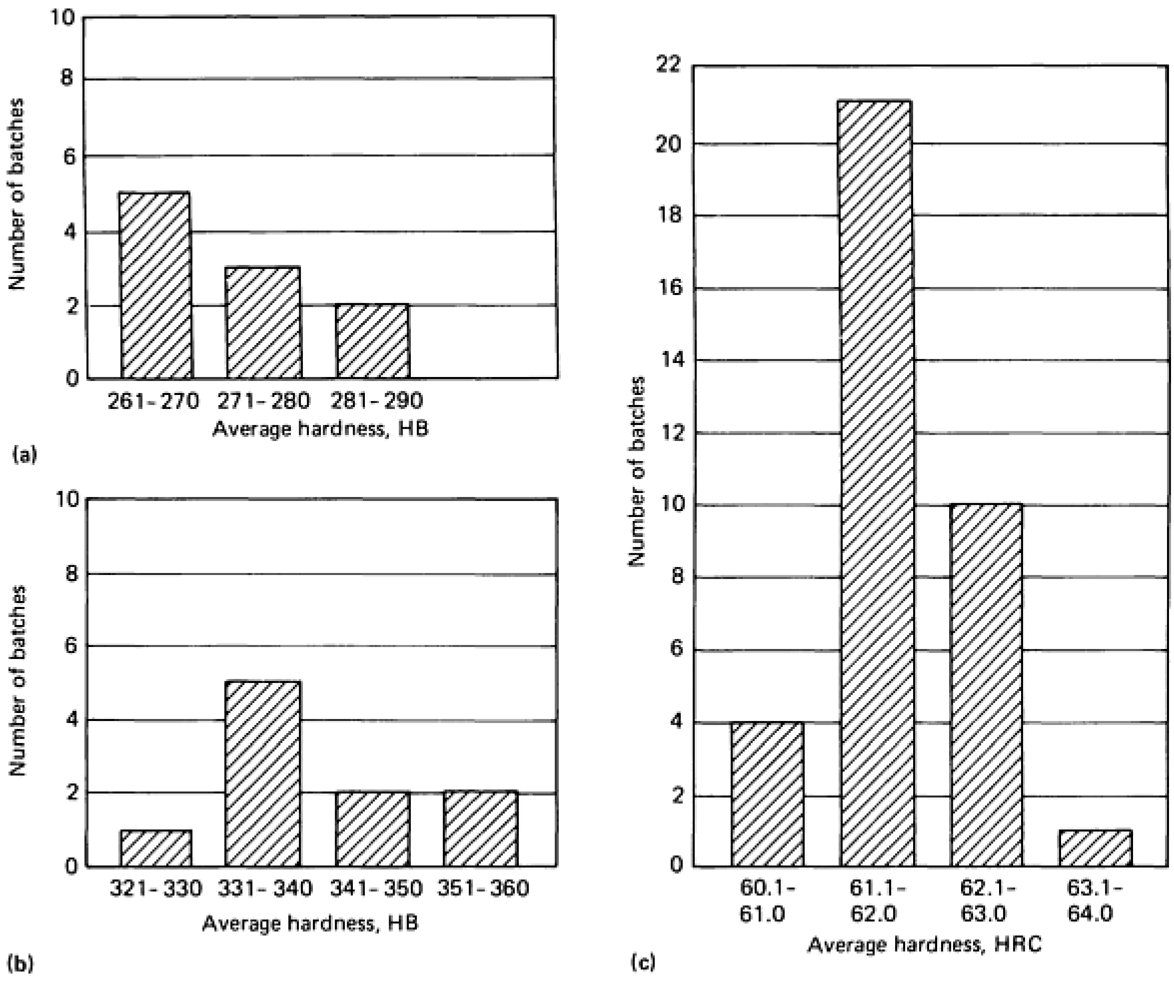

Fig. 15 Variations in room-temperature hardness of two alloy steels after production tempering. (a) Valve bonnets, 75 mm (3 in.) in diameter, made of 4140 steel from one mill heat. Parts were heated at 870 °C (1600 °F), oil quenched and tempered for 2 h at 605 °C (1125 °F) to a hardness specification of 255 to 302 HB. (b) Valve segments made of 4140 steel from one mill heat. Section thickness varied from 13 to 25 mm ($\frac{1}{2}$ to 1 in.). Parts were heated at 870 °C (1600 °F), oil quenched and tempered for 2 h at 580 °C (1075 °F) to a hardness specification of 321 to 363 HB. (c) Needle rollers made of E50100 steel wire varying in diameter from 2.2 to 2.6 mm (0.086 to 0.103 in.). Data represent 36 batches of parts (nine mill heats of steel) tempered to a hardness specification of 60 to 64 HRC. Each batch represents a minimum furnace load of 270 kg (600 lb). Average hardness data obtained by calculating average of high and low extremes of hardness specification range for each batch

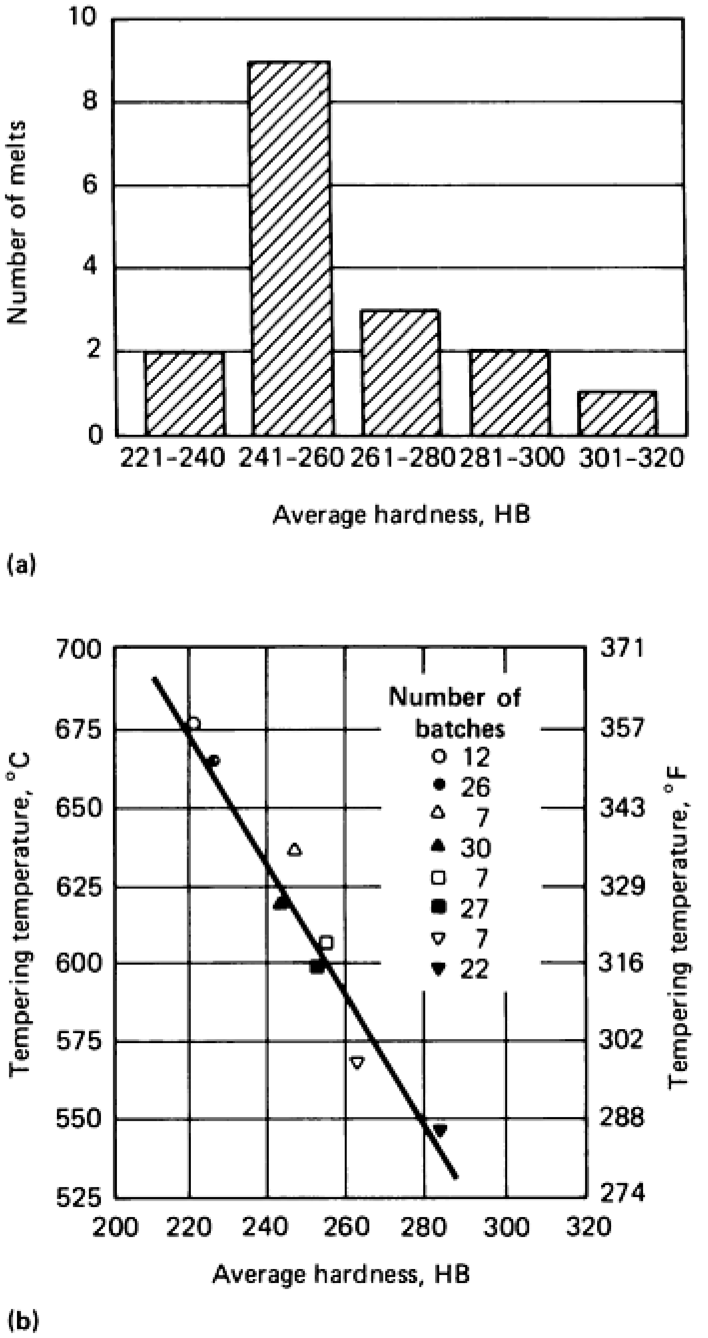

Fig. 16 Variations in room-temperature hardness of two cast steels after production tempering. (a) Cast C-V steel containing 0.25 to 0.30% C, 0.70 to 0.80% Mn, 0.08 to 0.12% V, and 0.40 to 0.60% Si, 25 mm (1 in.) thick, water quenched from 870 °C (1600 °F) and then tempered at 605 °C (1125 °F). Sample size was 17 batches. (b) Cast nickel-chromium-molybdenum steel containing 0.28 to 0.33% C, 0.70 to 0.90% Mn, 0.40 to 0.70% Ni, 0.40 to 0.60% Cr, 0.15 to 0.25% Mo, and 0.40 to 0.60% Si. Spread of hardness readings for various tempering temperatures

Tempering of Special Microstructures

Carburized Components. The tempering of carburized parts represents a special instance in that the combination of toughness, strength, hardness, residual stress, and retained austenite must be considered when selecting tempering time and temperature. Core properties cannot always be controlled by tempering when trying to achieve maximum case properties, and a favorable compressive residual stress pattern may be retained only at the expense of overall toughness.

The effect of tempering on the hardness of carburized cases is shown in Fig. 17, and the influence of tempering on residual stress is shown in Fig. 18. The transformation of retained austenite and the resultant change in the relative

volume of case and core are primarily responsible for the change in residual stress as a function of temperature. The effect of retained austenite on the performance of components is still a controversial issue. The reduction of retained austenite is apparently desirable for resistance to grinding abuse and to provide dimensional stability, but some retained austenite appears to be beneficial for contact-fatigue durability.

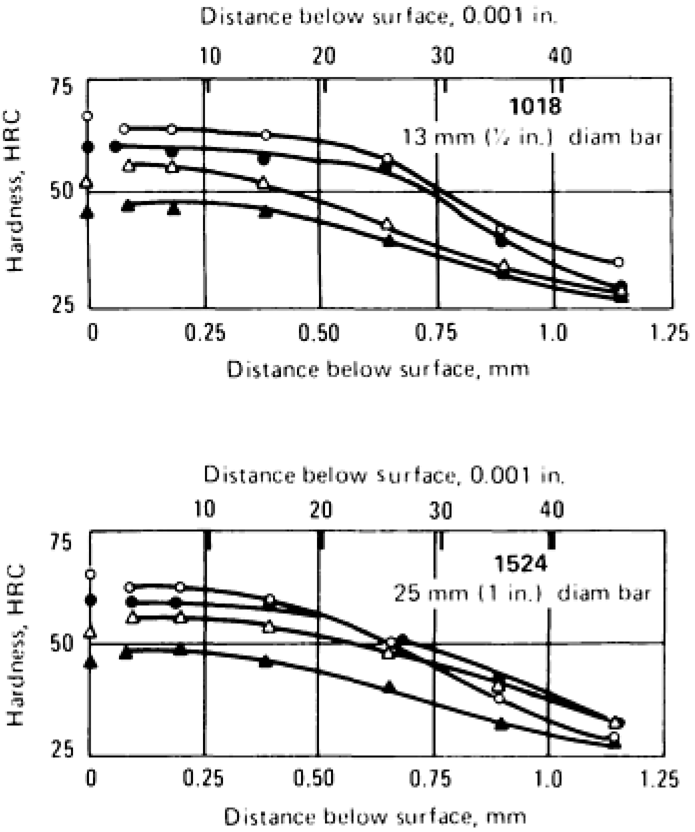

Fig. 17 Effect of tempering on room-temperature hardness of carburized cases. Carburized for 4.5 h at 925 °C (1700 °F), oil quenched and tempered. Data points: open circles, as quenched; closed circles, tempered at 205 °C (400 °F); open triangles, tempered at 315 °C (600 °F); closed triangles, tempered at 425 °C (800 °F)

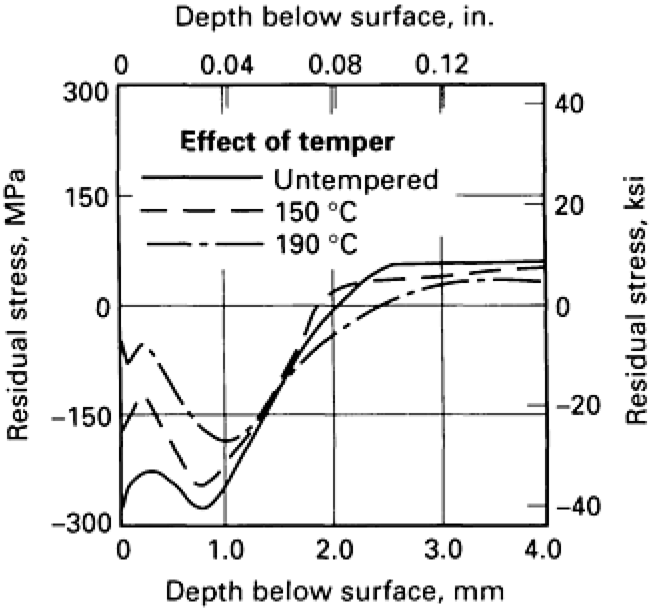

Fig. 18 Effect of tempering on residual stress in carburized steel. Bars of 8617 steel, 19 mm (0.75 in.) in

diameter, were carburized, direct oil quenched, and tempered for 1 h at the indicated temperature.

Nonmartensitic Structures. The tempering of microstructures other than martensite and retained austenite also represents special applications of tempering. Reactions of structures containing substantial amounts of lower bainite are relatively similar to that of martensite in terms of the phenomena associated with carbide growth and coalescence.

Upper bainite and fine pearlite formed by controlled or relatively slow cooling simply respond by carbide growth and eventual ferrite recrystallization. The softening associated with tempering in such instances is shown in Fig. 19. Impact properties of normalized and tempered and hardened and tempered structures at nearly equal hardnesses are shown in Fig. 20.

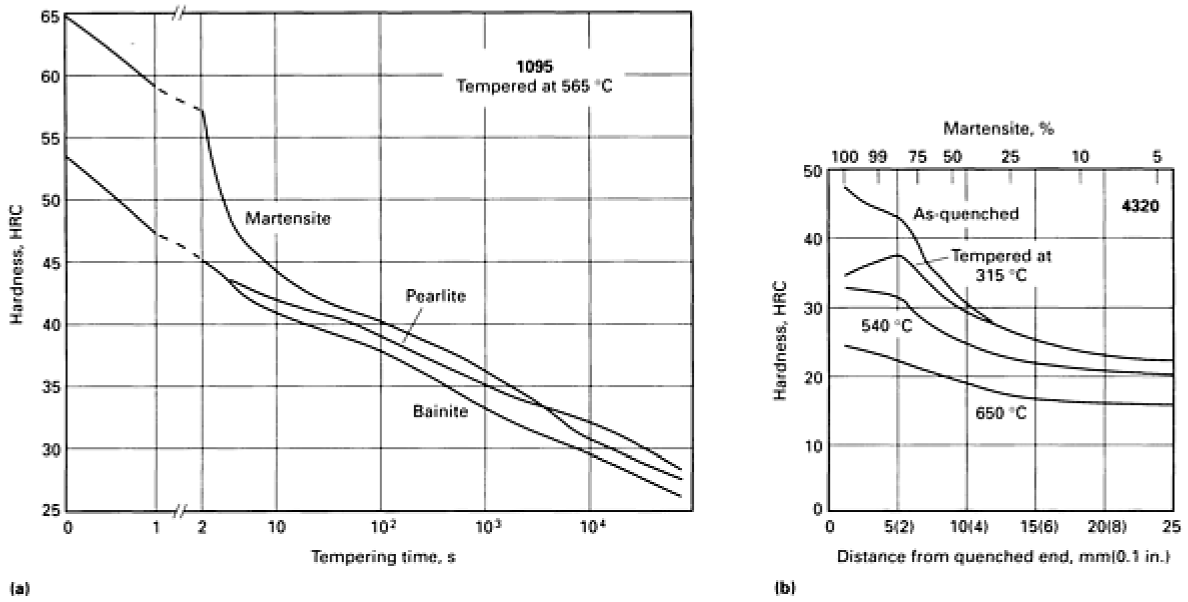

Fig. 19 Effect of prior microstructure on room-temperature hardness after tempering. (a) 1095 steel tempered at 565 °C (1050 °F) for various periods of time. (b) Room-temperature hardness before and after tempering, as well as amount of martensite present before tempering in 4320 steel end-quenched hardenability specimens tempered 2 h

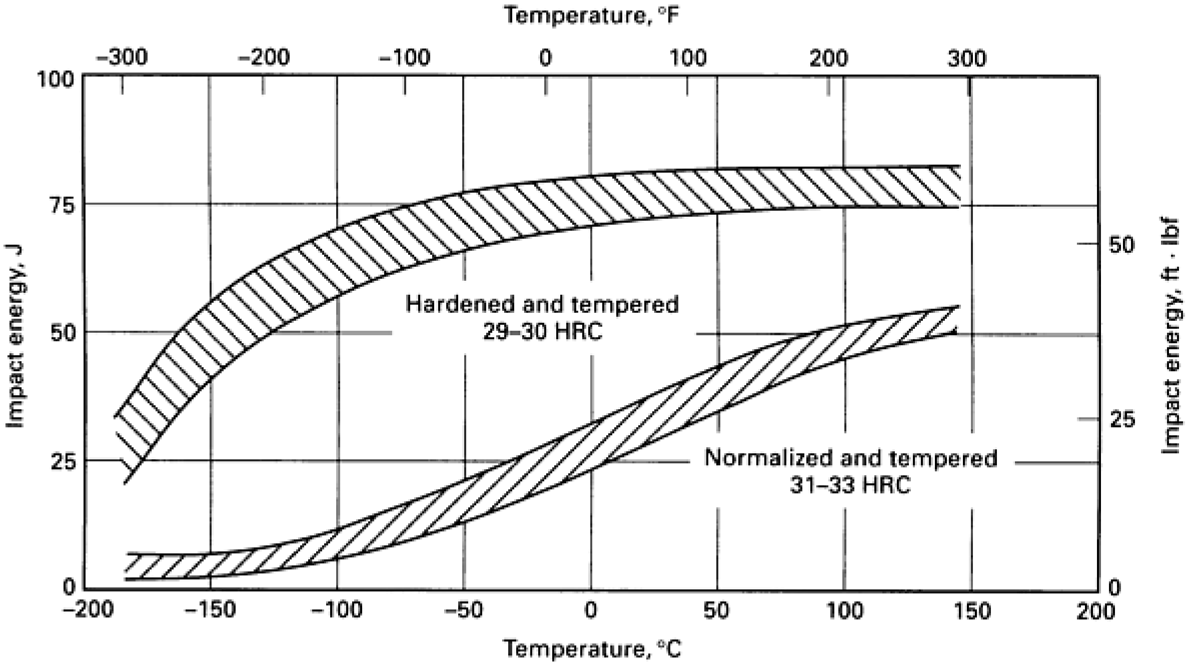

Fig. 20 Effect of microstructure on notch toughness. Variation in Charpy keyhole-notch impact energy with temperature for 4340 steel hardened and tempered to 29 to 30 HRC or normalized and tempered to 31 to 33 HRC

Induction Tempering

Extensive production experience has demonstrated the commercial success of induction tempering for many applications. Metallurgically, the success of induction tempering has been related fundamentally to the possibility of compensating for short tempering times with higher tempering temperatures. Economically, induction tempering has proved particularly adaptable to automation in production lines.

Application. At present, two principal areas of application exist for induction tempering:

- Selective tempering
- Progressive tempering of bar stock previously hardened by scanning

Many machine parts vary from one section to another with respect to load and wear requirements. Often, this variation in requirements is met by a compromise of properties obtained by uniform tempering to a single hardness level. However, it is apparent that superior performance might be expected if the mechanical properties could be adjusted to meet the particular requirements in each section by selective tempering. Within certain limitations, induction tempering is an economical means of accomplishing this. These limitations are that the parts must be of such a shape and size that they can be coupled by the inductor to heat uniformly to the desired temperature in critical sections. Although this is impossible or impracticable for some parts, many can be tempered selectively by induction to obtain different degrees of hardness in the same part, with a consequent improvement in quality.

Advantage. The principal advantage of induction tempering is the possibility of integration with machine lines to avoid excessive handling of work, thereby minimizing labor cost. This is illustrated in the preparation of bar stock of specified mechanical properties before machining into cylinder-head studs and miscellaneous machine parts. Frequently, the tempering operation is keyed to the hardening operation, or the same equipment may be used for both induction hardening and tempering either by merely changing the work coil or by reducing the power density and the heating time.

Selection of Frequency and Power Densities. Because tempering is performed below the lower transformation temperature 725 °C (1335 °F), lower-frequency induction tempering installations are generally used; such installations are necessary for tempering large sections to minimize any temperature gradient from the surface to the interior. Frequency

selection is basically related to the required depth of heating (see the article "Induction Heat Treating of Steel" in this Volume). It should be noted that line frequencies (60 Hz) may be used for tempering parts 25 to 50 mm (1 to 2 in.) in diameter or larger.

Because the usual objective of induction tempering is to produce uniform hardness throughout the cross section, rather than to heat the surface, the power density within the inductor is generally low, from 0.08 to 0.8 W/mm^2 (0.05 to 0.5 kW/in.^{2}). Power densities may be selected on the basis of experience, tests, or data such as those presented in Table 4. Furthermore, the heating time is comparatively long to help provide uniform heating throughout the part. To meet production requirements, length of the inductor can be increased, or more than one bar can be processed at a time.

Table 4 Approximate power density required for tempering

Frequency[(a)], Hz	**Input[(b)]**			
	W/mm^2		**kW/in.^{2}**	
	150-425 °C (300-800 °F)	**425-705 °C (800-1300 °F)**	**150-425 °C (300-800 °F)**	**425-705 °C (800-1300 °F)**
60	0.10	0.24	0.06	0.15
180	0.08	0.22	0.05	0.14
1,000	0.06	0.19	0.04	0.12
3,000	0.05	0.16	0.03	0.10
10,000	0.03	0.13	0.02	0.08

(a) Table is based on use of proper frequency and normal overall operating efficiency of equipment.

(b) In general, these power densities are for section sizes of 13 to 50 mm ($\frac{1}{2}$ to 2 in.). Higher inputs can be used for smaller section sizes and lower inputs may be required for larger section sizes.

In general, the control of induction tempering is achieved by selection of the power density and the rate of feed through the coil (scanning) on the basis of hardness tests of the tempered product. Automatic control may be obtained at tempering temperatures above 425 °C (800 °F) by use of a special radiation pyrometer and high-speed controller. This arrangement may be used to vary the speed of the scanning operation continuously or to control the power.

Selection of Induction Tempering Cycle. Fundamentally, the tempering cycle will be determined by the ultimate mechanical properties specified for the part. However, usual furnace tempering temperatures must be increased to compensate for the short heating times.

Figure 21 shows the increase in tempering temperature required to produce a given hardness as the tempering time is decreased from 1 h (furnace tempering) to 60 s and 5 s (induction tempering) in 1050 steel quenched in brine from 855 °C (1575 °F). Pieces with small cross section may be air cooled immediately upon reaching the tempering temperature, while slower heating rates or short periods of time at temperature (5 to 60 s) before cooling are desirable for larger sections to

allow penetration of heat. In scanning, of course, the power density, the rate of travel, and the length of the inductor will determine the time of tempering.

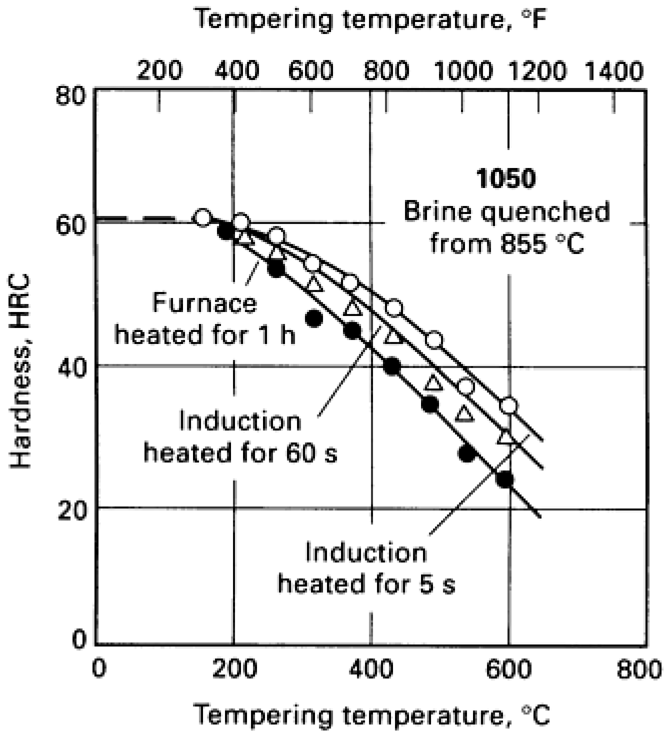

Fig. 21 Variations of room-temperature hardness with tempering temperature for furnace and induction heating

Results of Induction Tempering. Statistical studies over several years on cross-sectional hardnesses for similar bar stock that was induction hardened and tempered by scanning reveal that 67% of all average cross-sectional hardnesses resulted in a hardness spread of ±1.25 Rockwell C points and that approximately 95% were within ±2.5 points. Variations in resultant hardness occur more often from differences in hardenability between respective heats of steel than from discrepancies in the induction tempering process. If each mill beat is run separately, it is possible to compensate for differences in hardenability.

Special Tempering Procedures

Selective Tempering. Selective or localized tempering is applied to parts in which adjacent areas must have significantly different hardnesses. Chisels, punches, the upset ends of cold-formed rivets, and the threaded portions of carburized parts are typical examples. Localized tempering is also employed in preheating and postheating of weld areas when a lowering of the hardness in the beat-affected zone is desired.

Selective tempering entails heating a restricted area to the required tempering temperature without heating the remainder of the part to this temperature. Induction beating coils, special flame heads, and immersion in lead or salt baths are employed to achieve this selective heating. Selective tempering is also done by the use of defocused lasers or electron beam equipment. Induction heating and flame techniques are generally used in high-volume production applications and are easiest to control. Deeper penetration is achieved with low-frequency (3 to 10 kHz) induction heating and salt immersion than is obtained with the other techniques.

To obtain rapid heating for selective tempering by immersion in salt or lead baths, it is usually necessary that the bath temperature be considerably higher than the desired tempering temperature. Consequently, the immersion time becomes the controlling factor in obtaining the desired results. Lead, because of its higher rate of heat transfer, is more effective than salt.

Other factors, such as ease of fixturing, part configuration, heater frequency, and cost, also influence the choice of equipment for selective tempering. In induction tempering, the same heating system can be used for both hardening and tempering.

Both examples below illustrate how selective tempering can be used to produce specific hardnesses in certain areas of a workpiece.

Example 2: Use of Bulk Processing and Selective Tempering to Produce a Tack Hammer with a 50 to 55 HRC Striking Head.

An upholsterer's tack hammer, forged from 1086 steel, is hardened on all surfaces to 53 to 60 HRC and then is tempered in salt at 190 °C (375 °F). This treatment provides the desired combination of hardness, toughness, and magnetic properties for the horseshoe-magnet end of the hammer. However, the striking head must be selectively tempered in salt at 260 °C (500 °F) to produce the working hardness of 50 to 55 HRC.

Example 3: Use of Bulk Processing and Selective Tempering to Produce a Pipe Wrench with 47 to 52 HRC Chain Teeth and a 40 to 48 HRC Handle.

A chain pipe wrench handle forging, made of 4053 steel, is fully hardened and tempered for 1 h at 355 °C (675 °F) to produce an overall hardness of 47 to 52 HRC. This is an ideal hardness for the wrench teeth but does not provide sufficient toughness for the I-beam section of the handle. Thus this section is selectively tempered by induction heating for 1 min at 480 °C (900 °F) to produce a hardness of 40 to 48 HRC.

Multiple tempering is principally used to:

- Relieve the quenching and straightening stresses in irregularly shaped carbon and alloy steel parts and thereby lessen distortion
- Eliminate retained austenite and improve dimensional stability in such parts as bearing components and gear blocks
- Improve yield and impact strengths without decreasing hardness

The following examples illustrate these principal applications of the multiple-tempering process.

Example 4: Use of Multiple Tempering to Relieve Straightening-Induced Stresses in a 1046 Steel Diesel Engine Crankshaft.

A six-throw, seven-bearing, counterweighted diesel-engine crankshaft weighing 80 kg (175 lb) was distorted in rough machining to such a degree that cold straightening was required. The straightening operation induced additional stresses, which caused severe distortion in final machining. The problem was solved by first tempering the 1046 steel shaft at 455 °C (850 °F) to a hardness of about 321 HB, which allowed hot straightening. The shaft was then retempered at 480 to 540 °C (900 to 1000 °F), depending on the composition of the particular heat, to produce a hardness of 269 to 302 HB and to relieve residual stresses.

Example 5: Use of Multiple Tempering to Minimize Retained Austenite and to Improve Dimensional Stability in a W1 Tool Steel Gage Block.

In the manufacture of a gage block of W1 tool steel (final hardness, 65 to 66 HRC), the block is quench hardened after rough machining. It is then subjected to three consecutive cycles, each consisting of cold treatment at -100 °C (-145 °F) for 1 h followed by tempering at 70 °C (160 °F) for 1 h. This minimizes the retained austenite and enhances dimensional stability before the block is finish ground.

Use of Fixtures

Many high-strength steel components having a tensile strength greater than 1720 MPa (250 ksi) are finish machined before final heat treatment. To minimize distortion and satisfy stringent dimensional requirements, some of these

components, such as cylinders, pressure vessels, and thin parts, are held in fixtures during both hardening and tempering or during tempering only. Additional information is available in the article "Proper Fixturing" in Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

External rings, internal mandrels, jacks, screws, weights, wedges, dies, and other mechanical devices are used to aid in dimensional correction.

Example 6: Use of Tempering Fixture to Minimize Out-of-Round Condition in a 4135 Steel Welded Pressure Vessel.

A welded pressure vessel made of 4135 steel, 380 mm (15 in.) in outside diameter, 1.8 m (6 ft) long, and 3.18 mm (0.125 in.) thick, was found to be 1.3 to 3.8 mm (0.050 to 0.150 in.) out of round over its entire length when measured in the as-quenched condition. A tempering fixture consisting of a series of steel rings 125 mm (5 in.) wide reduced maximum out-of-roundness to 1.3 mm (0.050 in.) after tempering at 455 °C (850 °F) for $2\frac{1}{2}$ h.

Snap Draw. Steels that are susceptible to cracking at room temperature after hardening are given a low-temperature tempering treatment (a snap draw) immediately after hardening and prior to final tempering in fixtures

Cracking in Processing

Because of their carbon or alloy contents, some steels are likely to crack if they are permitted to cool to room temperature during or immediately following the quenching operation. This likelihood is caused by the generation of high tensile residual stresses during quenching, due to thermal gradients, abrupt changes in section thickness, decarburization, or other hardenability gradients. Another potential source is cracking due to quenchant contamination and the subsequent change in quenching severity. Accordingly, for carbon steels containing more than 0.4% C and alloy steels containing more than 0.35% C, it is recommended that the parts be transferred to tempering furnaces before they cool to below 100 to 150 °C (212 to 300 °F). Alternately, many heat-treating operations use quenching oil for the tempering operation (martempering) or to avoid cooling below 125 °C (255 °F). Steels that are known to be sensitive to this type of cracking include 1060, 1090, 1340, 4063, 4150, 4340, 52100, 6150, 8650, and 9850.

Other carbon and alloy steels are generally less sensitive to this type of delayed quench cracking but may crack as a result of part configuration or surface defects. These steels include 1040, 1050, 1141, 1144, 4047, 4132, 4140, 4640, 8632, 8740, and 9840. Some steels, such as 1020, 1038, 1132, 4130, 5130, and 8630, are not sensitive.

Before being tempered, parts should be quenched to room temperature to ensure the transformation of most of the austenite to martensite and to achieve maximum as-quenched hardness. Austenite retained in low-alloy steels will, upon heating for tempering, transform to an intermediate structure, reducing overall hardness. However, in medium- to high-alloy steels containing austenite-stabilizing elements (nickel, for example), retained austenite may transform to martensite upon cooling from tempering, and thus such steels may require additional tempering (double tempering) for the relief of transformation stresses.

Temper Embrittlement

When carbon or low-alloy steels are cooled slowly from tempering above 575 °C (1065 °F) or are tempered for extended times between 375 and 575 °C (705 and 1065 °F), a loss in toughness occurs that manifests itself in reduced notched-bar impact strength compared to that resulting from normal tempering cycles and relatively fast cooling rates (see Fig. 22). The cause of temper embrittlement is believed to be the precipitation of compounds containing trace elements such as tin, arsenic, antimony, and phosphorus, along with chromium and/or manganese. The intergranular nature of the fracture suggests that the embrittlement occurs at the prior austenite grain boundaries. Although manganese and chromium cannot be restricted, a reduction of the other elements and quenching from above 575 °C (1065 °F) are the most effective remedies for this type of embrittlement.

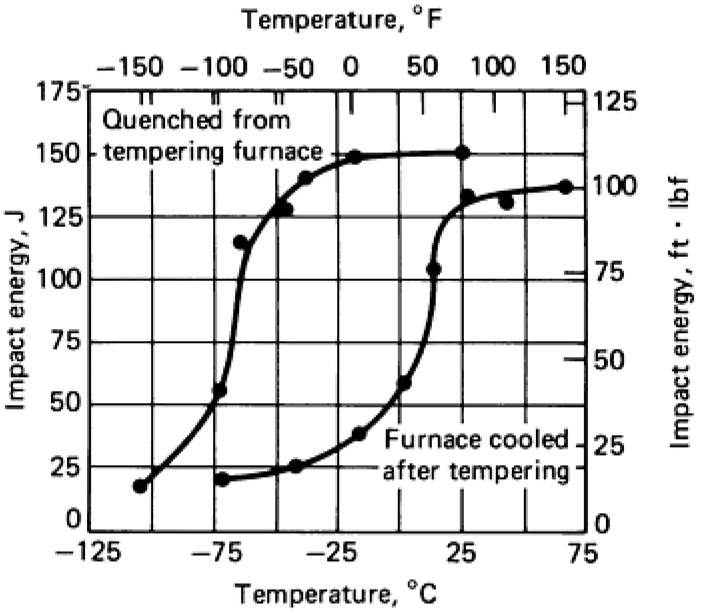

Fig. 22 Effect of temper embrittlement on notch toughness. Variation in Charpy V-notch impact energy with temperature for 5140 steel hardened and tempered at 620 °C (1150 °F); one series of specimens was quenched from the tempering temperature, and the other was furnace cooled. Slow cooling of susceptible steels causes temper embrittlement. Source: Ref 14

Steels that have been embrittled because of temper embrittlement can be de-embrittled by heating to about 575 °C (1065 °F), holding a few minutes, and subsequently, rapidly cooled or quenched. The time for de-embrittlement depends on the alloying elements present and the temperature of reheating (Ref 15). De-embrittlement is accompanied by a redistribution of impurities at the grain boundaries (Ref 16). Various surface-sensitive techniques such as x-ray photoelectron spectroscopy, Auger electron spectroscopy, and backscattering of energetic ions have been used to study the composition of grain boundaries of an embrittled steel.

Blue Brittleness

The heating of plain carbon steels or some alloy steels to the temperature range of 230 to 370 °C (450 to 700 °F) may result in increased tensile and yield strength, as well as decreased ductility and impact strength. This embrittling phenomenon is caused by precipitation hardening and is called blue brittleness because it occurs within the blue heat range.

If susceptible steels are heated within the 230 to 370 °C (450 to 700 °F) range, they may be embrittled and thus should not be used in applications in which they are subjected to impact loads.

Tempered Martensite Embrittlement

Both intergranular (Ref 17, 18, 19) and transgranular fracture modes may be observed in tempered martensite embrittlement (Ref 17, 20). The combination of the segregation of impurities such as phosphorus to the austenitic grain boundaries during austenitizing and the formation of cementite at prior austenitic grain boundaries during tempering are

responsible for the intergranular fracture mode of tempered martensite embrittlement (Ref 17, 19). The transgranular fracture mode is caused by the formation of cementite between parallel martensitic lathes during tempering (Ref 17, 20).

Figure 23 shows the impact absorbed as a function of tempering temperature for chromium-molybdenum steels with various phosphorus and carbon contents. The figure exhibits the effect of phosphorus and carbon on the impact toughness of low-alloy steels. There is a loss in impact toughness for steels tempered in the temperature range of 250 to 300 °C (480 to 570 °F). Steels with lower phosphorus content have superior impact properties than steels with a higher phosphorus level. Also, impact toughness decreases with increasing carbon content (Ref 21). The effect of tempered martensite embrittlement on 4140 steel is shown in Fig. 4. Generally, with steels containing either potent carbide forms such as chromium or other impurities that make them susceptible to tempered martensite embrittlement, tempering between 200 to 370 °C (390 to 700 °F) should be avoided.

Hydrogen Embrittlement

The selection of tempering temperature and the resultant hardness or plasticity must include the consideration of the potential problem of hydrogen embrittlement, if the part were to be exposed to hydrogen through electroplating, phosphating, or other means, or if environmental conditions cause the cathodic absorption of hydrogen during service.

Generally, the restricted notch ductility of steels with hardnesses above 40 HRC presents ideal conditions for the development of stress concentrations in parts containing notches or defects that would, in the presence of relatively low hydrogen concentrations, lead to the failure of parts at stresses far below the nominal tensile strength of the material. Thus, tempering should be carried out to achieve a hardness below 40 HRC if the part is to be subjected to relatively high stresses and probable exposure to hydrogen. Additional information is available in the articles "Elevated-Temperature Properties of Ferritic Steels" and "Embrittlement of Steels" in Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*

Martempering of Steel

Revised by Herb Webster, Phoenix Heat Treating, Inc.; and W. James Laird, Jr., The Metal Works Industrial Furnaces, Inc.

Introduction

MARTEMPERING is a term used to describe an interrupted quench from the austenitizing temperature of certain alloy, cast, tool, and stainless steels. The purpose is to delay the cooling just above the martensitic transformation for a length of time to equalize the temperature throughout the piece. This will minimize the distortion, cracking, and residual stress. The term martempering is somewhat misleading and is better described as marquenching. The microstructure after martempering is essentially primary martensitic that is untempered and brittle.

Figure 1(a and b) shows the significant difference between conventional quenching and martempering. Martempering of steel (and of cast iron) consists of:

- Quenching from the austenitizing temperature into a hot fluid medium (hot oil, molten salt, molten metal, or a fluidized particle bed) at a temperature usually above the martensite range (M_s point)
- Holding in the quenching medium until the temperature throughout the steel is substantially uniform
- Cooling (usually in air) at a moderate rate to prevent large differences in temperature between the outside and the center of the section

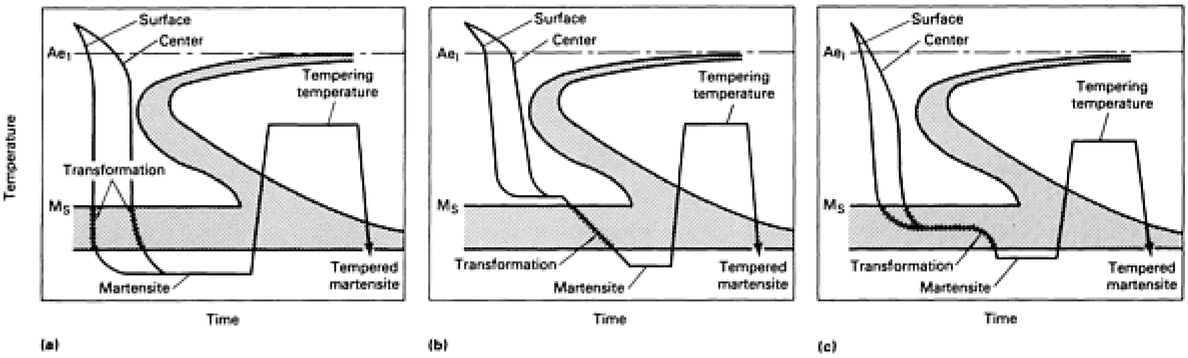

Fig. 1 Time temperature transformation diagrams with superimposed cooling curves showing quenching and tempering. (a) Conventional process. (b) Martempering. (c) Modified martempering

Formation of martensite occurs fairly uniformly throughout the workpiece during cooling to room temperature, thereby avoiding formation of excessive amounts of residual stress. Straightening or forming is also easily accomplished upon removal from the marquenching bath while the part is still hot. The piece will hold its shape upon subsequent cooling in fixturing or in air cooling after removal from the forming die. The marquenching can be accomplished in a variety of baths including hot oil, molten salt, molten metal, or a fluidized particle bed. Martempered parts are tempered in the same manner as conventional quenched parts. The time lapse before tempering is not as critical because the stress is greatly reduced.

Advantages

The advantage of martempering lies in the reduced thermal gradient between surface and center as the part is quenched to the isothermal temperature and then is air cooled to room temperature. Residual stresses developed during martempering are lower than those developed during conventional quenching because the greatest thermal variations occur while the steel is in the relatively plastic austenitic condition and because final transformation and thermal changes occur throughout the part at approximately the same time. Martempering also reduces or eliminates susceptibility to cracking.

Another advantage of martempering in molten salt is the control of surface carburizing or decarburizing. When the austenitizing bath is neutral salt and is controlled by the addition of methane gas or proprietary rectifiers to maintain its neutrality, parts are protected with a residual coating of neutral salt until immersed in the marquench bath.

Although martempering is used primarily to minimize distortion, eliminate cracking, and minimize residual stresses, it also greatly reduces the problems of pollution and fire hazard as long as nitrate-nitrite salts are used rather than martempering oils. This is especially true where nitrate-nitrite salts are recovered from wash waters with systems that provide essentially no discharge of salts into drains. Any steel part or grade of steel responding to oil quenching can be martempered to provide similar physical properties. The quenching severity of molten salt is greatly enhanced by agitation and water additions to the nitrate-salt bath. Both techniques are particularly beneficial in heat treating of carbon steels that have limited hardenability. Table 1 compares the properties obtained in 1095 steel by martempering and tempering with those obtained by conventional quenching and tempering.

Table 1 Mechanical properties of 1095 steel heat treated by two methods

Specimen number	Heat treatment	Hardness, HRC	Impact energy		Elongation[(a)], %
			J	ft · lbf	
1	Water quench and temper	53.0	16	12	0

2	Water quench and temper	52.5	19	14	0
3	Martemper and temper	53.0	38	28	0
4	Martemper and temper	52.8	33	24	0

(a) In 25 mm or 1 in.

In many instances, martempering eliminates the need for quenching fixtures that would be required for minimizing distortion during conventional quenching and thus reduces the cost of tooling and handling. However, changing from conventional quenching to martempering may require that dimensional variations in individual parts be studied before preheat-treatment dimensions are established.

Modified martempering differs from standard martempering only in that the temperature of the quenching bath is below the M_s point (Fig. 1c). The lower temperature increases the severity of quenching. This is important for steels of lower hardenability that require faster cooling in order to harden to sufficient depth, or when the M_s is high and some bainite is detrimental to the finished part. Therefore, modified martempering is applicable to a greater range of steel compositions than is the standard process.

Although hot oil is invariably the quenchant employed for modified martempering at 175 °C (350 °F) and lower, molten nitrate-nitrite salts (with water addition and agitation) are effective at temperatures as low as 175 °C (350 °F). Because of their higher heat-transfer coefficients, molten salts offer some metallurgical and operational advantages.

Martempering Media

Molten salt and hot oil are both widely used for martempering. Several factors must be considered when choosing between salt and oil. Operating temperature is the most common deciding factor. Oils are widely used for martempering at up to 205 °C (400 °F) and sometimes at temperatures as high as 230 °C (450 °F). Molten salt is used for martempering in the range of 160 to 400 °C (320 to 750 °F).

Composition and Cooling Power of Salt. A salt commonly used for martempering is composed of 50 to 60% potassium nitrate, 37 to 50% sodium nitrite, and 0 to 10% sodium nitrate. It melts at about 140 °C (280 °F) and may be used within a working range of 165 to 540 °C (325 to 1000 °F). Higher-melting-point (less costly) salts can be used for higher operating temperatures. These salts are comprised of 40 to 50% potassium nitrate, 0 to 30% sodium nitrite, and 20 to 60% sodium nitrate.

The cooling power of agitated salt at 205 °C (400 °F) is about the same as that of agitated oil in conventional oil quenching. Addition of water to salt increases its cooling power, as indicated by the cooling curves for 1045 steel in Fig. 2 and by the hardness values for 1046 steel in Fig. 3. The cooling power of salt is compared with the cooling power of water, and of three types of oil, in Fig. 3.

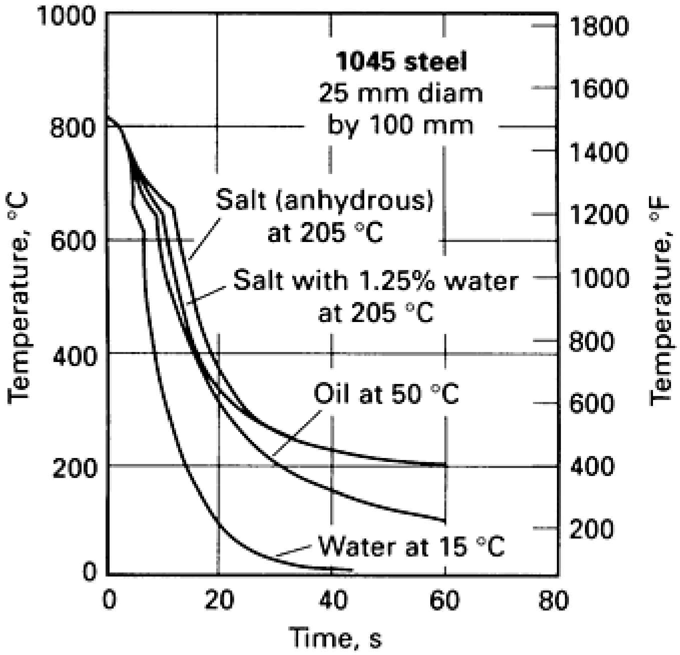

Fig. 2 Cooling curves for 1045 steel cylinders quenched in salt, water, and oil. Thermocouples were located at centers of specimens.

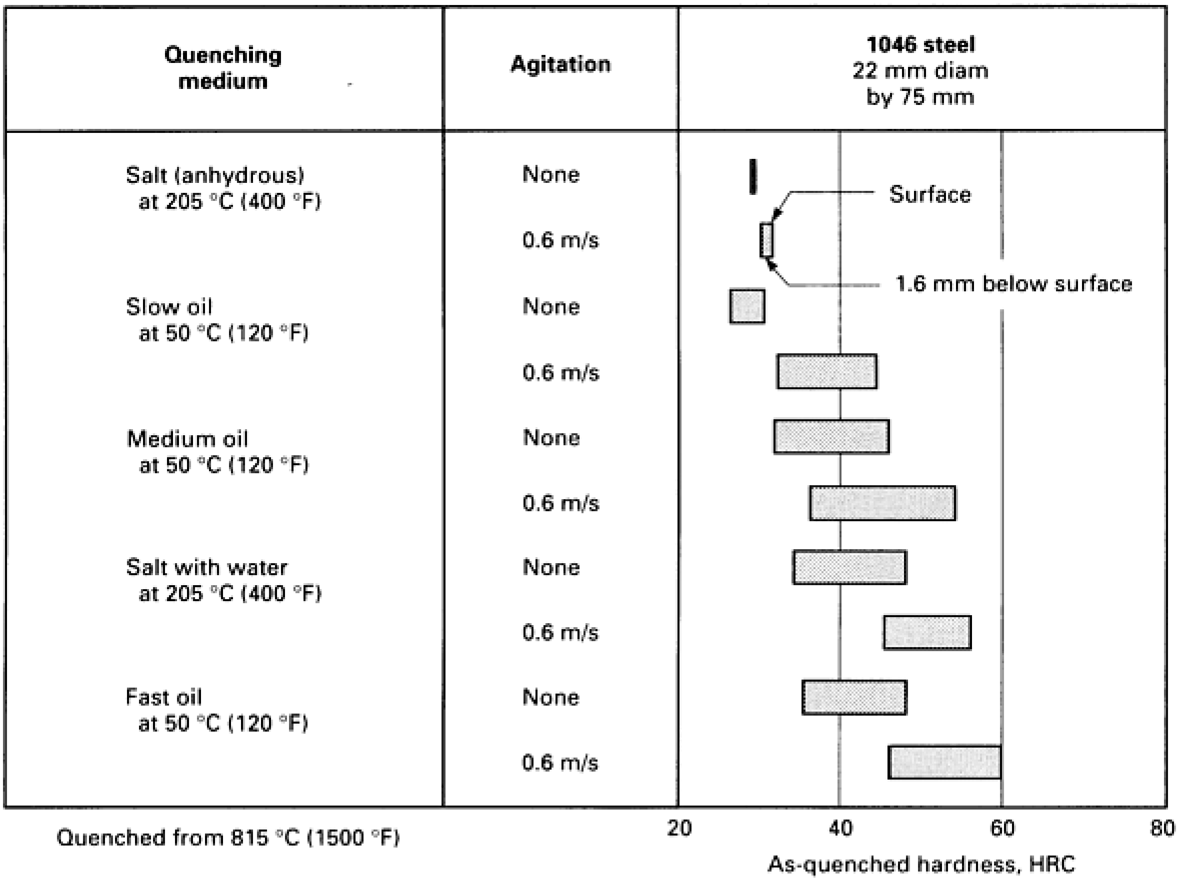

Fig. 3 Effects of quenchant and agitation on hardness of 1046 steel

Advantages of salt in comparison with oil for martempering are as follows:

- The viscosity of salt changes only slightly over a wide temperature range
- Salt retains chemical stability, so that replenishment is usually required only to replace dragout loss. This is not always the case, however. In an installation for high-volume martempering of cylinder liners, for instance, breakdown of the salt did occur, forming a carbonate. This occurred on quenching from an endothermic atmosphere into an open-top salt quench bath at 245 °C (475 °F). The same operation conducted with a nitrogen atmosphere in the heating furnace does not produce such breakdown
- Salt has a wide operating temperature range
- Salt is easily washed from the work with plain water
- Less time is required for workpieces to attain temperature equalization in salt
- No unusual disposal problems attend the rinsing operation
- Salt is relatively easy to handle in powder form and easy to clean up if spilled; however, it is necessary to keep salts separated

Disadvantages of salt in comparison with oil include the following:

- The minimum operating temperature of salt is 160 °C (320 °F)
- Quenching from cyanide-based carburizing salts is hazardous because of possible explosion
- Explosion and splatter of high-temperature salt can occur if wet or oily parts are immersed
- Potentially explosive reactions also occur with sooty atmospheres in atmosphere furnaces connected to martempering salt quenches
- Quench salt can be contaminated by high-temperature neutral salt used for heating. Sludging operations are required to maintain quenching severity

Fluidized Beds. Although fluidized beds are somewhat limited, they have the advantage of equal heat transfer throughout the entire temperature range of quenching. This leads to a quench rate that is reproducible, does not degrade with time, and can be adjusted within wide limits. In addition, fluid beds do not have the environmental drawbacks of oils or salt quenchants.

Oils for Martempering. Physical properties of two oils commonly used for martempering are listed in Table 2. Such oils are compounded especially for martempering, and in comparison with conventional quenching oils, offer higher rates of cooling during the initial stage of quenching.

Table 2 Physical properties of two oils used for martempering of steel

Property	Value, for oil with operating temperature of	
	95 to 150 °C (200 to 300 °F)[a]	150 to 230 °C (300 to 450 °F)
Flash point (min), °C (°F)	210 (410)	275 (525)
Fire point (min), °C (°F)	245 (470)	310 (595)
Viscosity, sus, at:		
38 °C (100 °F)	235-575	. . .

100 °C (210 °F)	50.5-51	118-122
150 °C (300 °F)	36.5-37.5	51-52
175 °C (350 °F)	. . .	42-43
205 °C (400 °F)	. . .	38-39
230 °C (450 °F)	. . .	35-36
Viscosity index (min)	95	95
Acid number	0.00	0.00
Fatty-oil content	None	None
Carbon residue	0.05	0.45
Color	Optional	Optional

(a) Temperature range for modified martempering

Quenching oil requires special handling when used in the temperature range from 95 to 230 °C (200 to 450 °F). To prolong its life, the oil must be maintained under a protective atmosphere (reducing or neutral). Deterioration is accelerated when oil is exposed to air at elevated temperatures. For example, for every 10 °C above 60 °C (every 18 °F above 140 °F), the rate of oxidation is approximately doubled. This causes formation of acid and sludge, which may affect both hardness and color of workpieces.

Example 1: Martempering of Carburized Transmission Components in Oil.

A manufacturer of transmission components and axles martempers carburized parts at a rate of 115 kg/h (250 lb/h) in a 7550 L (2000 gal) oil tank that is completely covered by a vestibule hood and that is located directly beneath the discharge door of the continuous carburizing furnace. The vestibule contains a protective atmosphere consisting of carburizing gases that emanate from the furnace. The vestibule is equipped with an elevator that lowers the tray of parts into the martempering oil.

The ambient temperature in the vestibule immediately above the oil is 89 to 92 °C (193 to 197 °F) when the furnace discharge door is closed. The temperature of the oil is controlled at 150 °C (300 °F). However, during high-production quenching, the temperature of the martempering oil will rise to as high as 165 °C (325 °F). The atmosphere in the vestibule protects the carburized parts and the martempering oil from oxidation. To avoid possible oil fires, the furnace discharge door is closed before the work-load is lowered into the martempering oil.

The martempering oil in this tank has not been replaced in several years of continuous operation (24 h per day, 7 days per week); makeup oil is added to the tank at a rate of about 755 L (200 gal) per month.

Bypass or continuous types of filter units with suitable filtering media (clay, cellulose cartridge, or waste cloth) or centrifugal filtering help prolong oil life and maintain clean work. Filtering units are effective and relatively inexpensive.

Oils should be circulated at a rate no lower than 0.9 m/s (180 ft/mm) to break up excessive vapor that is formed during quenching.

Continuous operation of oils above 205 °C (400 °F) can cause excessive breakdown of the oils unless the correct oil is used for each specific application. Once every one to six months, the oil should be subjected to complete physical and chemical testing to determine its condition. Such testing usually includes determinations of flash point, viscosity, degree of oxidation, quenching effect, contamination, and cooling power.

Advantages of oil in comparison with salt are as follows:

- Oil can be used at lower temperatures
- Oil is easier to handle at room temperature
- Less dragout loss occurs with oil
- Oil is compatible with all austenitizing salts

Disadvantages of oil include the following:

- Oil is limited to a maximum operating temperature of 230 °C (450 °F)
- Oil deteriorates with use, therefore requiring closer control
- When martempered in oil, workpieces require more time to attain temperature equalization
- Oil, whether hot or cold, is a fire hazard
- Soap or an emulsifier is necessary to wash off the oil. Washers must be drained and refilled periodically. Oily wastes create disposal problems

Safety Precautions

In operation of a martempering installation (salt or oil), the precautions appropriate for operating any other hot liquid bath are applicable. The following operator-safety precautions are recommended:

- Operators of equipment should be thoroughly familiar with equipment manufacturer's instructions and with company safety recommendations before attempting to operate or service the equipment
- Operators should wear gloves, face shields, and protective clothing, as required. Safety equipment contaminated with oil or nitrate-nitrite salts should be discarded
- Adequate first aid materials should be available where salts are used, and personnel should be trained and available in treating alkali burns

Nitrate-Nitrite Salts. Several precautions should be taken in operating nitrate-nitrite salt baths:

- All racks, fixtures, and cleaning tools must be thoroughly cleaned of salts (hot water preferred) and thoroughly dried before being reused; otherwise, the presence of salt could contaminate the austenitizing furnace, and residual water could cause spattering of molten salt
- All salt bath furnaces should be labeled so that the proper salt is used. Cyanide-containing salts should not be combined with nitrate-nitrite salts because such mixtures result in explosive reactions. Good house-keeping is essential to prevent accidents. Martempering salts must be stored in closed, well-marked containers. These salts are hygroscopic and will absorb water if exposed. Yellow, orange, or red coloring is commonly used for identification of nitrate-nitrite salts. Cyanide-containing materials may be identified by white, blue, or gray. Color coding is not universally practiced but is strongly recommended. Everyone handling these materials should be familiarized with the explosion hazard of intermixing. For a discussion of attendant hazards and recommended practices, see the sections of this article entitled "Salt Contamination" and "Selection of Austenitizing Equipment"
- When water is added to a nitrate-nitrite salt to increase its quenching severity, the water should be trickled or atomized onto the surface of the bath and should never be introduced below the surface or

under pressure. Otherwise, spattering or eruption can occur. Equipment manufacturers should be consulted as to recommended procedures and hardware
- The salt bath should be equipped with a high-temperature limit controller to prevent the bath from exceeding 595 °C (1100 °F). At higher temperatures, nitrate salts decompose and may cause fire or explosion. Although nitrate-nitrite salts do not burn, they are oxidizing and will support combustion. Therefore, oxidizable materials should not be stored near the bath, and combustible materials should not be introduced into the bath unless designed for the purpose. In the event of a fire, a carbon dioxide extinguisher should be used. Sand is also effective in smothering floor fires. *Caution: To avoid explosive spread of the molten medium, water should never be used to extinguish a fire in or around a molten salt (or molten metal) bath*
- Soot and carbonaceous materials should not be allowed to accumulate on the surface of the molten bath
- Signs are provided by local fire departments for placing on the outside of buildings that house salt baths. These signs tell the fire department what materials are present and what means can be used to extinguish the fire

Hot oil also requires safety precautions. Among the hazards that accompany its use are: fire; overflow caused by the increase in the volume of the oil during heating; explosion, when no atmosphere cover is used over the quench tank; and contamination by water, which can result in fire.

Equipment normally used for protection against these hazards includes:

- Alarm system on temperature-control instrument. (Recommended maximum operating temperature is 55 °C, or 100 °F, below the flash point of the quenching oil.) Often, an additional system is added for maximum temperature alarm
- An oil-level indicator
- If the oil is heated by gas-fired tubes, which are not recommended for heating martempering oils, a safety control system to prevent firing when the air cooling system is off
- Electric heating elements should have a maximum heat flux density of 0.016 $W \cdot mm^{-2}$ (10 $W \cdot in.^{-2}$)
- Expansion system to accommodate the change in volume that occurs when the oil is heated from room temperature to the operating temperature. A suitable system is a small tank equipped with an overflow return line from the main quench tank. The main tank is equipped with a small pump to return the oil from the expansion tank. The capacity of the pump is usually about 20 L/min (5 gal/min)
- A safety control to prevent oil from being heated unless it is agitated
- A carbon dioxide or foam system installed over the quench tank for fire protection
- A water-detection system, with automatic alarm, that monitors the oil for water content

Caution should be used in installing ventilating systems and any other system that could cause addition of water to the hot oil. When an atmosphere is used over the quenching medium, the general safety precautions outlined in the article "Gas Carburizing" should be followed.

Suitability of Steels for Martempering

Alloy steels generally are more adaptable than carbon steels to martempering. In general, any steel that is normally quenched in oil can be martempered. Some carbon steels that are normally water quenched can be martempered at 205 °C (400 °F) in sections thinner than 5 mm ($\frac{3}{16}$ in.), using vigorous agitation of the martempering medium. In addition, thousands of gray cast iron parts are martempered on a routine basis.

The grades of steel that are commonly martempered to full hardness include 1090, 4130, 4140, 4150, 4340, 300M (4340M), 4640, 5140, 6150, 8630, 8640, 8740, 8745, SAE 1141, and SAE 52100. Carburizing grades such as 3312, 4620, 5120, 8620, and 9310 also are commonly martempered after carburizing. Occasionally, higher-alloy steels such as type 410 stainless are martempered, but this is not a common practice.

Success in martempering is based on a knowledge of the transformation characteristics (TTT curves) of the steel being considered. The temperature range in which martensite forms is especially important. Figure 4 shows the martensite temperature ranges for 14 carbon and low-alloy steels. Two trends may be observed in these data: As carbon content increases, the martensite range widens and the martensite transformation temperature is lowered; and the martensite range of a triple-alloy (nickel-chromium-molybdenum) steel is usually lower than that of either a single-alloy or a double-alloy steel of similar carbon content.

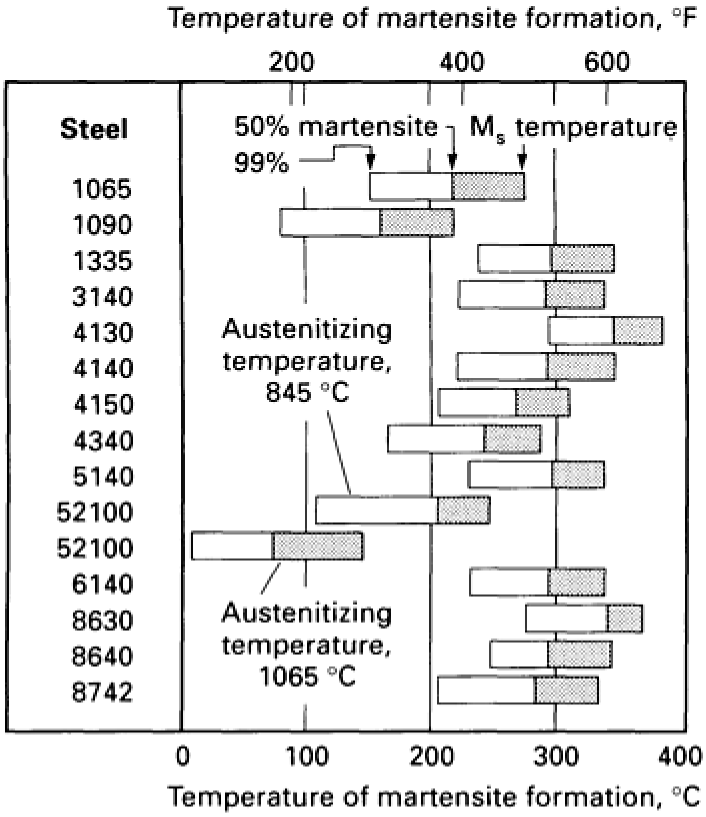

Fig. 4 Temperature ranges of martensite formation in 14 carbon and low-alloy steels

Any steel that is to be martempered successfully must contain sufficient carbon or alloying additions to move the nose of the TTT curve to the right, thus permitting sufficient time for quenching of workpieces past the nose of the TTT curve.

The TTT diagrams for a hypoeutectoid steel (1034), which is discussed later, and a hypereutectoid steel (1090) are shown in Fig. 5. The diagram for 1090 steel is the simplest form of transformation diagram because no proeutectoid constituents (free ferrite or free carbide) are involved in the transformation at temperatures above that corresponding to the nose of the curve. The speed of transformation at the nose is related to the hardenability of the steel; when the nose of the TTT curve is far to the left on the diagram, the steel has lower hardenability; when the nose is to the right, the steel has higher hardenability. To achieve full hardening during quenching, the cooling curve of the steel must pass to the left of the curve farthest to the left on the diagram. In production, some loss in as-quenched hardness is usually accepted in order to achieve minimum distortion.

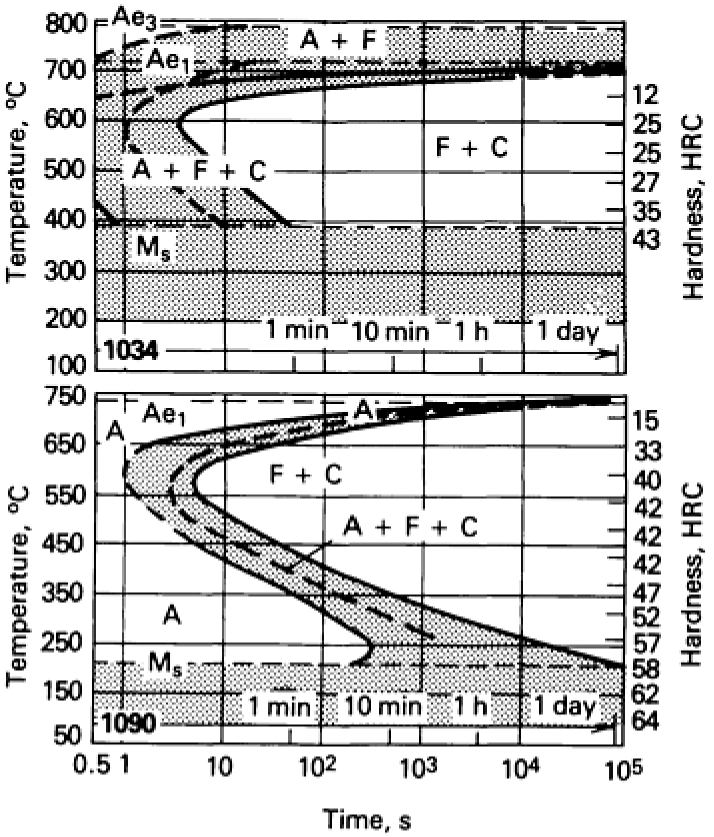

Fig. 5 Time-temperature transformation diagrams for 1034 and 1090 steels. The 1090 steel was austenitized at 885 °C (1625 °F) and had a grain size of 4 to 5.

A TTT diagram for a hypoeutectoid low-alloy steel (5140) suitable for martempering is shown in Fig. 6. The chromium in this steel causes the characteristic shape of the TTT curve near 540 °C (1000 °F).

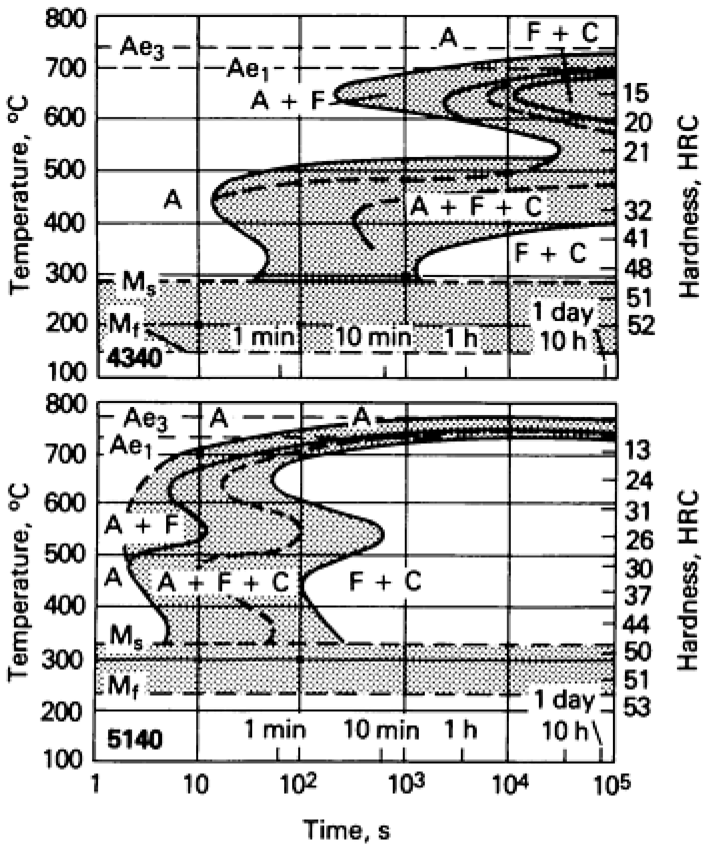

Fig. 6 Time-temperature transformation diagrams for 4340 and 5140 steels. The austenitizing temperature for both steels was 845 °C (1550 °F); grain size was 7 to 8 for 4340 and 6 to 7 for 5140.

The TTT diagram for an extremely high-hardenability steel (4340) is also shown in Fig. 6. The combined effect of nickel, chromium, and molybdenum on hardenability is illustrated in this diagram. These elements cause a double nose on the TTT curve. The nose that occurs at about 480 °C (900 °F) is more significant in martempering than the one occurring near 650 °C (1200 °F). Steels having such high hardenability are easily martempered to fully martensitic structures.

Low-carbon and medium-carbon steels 1008 through 1040 are too low in hardenability to be successfully martempered, except when carburized. The TTT curve for the 1034 steel in Fig. 5 is characteristic of a steel that is unsuitable for martempering; except in sections only a few thousandths of an inch thick, it would be impossible to quench the steel in hot salt or oil without encountering upper transformation products.

Borderline Grades. Some carbon steels higher in manganese content such as 1041 and 1141 can be successfully martempered in thin sections. Low-alloy steels that have limited applications for successful martempering are listed (the lower-carbon grades are carburized before martempering): 1330 to 1345, 4012 to 4042, 4118 to 4137, 4422 and 4427, 4520, 5015 and 5046, 6118 and 6120, 8115.

Most of these alloy steels are suitable for martempering in section thicknesses of up to 16 to 19 mm ($\frac{5}{8}$ or $\frac{3}{4}$ in.). Martempering at temperatures below 205 °C (400 °F) will improve hardening response, although greater distortion may result than in martempering at higher temperatures.

Effect of Mass. The limitation of section thickness or mass must be considered in martempering. With a given severity of quench, there is a limit to bar size beyond which the center of the bar will not cool fast enough to transform entirely to martensite. This is shown in Fig. 7, which compares the maximum diameter of bar that can be hardened by martempering, oil quenching, and water quenching for 1045 steel and five alloy steels of various hardenabilities.

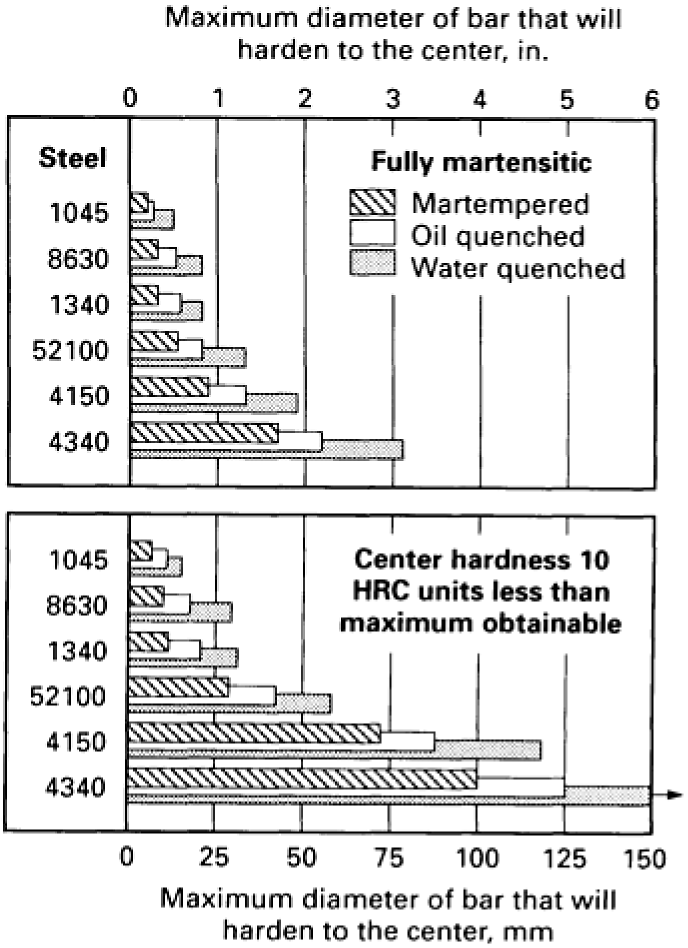

Fig. 7 Approximate maximum diameters of bars that are hardenable by martempering, oil quenching, and water quenching

For some applications, a fully martensitic structure is unnecessary and a center hardness 10 HRC units lower than the maximum obtainable value for a given carbon content may be acceptable. By this criterion, maximum bar diameter is 25 to 300% greater than the maximum diameter that can be made fully martensitic (see lower graph in Fig. 7). Non-martensitic transformation products (pearlite, ferrite, and bainite) were observed at the positions on end-quenched bars corresponding to this reduced hardness value, as follows:

Steel	Transformation
1045	15% pearlite
8630	10% ferrite and bainite
1340	20% ferrite and bainite
52100	50% pearlite and bainite

4150	20% bainite
4340	5% bainite

The influence of mixed structures such as these on the mechanical properties of the steel would have to be determined for each application.

Steels selected for martempering must be judged on hardenability and section size. To form the same amount of martensite for a given section size, the carbon content, alloy content, or both must be somewhat higher for martempering than for conventional (uninterrupted) quenching.

Control of Process Variables

The success of martempering depends on close control of variables throughout the process. It is important that the prior structure of the material being austenitized be uniform. Also, use of a protective atmosphere (or salt) in austenitizing is required because oxide or scale will act as a barrier to uniform quenching in hot oil or salt.

The process variables that must be controlled in martempering include austenitizing temperature, temperature of martempering bath, time in martempering bath, salt contamination, water additions to salt, agitation, and rate of cooling from the martempering bath.

Austenitizing temperature is important because it controls austenitic grain size, degree of homogenization, and carbide solution, and because it affects the M_s temperature, which is important in establishing martempering procedures. As indicated in Fig. 8 for 52100 steel, an increase in austenitizing temperature lowers M_s temperature and increases grain size.

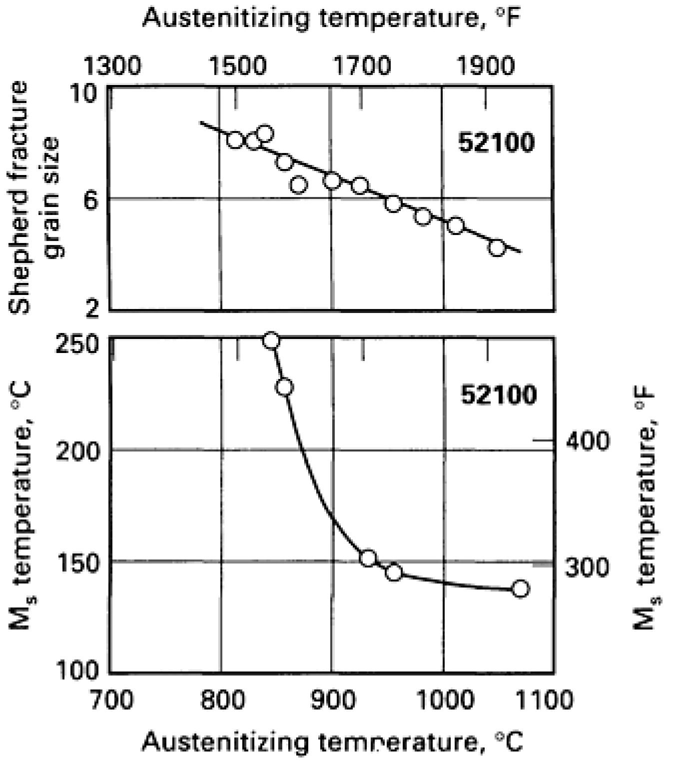

Fig. 8 Effects of austenitizing temperature on grain size and M_s temperature of 52100 steel

Temperature control during austenitizing is the same for martempering as for conventional quenching: A tolerance of 8 °C (15 °F) is common. The austenitizing temperatures most commonly used for several different steels are indicated in Table 3.

Table 3 Typical austenitizing and martempering temperatures for various steels

Grade	Austenitizing temperature		Martempering temperature

(a) Time is oil varies from 4 to 20 min, depending on section thickness.

(b) Martempering temperature depends on shape and mass of parts being quenched; higher temperatures in range (and sometimes above range) are used for thinner sections and more intricate parts.

In most instances, austenitizing temperatures for martempering are the same as those for conventional oil quenching. Occasionally, however, medium-carbon steels are austenitized at higher temperatures prior to martempering to increase as-quenched hardness.

For carburized parts, low austenitizing temperatures usually yield better size control during martempering. To obtain minimum dimensional changes, the lowest austenitizing temperature that will yield satisfactory core properties should be used. The ratio of case depth to core, as well as the prior processing history of the steel (such as forging, rolling, or drawing), can also be controlling factors, particularly for critical section shapes and sizes. Austenitizing temperatures that have been used for several carburizing steels are indicated in Table 3.

Salt Contamination. When parts are carburized or austenitized in a salt bath, they can be directly quenched in an oil bath operating at the martempering temperature. However, if the parts are carburized or austenitized in salt containing cyanide, they must *not* be directly martempered in salt because the two types of salts are not compatible and explosions can occur if they are mixed. Instead, one of two procedures should be used: Either air cool from the carburizing bath, wash, reheat to the austenitizing temperature for case and/or core in a chloride bath, and then martemper; or quench from the cyanide-containing bath into a neutral chloride rinse bath maintained at the austenitizing temperature and then martemper.

If the latter method is used, it is essential to control the amount of cyanide buildup in the neutral rinse. When tests indicate more than 5% cyanide in the chloride rinse, part of the salt should be discarded and the remainder diluted with new salt.

All fixtures must be thoroughly cleaned after martempering to prevent transfer of quenching salt to either cyanide baths or neutral chloride baths. Mixing of cyanide with nitrate-nitrite salts will cause explosion. A chloride bath that is contaminated with nitrate-nitrite salts will produce pitting and decarburization of parts immersed in it.

Temperature of the martempering bath varies considerably, depending on composition of workpieces, austenitizing temperature, and desired results. In establishing procedures for new applications, many plants begin at 95 °C (200 °F) for oil quenching, or at about 175 °C (350 °F) for salt quenching, and progressively increase the temperature until the best combination of hardness and distortion is obtained. Martempering temperatures (for oil and salt) that represent the experience of several plants are listed in Table 3.

Time in the martempering bath depends on section thickness and on the type, temperature, and degree of agitation of the quenching medium. The effects of section thickness and of temperature and agitation of the quench bath on immersion time are indicated in Fig. 9.

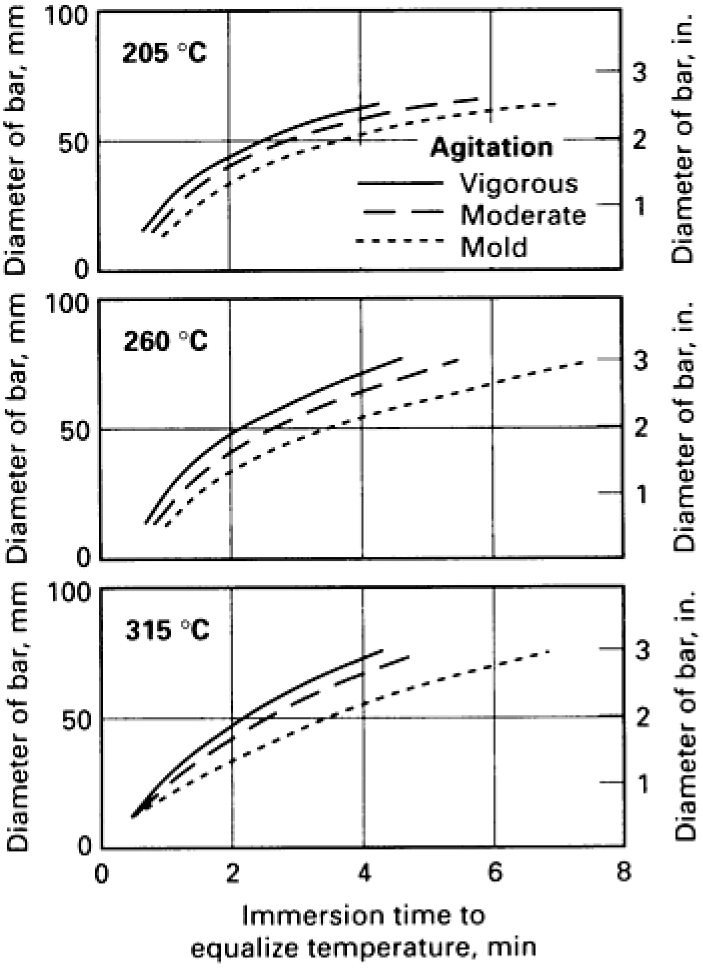

Fig. 9 Martempering time versus section size and agitation of quench bath for 1045 steel bars. Effects of bar diameter and agitation of quench bath on time required for centers of 1045 steel bars to reach martempering temperature when quenched from a neutral chloride bath at 845 °C (1550 °F) into anhydrous nitrate-nitrite martempering salt at 205, 260, and 315 °C (400, 500, and 600 °F). Length of each bar was three times the diameter.

Because the object of martempering is to develop a martensitic structure with low thermal and transformation stresses, there is no need to hold the steel in the martempering bath for extended periods. Excessive holding lowers final hardness because it permits transformation to products other than martensite. In addition, stabilization may occur in medium-alloy steels that are held for extended periods at the martempering temperature.

The martempering time for temperature equalization in oil is about four to five times that required in anhydrous salt at the same temperature. For example, for a 25 mm (1 in.) diam bar martempered in salt at 205 °C (400 °F) with moderate agitation, the customary immersion time is about $1\frac{1}{2}$ to 2 min, whereas about 8 to 10 min are required for the bath to attain temperature equalization in oil at 205 to 220 °C (400 to 425 °F). The immersion time required in salt can be reduced by as much as 50% by addition of 0.5 to 2% water.

Water Additions to Salt. The quenching severity of a nitrate-nitrite salt can be increased significantly by careful addition of water. Agitation of the salt is necessary to disperse the water uniformly, and periodic additions are needed to maintain required water content. The water can be added with complete safety as follows:

- Water can be misted at a regulated rate into a vigorously agitated area of the molten bath
- In installations where the salt is pump circulated, returning salt is cascaded into the quench zone. A controlled fine stream of water can be injected into the cascade of returning salt

- The austempering bath can be kept saturated with moisture by introducing steam directly into the bath. The steam line should be trapped and equipped with a discharge to avoid emptying condensate directly into the bath
- Steam addition of water to the bath is done on baths with operating temperatures above 260 °C (500 °F)

The addition of water to increase the severity of salt is usually made by directing a stream of water onto the molten salt at the agitator vortex. A protective shroud surrounds the water spray to prevent spattering (see the section "Safety Precautions" in this article). The turbulence of the salt carries the water into the bath without spattering or hazard to the operator. Water should never be added to a salt bath from a pail or dipper.

Water is continuously evaporating from the bath surface, and the rate of evaporation increases during quenching of hot work. Therefore, it is necessary to add water periodically to maintain the water concentration and a uniform quenching severity. The amount of water to be added varies with the operating temperature of the salt, as indicated by the following recommended concentrations:

Temperature		**Water concentration, %**
°C	**°F**	
205	400	$\frac{1}{2}$-2
260	500	$\frac{1}{2}$-1
315	600	$\frac{1}{4}$-$\frac{1}{2}$

At present, there is no known means of automatically controlling the concentration of water in molten nitrate-nitrite salt. Water is usually controlled at the discretion of the operator, who will add water as needed. On the basis of experience, however, it is possible to anticipate the need for water; here the addition of water may be simplified by use of timers that can be adjusted to time the frequency and duration of water additions.

The presence of water is visually detectable by the operator because steam is released when the hot work is immersed into the nitrate-nitrite salt. The steam causes a visible mounding of the salt above the quench area, and there is a characteristic sizzling caused by the vapor phase.

Besides visual appearance, periodic hardness checks of the work will indicate the activity of the bath. A more exact determination can be made by removing a small quantity of the salt and weighing it accurately before and after dehydrating it by heating to 370 to 425 °C (700 to 800 °F). Another method is to determine the freezing point of a small sample and to then refer to a published curve that relates freezing point to water content for that specific salt.

The use of periodic histograms is another method for determining the quenching effect of the marquench bath. Complete statistical process control is the best method to ensure consistency of the marquench process.

Agitation of the martempering salt or oil considerably increases the hardness obtainable for a given section thickness, in comparison to that possible in still quenching. This is demonstrated in Fig. 10, which presents data for 52100 steel that relate section thickness, hardness, and agitation.

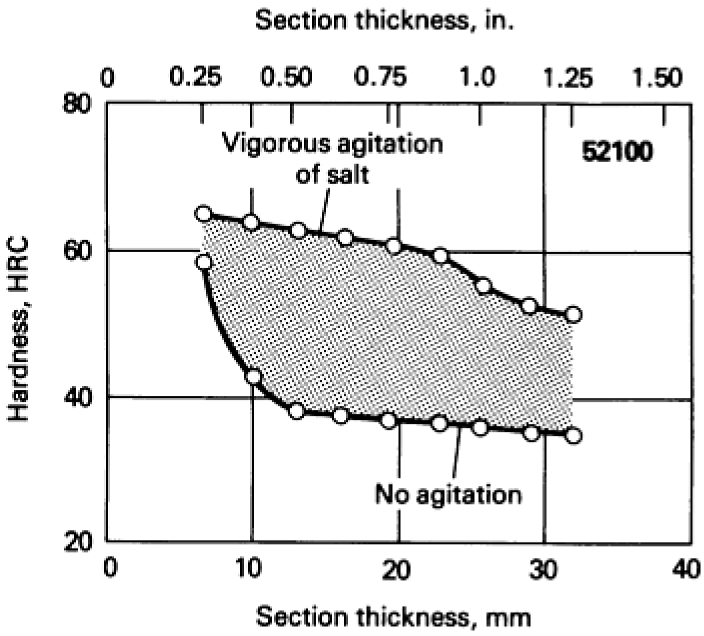

Fig. 10 Influence of agitation on surface hardness of 52100 steel in various section thicknesses martempered in hot salt

In some instances, the rapid cooling produced by the most vigorous agitation increases distortion. Thus, mild agitation is often used in combination with water addition to obtain minimum distortion without sacrificing hardness.

Cooling from the martempering bath ordinarily is done in still air to avoid large differences in temperature between the surface and the interior of the steel. Forced-air cooling by means of fans is occasionally used on sections over 19 mm ($\frac{3}{4}$ in.) thick, but caution is required if the part varies in section thickness or has more surface exposed on one section, such as on threads or serrations, because objectionable amounts of distortion can occur on rapid cooling through the martensite range. Generally, cooling of workpieces in cool oil or water after removal from the martempering bath is considered undesirable because cooling can reestablish thermal gradients and unequal stress patterns that can increase distortion.

Cooling time varies with the mass and density of the charge, the maximum section thickness of the workpiece, and the ambient air temperature. Usually, production loads of 365 to 815 kg (800 to 1800 lb) from either continuous or batch-type furnaces will require $2\frac{1}{2}$ to 5 h to reach room temperature. Figure 11 shows the effect of section thickness. As indicated, the 25 mm (1 in.) diam sections were completely cooled in about half the time required for complete cooling of the 75 mm (3 in.) diam sections.

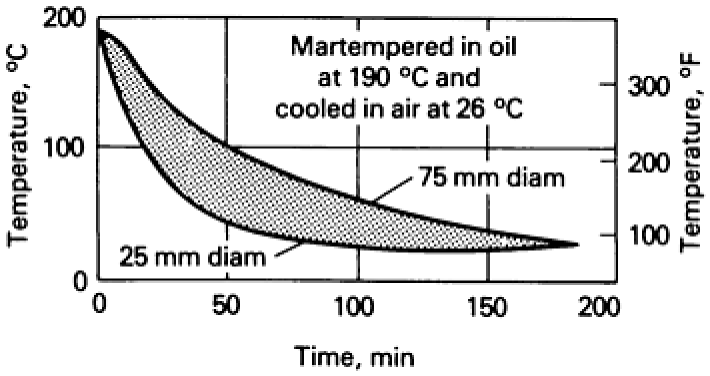

Fig. 11 Effect of section thickness on time required for air cooling of steel after martempering at 190 °C (375 °F). Temperature measurements were made at the surface. Times can be reduced by approximately 30% by forced fan cooling.

After being cooled to room temperature, martempered parts usually can be held at room temperature for several hours, and sometimes days, without risk of cracking because residual stresses are low compared to those in conventionally quenched parts. Holding of parts at room temperature also permits more nearly complete transformation of steels in which transformation is sluggish.

Dimensional Control

In many instances, distortion is significantly lower in martempered parts than in parts hardened by uninterrupted (conventional) quenching. However, prior processing often has a significant effect on distortion, regardless of the heat-treating method used. Therefore, for some applications martempering may fail to solve distortion problems because excessive dimensional changes occurred during heating prior to martempering.

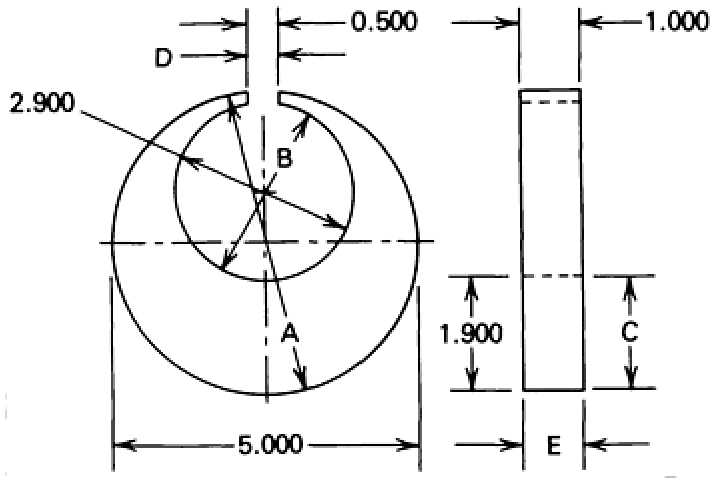
Occasionally, it is necessary to consider the effects of fabricating stresses that occur during forging, stamping, rolling, and machining. When the workpiece is heated, these stresses can cause a significant amount of distortion. A process anneal at 650 to 705 °C (1200 to 1300 °F) after rough machining or forming usually will relieve such stresses. Any resulting change in the size or shape of the part can then be corrected by finish machining prior to austenitizing and martempering. During heating, distortion also can occur as the result of temperature differences in a part having both light and heavy sections. This condition is often corrected by preheating at 650 to 705 °C (1200 to 1300 °F) prior to austenitizing.

Relatively large parts that require extreme flatness often must be press quenched. For example, a gear 178 mm (7 in.) in diameter, 13 mm ($\frac{1}{2}$ in.) thick at the rim, and with a 6.4 mm ($\frac{1}{4}$ in.) web could not be martempered with an acceptable degree of flatness. A large ring gear with internal teeth and a thin wall is another part for which martempering has been replaced by press quenching to obtain dimensions within acceptable limits.

The following examples describe specific situations in which distortion problems have been encountered. In some instances, the effects (on identical parts) of martempering and of oil quenching are presented for comparison.

Example 2: Comparison of Distortion in Navy C Specimens after Conventional Quenching and Martempering.

Figure 12 shows data for nine Navy C specimens made of a high-carbon alloy steel containing 0.95% C, 0.30% Si, 1.20% Mn, 0.50% W, 0.50% Cr, and 0.20% V were austenitized for 40 min at 845 °C (1550 °F); three of the specimens were subjected to conventional quenching in oil at 60 °C (140 °F), three were martempered for 2 min in salt at 205 °C (400 °F), and three were martempered for 2 min in salt at 245 °C (475 °F). Each quenching medium was agitated vigorously. All specimens were tempered to 63 to 64 HRC before being measured for dimensional changes.



Type of quench	Dimensional change, mm (mil)				
	A	B	C	D	E
Conventional (oil at 60 °C, or 140 °F)	0.21 (8.3)	0.24 (9.5)	0.20 (8.0)	0.61 (24)	0.075 (3)
Martempering in salt at 205 °C (400 °F)	0.137 (5.2)	0.15 (6)	0.13 (5)	0 (0)	0.025 (1)

Fig. 12 Dimensional changes in Navy C specimens austenitized at 1550 °F and quenched in three vigorously agitated mediums (Example 2). Figure dimensions given in inches

The data accompanying Fig. 12 indicate that the martempered specimens--especially those quenched in salt at 245 °C (475 °F)--exhibited less distortion in every dimension. These test results indicate that lower stresses result from martempering than from conventional oil quenching.

Example 3: Martempering of Bearing Races for Distortion Control.

Bearing races, 215 mm ($8\frac{3}{8}$ in.) in outside diameter by 190 mm ($7\frac{1}{2}$ in.) in inside diameter by 130 mm ($5\frac{1}{8}$ in.), made of 52100 steel, were austenitized in chloride salt at 850 °C (1560 °F) for 25 min, martempered in salt at 230 °C (450 °F) for $2\frac{1}{2}$ min, and air cooled to room temperature. The resulting hardness was 63 to 64 HRC. This treatment produced an average growth of 0.08 mm (0.003 in.) and an average distortion (out-of-roundness) of 0.25 mm (0.010 in.). Prior to heat treatment, the machined races had an average out-of-roundness of 0.18 mm (0.007 in.). Thus, the average increase in out-of-roundness was only 0.08 mm (0.003 in.).

In this application, martempering reduced grinding time from 50 to 7 min per race by permitting a reduction in the grinding stock required for conventionally oil-quenched parts.

Example 4: Warpage of Oil-Quenched Rods.

Rods 6.4 mm ($\frac{1}{4}$ in.) in diameter by 255 mm (10 in.) long, with a 3.2 mm ($\frac{1}{8}$ in.) hole near one end, were made from oil-hardening drill rod. The requirements were a hardness of 60 to 62 HRC and maximum warpage of 0.25 mm (0.010 in.) (indicator reading between centers).

The rods were heated by being suspended in a salt bath at 805 °C (1480 °F), and then were quenched in oil at 55 °C (135 °F). This treatment produced the required hardness, but warpage was excessive (up to 0.76 mm, or 0.030 in.). The problem was solved by replacing oil quenching with martempering in unagitated salt at 175 °C (350 °F).

Example 5: Martempering of Carburized Gears to Reduce Distortion.

Figure 13 shows a thin-wall ring gear of 8625 steel, with a flange on one end, that had to be carburized to a depth of 1.3 mm (0.050 in.) and hardened. After carburizing followed by martempering in oil at 190 °C (375 °F), out-of-roundness ranged from 0.43 to 0.66 mm (0.017 to 0.026 in.), which was not acceptable. The problem was solved by martempering and then placing the ring gears over a plug machined to the final inside diameter of the gear for cooling to room temperature. This produced acceptable parts having a maximum runout of 0.09 mm (0.0035 in.). The runout for eight gears tested before heat treating and after plug cooling is indicated in Fig. 13.

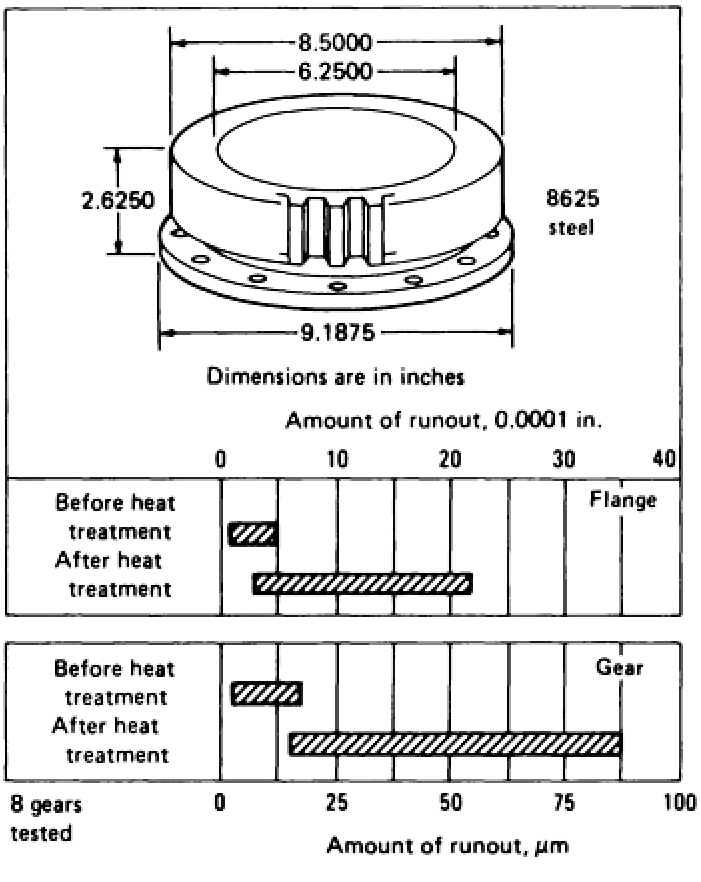


Fig. 13 Control range for 8625 steel ring gears (Example 5). Eight ring gears made of 8625 steel were carburized to a depth of 1.3 mm (0.050 in.), martempered in oil at 190 °C (375 °F), and placed on a plug for cooling to room temperature. Measurements are total indicator readings.

Figure 14 indicates the dimensional changes that occurred when different types and sizes of gears made of 8625H steel were carburized at 925 °C (1700 °F) to a depth of 1.0 to 1.5 mm (0.040 to 0.060 in.) and then martempered in oil at either 165 or 190 °C (325 or 375 °F).

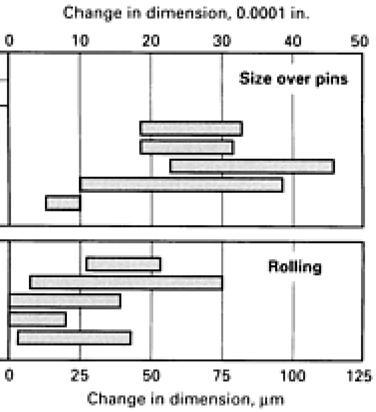

Fig. 14 Dimensional changes in carburized and martempered gears of 8625H steel (Example 5). All gears were carburized at 925 °C (1700 °F) to a depth of 1.0 to 1.5 mm (0.040 to 0.060 in.) and martempered directly from the carburizing temperature in oil at 165 °C (325 °F). Gears 1, 2, and 5 were measured over 7.32 mm (0.288 in.) diam pins; gear 3 over 3.66 mm (0.144 in.) diam pins; and gear 4 over 8.78 mm (0.3456 in.) diam pins.

Figure 15 shows the dimensional changes that were encountered in carburizing and martempering seven different sizes of automatic-transmission gears made of 8620H steel. The gears were martempered in oil at 150 °C (300 °F). Shrinkage of the largest gear is associated with lower core hardness in the considerably heavier section of the gear.

(a) Size over 12.2 mm (0.480 in.) diam pins

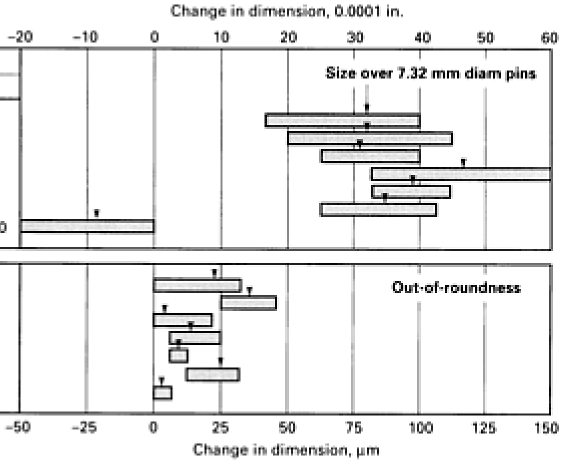

Fig. 15 Dimensional changes in carburized and martempered automatic-transmission gears made of 8620H steel. All gears were carburized at 925 °C (1700 °F) and then martempered directly from the carburizing temperature in oil at 150 °C (300 °F).

Figure 16 indicates the effects of various combinations of carburizing and quenching methods on the dimensions of 25-tooth reverse-idler gears for power-grader transmissions. All gears were carburized to a depth of 0.76 to 1.0 mm (0.030 to 0.040 in.). The smallest dimensional changes occurred in gears that were liquid carburized and then martempered in salt at 205 °C (400 °F); the greatest changes occurred in those that were gas carburized and quenched in agitated oil at 45 °C (110 °F).

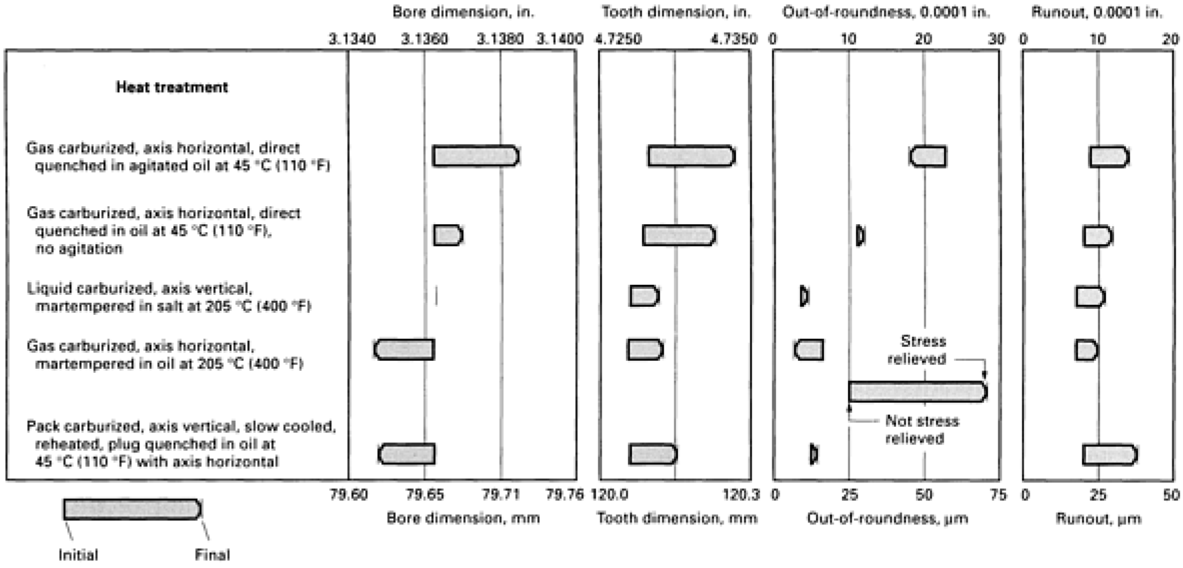

Fig. 16 Effects of various carburizing and quenching methods on dimensions of 4620H steel reverse-idler gears for power-grader transmissions. Gears were carburized to a depth of 0.8 to 1.0 mm (0.030 to 0.040 in.) and quenched to a hardness of 58 to 63 HRC.

The effect of stress relieving on out-of-roundness is also indicated in Fig. 16. The data for bore, teeth, and runout are for gears that were stress relieved before heat treating.

Example 6: Distortion in Martempering of 8625 Steel Shafts.

Figures 17 and 18 are histograms of distortion data, in terms of total indicator readings, for various shafts made of 8625 steel. The shafts depicted in Fig. 17 were machined from bar stock, whereas those in Fig. 18 were forged. All shafts were carburized at 925 °C (1700 °F) and martempered in oil at 165 °C (325 °F). Also, all shafts were in the vertical position during heat treating--some suspended, and some supported on one end--as indicated in Fig. 17 and 18.

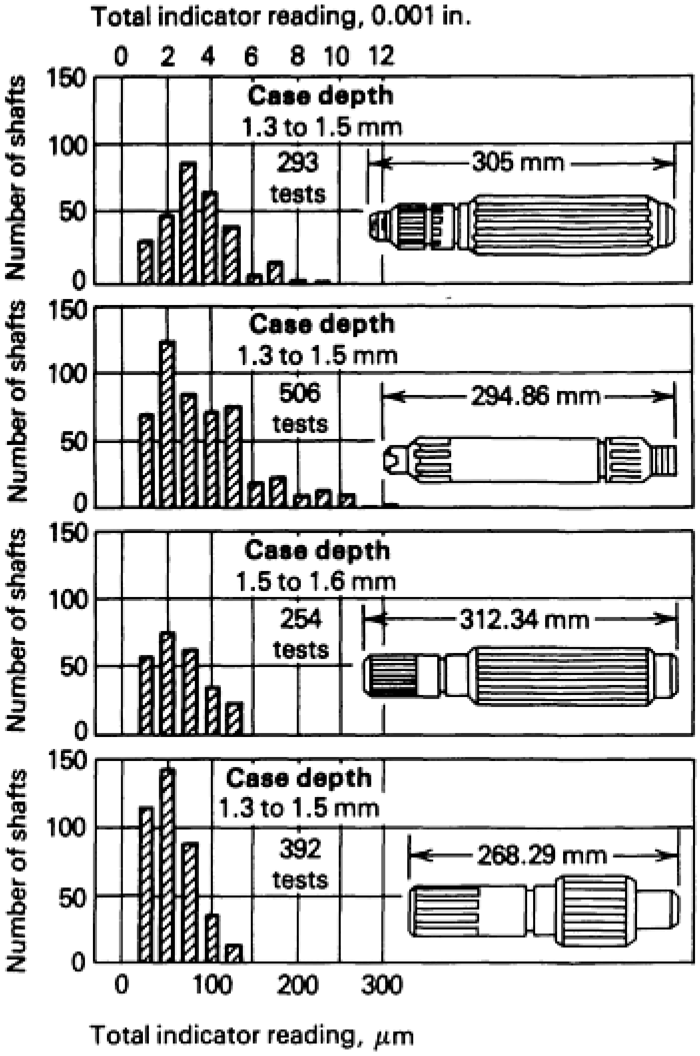

Fig. 17 Distortion in martempering (Example 6). Histograms of distortion data on shafts of 8625 steel (machined from bar stock) after carburizing at 925 °C (1700 °F) and martempering in oil at 165 °C (325 °F). Shafts were heat treated in the vertical position: the top two shafts were suspended vertically from the threaded end; the lower two shafts were supported on one end.

Fig. 18 Distortion in martempering (Example 6). Histograms of distortion data on forged shafts of 8625 steel after carburizing at 925 °C (1700 °F) and martempering in oil at 165 °C (325 °F). Shafts were supported vertically on one end during heat treatment.

Stabilizing after Martempering. Parts such as shafts, chain-saw guides, washers, and springs require straightening or re-forming after heat treatment. This is sometimes not feasible after normal quenching and tempering. However, after such parts are removed from a martempering bath, straightening is readily accomplished, either by hand pressure or in a die press, while the parts are still essentially austenitic.

When parts are clamped between plates held at approximately 150 °C (300 °F), the parts cool to the temperature of the plate. At this temperature, depending on the M_f temperature of the steel, the transformation to martensite may be only partial, but it is usually near enough to completion for the part to set permanently before it is removed from the clamped position. At this temperature, the film of salt (melting point, about 145 °C, or 290 °F) adhering to the part will not freeze, and therefore removal of the part from the clamps or die can be accomplished without difficulty. The transformation of martensite is completed during subsequent air cooling to room temperature, and the part is within dimensional tolerance.

Forming after Martempering. Difficult-to-form materials, such as hot-work die steels (H11) and some martensitic stainless steels used for missiles, rockets, and high-speed aircraft, can be accurately formed and hardened by austenitizing, martempering, and hot forming to shape immediately after they are extracted from the quench bath, if the martempering temperature is above the martensite transformation temperature for the specific alloy being treated. During hot forming by rolling, forging, drawing, or extruding, the metal consists of metastable austenite, which transforms to martensite on subsequent cooling to room temperature.

Parts of both simple and complex shape have been formed in this manner; after being air cooled to room temperature in or out of the forming die, the parts will accurately maintain their as-formed dimensions and yet be in the fully heat-treated condition, requiring only a subsequent tempering operation.

This method of heat treating and forming has been successfully applied to sheet and plate that require nearly perfect flatness. It also has been used for forming type 420 stainless steel sheet into cups that require close dimensional tolerances and hardness values of 55 to 58 HRC. Working of metastable H11 that results in deformation of 58 to 94% at 480 °C (900 °F) produces a 19 to 32% increase in tensile strength.

Applications

Typical applications of martempering in salt and oil are indicated in Tables 4 and 5, which list and describe steel parts commonly treated and give details of martempering procedures and hardness requirements. From these tables, it is evident that martempering is used for parts of diverse shapes, weights, section sizes, and steel compositions.

Table 4 Typical applications of martempering steel parts in salt

Part	Grade	Maximum section thickness		Weight		Martempering conditions			Required hardness, HRC

(a) Minimum time in oil, 5 min.

(b) Carbonitriding temperature

Although about a third of the applications in Table 4 and most of the applications in Table 5 are carburized parts, it is believed that in current industrial practice the tonnage of martempered through-hardening steels markedly exceeds that of martempered carburized steels. However, martempering is especially appropriate for carburized parts (particularly for splined shafts, cams, and gears) because these parts generally are more difficult to grind and more costly to fabricate, and are made to closer dimensions, than are parts made of through-hardening steels.

Special adaptations of martempering are sometimes employed to achieve desired characteristics and to solve specific problems. Such modified techniques, however, usually require that all conditions be closely controlled, lest still greater problems result. One special technique that has been employed is described in the following example.

Example 7: Adaptation of Martempering Involving a Brief Quench in Brine.

A problem was encountered in obtaining a sufficient depth of hardness in forged balls made of 52100 steel, which ranged in diameter from 25 to 64 mm (1 to $2\frac{1}{2}$ in.). Investigation ruled out both conventional oil quenching and martempering because of low hardness penetration and the existence of quenching pearlite (an intermediate transformation product) in the microstructure.

This problem was solved by preceding martempering with a brief, timed quench in agitated brine at 23 °C (74 °F). Heat treatment of the balls then consisted of:

- Austenitizing in salt at 855 °C (1575 °F) for times ranging from 15 min for 25 mm (1 in.) diam balls to 50 min for 64 mm ($2\frac{1}{2}$ in.) diam balls
- Quenching in agitated brine at 23 °C (74 °F) for times ranging from 15 s for 25 mm diam balls to 40 s for 64 mm diam balls and removing parts while hot (above 100 °C, or 212 °F) to accelerate evaporation of moisture
- Martempering in salt at 165 °C (325 °F) for 8 min (all diameters)
- Air cooling
- Tempering at 140 °C (285 °F) for 3 h (all diameters). By use of this treatment, the parts were successfully hardened to the desired depth. Surface hardness values were as follows:

Diameter of ball		Surface hardness, HRC
mm	in.	
27	$1\frac{1}{16}$	64.0-64.5
29	$1\frac{1}{8}$	64.5-65.5
32	$1\frac{1}{4}$	63.5-64.5

33	$1\frac{5}{16}$	64.0-64.5
35	$1\frac{3}{8}$	63.0-64.0
38	$1\frac{1}{2}$	63.0-63.5
41	$1\frac{5}{8}$	63.5-64.5
43	$1\frac{11}{16}$	63.0-64.0
44	$1\frac{3}{4}$	63.5-64.5
48	$1\frac{7}{8}$	63.5-64.0
49	$1\frac{15}{16}$	63.5-64.0
54	$2\frac{1}{8}$	61.5-63.5

Selection of Austenitizing Equipment

Austenitizing of steel prior to martempering may be done in virtually any furnace. This phase of the operation has been successfully accomplished in furnaces ranging from small, simple box furnaces to large, fully automated, high-production installations. Both atmosphere-controlled furnaces and molten salt baths are widely used. Fluid beds are also being used to austenitize loads prior to martempering.

The choice of austenitizing equipment depends mainly on availability, shape and size of workpieces, production requirements, and permissible distortion.

Work that is austenitized in a gaseous atmosphere can be oxidized while being transferred to an oil or salt martempering furnace. However, no special considerations are necessary when salt media are used for austenitizing before martempering in salt because chloride salts are compatible with, and are easily separated from, the martempering bath. The composition and characteristics of a typical chloride salt medium are as follows. composition, 45 to 55% NaCl and 45 to 55% KCl; melting range, 650 to 675 °C (1200 to 1250 °F); working range, 705 to 900 °C (1300 to 1650 °F).

If it is necessary to austenitize in a bath that contains cyanide, such as a liquid carburizing bath, the work should be transferred to a neutral salt (chloride-type) rinse at the austenitizing temperature prior to martempering in salt. Direct quenching from a noncyanide-type liquid carburizing bath is permissible (see the article "Liquid Carburizing and Cyaniding" in this Volume).

Salt bath furnaces for austenitizing (and neutral rinsing, if used) are most commonly of the submerged- or immersed-electrode type, although externally heated pots are also satisfactory.

Selection of Martempering Equipment

The furnace used for martempering is essentially a heat exchanger. Its basic functions are to absorb heat from the work being quenched, and then to dissipate this heat to the surroundings to maintain a constant temperature.

In its simplest form, the martempering furnace consists of a steel pot that contains the oil or nitrate-nitrite salt and that is heated internally or externally. Such a simple furnace can be successfully used for martempering in limited production quantities.

For continuous production, more complex equipment is needed to maintain optimum quenching conditions.

Fuel-fired (usually gas-fired) immersion tubes, electrodes, or immersion heaters, located across the back wall and sides of the furnace, are also used for internal heating. Occasionally, furnaces are externally heated by fuel or electricity, but such furnaces are limited to relatively small installations because they are difficult to control.

With internal heating, furnace size is unlimited and is based on production requirements. Sizes may range from 0.06 m^3 (2 ft^3) to lengths of more than 18 m (60 ft) and depths of more than 14 m (45 ft).

The operating temperature range for martempering usually is 165 to 595 °C (325 to 1100 °F). Temperature is measured by one or more thermocouples (depending on the size of the furnace), which are connected to controlling pyrometers that automatically control temperature within by actuating the heating or cooling systems as required.

In continuous production, heat input from the work usually exceeds heat losses by radiation. Therefore, arrangements for cooling as well as for heating the martempering medium are required. To supplement heat losses by radiation from the surface of the bath, the exterior surface of the pot may be designed with cooling fins so that additional heat can be removed by forcing air through the cooling chamber between the pot and the casing walls. To increase heat dissipation, atomized water may be added to the stream of air. The mixture is then passed through a heat exchanger placed in the bath.

Agitation of the molten salt greatly improves the rate at which heat is extracted from the work. The furnace can be provided with a propeller-type pump that delivers the molten salt to the quench header into which the hot work is placed for quenching. By directing the flow of salt upward or downward through this quench header, effective control of the quenching severity of the salt is maintained, particularly if the speed of the pump can be varied. The salt also may be agitated by propeller mixers, centrifugal pumps, or air bubblers located to produce effective agitation in the quench area. The use of air bubblers is not recommended because they are not efficient and may cause carbonate buildup in the bath.

The furnace may have a second chamber in which the contaminating chlorides of barium, sodium, and potassium that may be carried over from the austenitizing salt bath are separated by gravity from the nitrate-nitrite martempering salt. Contaminated salt is continuously circulated through the separating chamber, and with a drop in salt temperature, more chlorides are precipitated from solution and settle to the bottom of the separating chamber. Because clarification is continuous, a uniform quenching condition is provided at all times. When work is austenitized in an atmosphere-controlled furnace, this chamber is not required.

The equipment required for martempering in hot oil is essentially the same as that for martempering in salt. Although the operating temperature range of oil baths is lower (95 to 230 °C, or 200 to 450 °F), the problem of maintaining a constant bath temperature is the same for salt.

Examples of equipment requirements for several specific operations are given in Tables 6, 7, 8, 9, 10, 11, and 12. Each example is described further below.

Table 6 Equipment requirements for oil martempering carburized parts made of 4024 and 4028 steels

Production requirements	
Production rate, kg/h (lb/h)	455 (1000)
Weight of each piece, kg (lb)	70 g-1.0 (0.15-2.2)
Number of pieces per hour	Variable
Equipment requirements	
Capacity of quench tank, 1 (gal)	18,925 (5000)
Type of oil	Mineral oil (viscosity at 99 °C, or 210 °F; 110 sus)
Temperature of oil, °C (°F)	190 (375)
Agitation	High and low, as required

Table 7 Equipment requirements for oil martempering carburized parts made of 8617 steel

Production requirements	
Weight of load, kg (lb)	455 (1000) net
Weight of each piece, kg (lb)	1.5 (3.3)
Number of pieces treated per hour	75
Equipment requirements	
Capacity of quench tank, 1 (gal)	7570 (2000)
Type of oil	Mineral oil with additives (viscosity at 38 °C, or 100 °F, 250 sus)
Temperature of oil, °C (°F)	150 (300)
Agitation	Direct flow[(a)]

(a) Agitation provided by two 3.7 kw (5 hp) motors driving 455 mm (18 in.) propellers at 370 rpm, causing the oil to flow at a rate of 915 mm/s (36 in./s)

Table 8 Equipment requirements for salt martempering automotive transmission shafts of 5040 steel

Production requirements	
Weight of each piece, kg (lb)	1.1 (2.5)
Pieces per fixture	14
Production per hour	
Number of loaded fixtures	10.7
Number of pieces	150
Weight of pieces, kg (lb)	170 (375)
Equipment requirements	
Martempering furnace	Steel salt pot with resistance immersion heaters (70 kW)
Size of chamber[(a)]	1.22 m by 510 mm by 560 mm (48 by 20 by 22 in.)
Size of chloride-separating chamber, mm (in.)	380 by 815 by 940(15 by 32 by 37)
Capacity of salt pot, kg (lb)	3630 (8000)
Type of salt	Nitrate-nitrite
Operating temperature. °C (°F)	260 ± 3 (500 ± 5)
Agitation, kW (hp); mm (in.)	One 2.2 (3) 150 (6) propeller pump
Cooling system[(b)], kW (hp); m^3/min (ft^3/min)	One 0.25 ($\frac{1}{3}$) blower (25.5, or 900)

(a) Total depth of salt was 940 mm (37 in.)

(b) Cooling capacity of system was 215 kg/h (475 lb/h) (gross) from 845 to 230 °C (1550 to 450 °F) without exceeding 230 °C.

Table 9 Equipment requirements for salt martempering gears made of 6150 steel

Production requirements

Weight of each piece, kg (lb)	0.9 (2)
Pieces per furnace load	32
Production per hour[a]	
Number of pieces	128
Net work load, kg (lb)	116 (256)
Gross furnace load[b], kg (lb)	152 (336)
Equipment requirements	
Martempering furnace	Immersion-heated salt pot[c]
Size of salt pot, mm (in.)	610 by 380 by 840 (24 by 15 by 33)
Capacity of salt pot, kg (lb)	270 (600)
Type of salt	Nitrate-nitrite (2% water added)
Quenching capacity of salt pot, kg/h (lb/h)	180 (400)
Operating temperature, °C (°F)	205 (400)
Agitation	Air-operated stirrer

(a) Cycle time, 15 min.

(b) Work plus fixtures: each fixture had an empty weight of 9.1 kg (20 lb) and contained eight gears.

(c) Salt pot rated at 21 kV · A (3 phase, 60 cycle, 220 to 440 V) for heating to temperature range of 175 to 400 °C (350 to 750 °F); 0.37 kW ($\frac{1}{2}$ hp) blower (3 phase, 60 cycle, 220 V) used for cooling by driving room-temperature air between wall of pot and exterior shell of furnace

Table 10 Equipment requirements for salt martempering a variety of steel parts

Martempering furnace	Steel salt pot
Method of heating, mm (in.)	100 (4) immersion tube fired by natural gas[a]

Rated heat input, kW (Btu/h)	38.4 (131 000)
Operating temperature range[(b)], °C (°F)	205-400 (400-750)
Capacity of salt pot, kg (lb)	1725 (3800)
Type of salt	Nitrate-nitrite
Size of chloride-separating chamber[(c)]	205 mm by 1.07 m (8 by 42 in.)
Agitation method, kW (hp)	0.19 ($\frac{1}{4}$) propeller mixer
Cooling method[(d)]	Air through immersion tube

(a) Gas rated at 39.12 MJ/m^3 (1050 Btu/ft^3).

(b) Temperature automatically controlled to ±3 °C (±5 °F).

(c) Depth of salt, 760 mm (30 in.).

(d) Cooling capacity, 180 kg/h (400 lb/h) (gross) from 845 to 260 °C (1550 to 500 °F) without exceeding 260 °C

Table 11 Equipment requirements for salt martempering piston rings made of 52100 steel

Production requirements	
Production rate[(a)]	
Gross, kg/h (lb/h)	210 (465)
Net, kg/h (lb/h)	68 (150)
Equipment requirements	
Martempering furnace	Immersion-heated steel salt pot[(b)]
Size of work chamber[(c)], mm (in.)	915 by 455 (36 by 18)
Size of chloride-separating chamber[(d)], mm (in.)	380 by 785 (15 by 31)

Capacity of salt pot, kg (lb)	1950 (4300)
Type of salt	Nitrate-nitrite
Operating temperature of salt pot[e], °C, (°F)	260 (500)
Agitation, kW (hp); mm (in.)	One 2.2 (3), 150 (6) propeller pump
Cooling system, kW (hp); m^3/min (ft^3/min)	One 0.25 ($\frac{1}{3}$) blower (25.5, or 900)
Cooling capacity, kg/h (lb/h); °C (°F)	210 (465) (gross) from 845 to 260 (1550 to 500)

(a) Heavy mandrels were used as fixtures to retain shape of piston rings, which accounts for wide difference between gross and net weights.

(b) Resistance immersion heaters (60 kW).

(c) Depth of salt, 760 mm (30 in.).

(d) Depth of salt, 1.04 m (41 in.).

(e) Automatically controlled to ±3 °C (±5 °F)

Table 12 Equipment requirements for salt martempering aircraft landing-gear parts of 4330 steel

Production requirements	
Production per hour, kg (lb)	One load of 270 (600)
Equipment requirements	
Martempering furnace	Immersion-heated steel salt pot[a]
Size of work chamber[b], m (in.)	1.5 by 1.9 (60 by 75)
Capacity of salt pot, kg (lb)	21,850 (48,200)
Type of salt	Nitrate-nitrite
Operating temperature of salt pot[c], °C (°F)	205 (400)

Agitation, kW (hp); mm (in.)	Two 2.2 (3), 180 (7) propeller agitators
Cooling system	Natural draft
Cooling capacity, kg/h (lb/h); °C (°F)	455 (1000) (gross) from 845-205 (1550-400)[d]

Note: Parts were treated as follows: austenitize for 45 to 60 min at 845 °C (1550 °F), martemper for 5 to 7 min at 205 °C (400 °F), air cool to room temperature, and then temper at 425 °C (800 °F) to produce a hardness of 37 to 42 HRC.

(a) Resistance immersion heaters (120 kW).

(b) Depth of salt, 4.72 m (186 in.).

(c) Temperature automatically controlled to ±3 °C (±5 °F).

(d) Maximum temperature rise to 215 °C (415 °F)

Examples in Table 6. The equipment required for martempering miscellaneous carburized parts (70 g to 1.0 kg, or 0.15 to 2.2 lb, per piece) made from 4024 and 4028 steels, at a rate of 455 kg/h (1000 lb/h), is listed in Table 6. Oil at 190 °C (375 °F) was the martempering medium used in this installation.

The parts were carburized at 915 to 925 °C (1680 to 1700 °F) to a depth of 0.5 to 0.75 mm (0.020 to 0.030 in.) in a radiant-tube, gas-fired, three-row continuous pusher furnace with automatic quenching facilities. Parts were quenched from the final zone at 895 to 905 °C (1640 to 1660 °F). The carburizing atmosphere consisted of endothermic gas provided by a gas generator and 4.8 m^3/h (170 ft^3/h) of natural gas.

Example in Table 7. In the operation for which equipment requirements are detailed in Table 7, oil at 150 °C (300 °F) was used as the martempering medium. In this operation, a 455 kg (1000 lb) load of 1.5 kg (3.3 lb) parts made of 8617 steel was quenched from an automatic batch-type furnace.

These parts were carburized to a depth of 1.0 mm (0.040 in.) in a radiant-tube, gas-fired batch furnace with automatic quenching facilities. The parts were carburized at 925 °C (1700 °F) and cooled in the furnace to a quenching temperature of 845 °C (1550 °F). The carburizing atmosphere consisted of endothermic gas and natural gas.

Example in Table 8. Table 8 lists details of equipment required for salt martempering 1.1 kg (2.5 lb) transmission shafts made of 5040 steel at a rate of 170 kg/h (375 lb/h). The complete treatment was as follows:

- Austenitize for 35 min in neutral chloride salt at 845 °C (1550 °F)
- Martemper for 5 min at 260 °C (500 °F)
- Air cool (30 min) to 65 to 95 °C (150 to 200 °F)
- Temper for 45 min at 425 °C (800 °F)
- Air cool (5 min) to 95 to 120 °C (200 to 250 °F)
- Wash, rinse, and dry

Hardness after tempering and cooling to room temperature was 40 to 42 HRC (required hardness was 38 to 42 HRC).

Example in Table 9. Table 9 lists equipment requirements for salt martempering 0.9 kg (2 lb) gears made of 6150 steel at a rate of 128 pieces per hour. The gears were austenitized in a 60 kV · A submerged-electrode salt pot capable of

heating 180 kg/h (400 lb/h) to 870 °C (1600 °F). The austenitizing pot measured 455 by 380 by 760 mm (18 by 15 by 30 in.) and contained 180 kg (400 lb) of alkali-chloride salt at an operating temperature of 845 °C (1550 °F). Table 9 gives martempering requirements.

Example in Table 10. Details of a salt martempering furnace used in a commercial heat-treating plant for quenching up to 180 kg/h (400 lb/h) are given in Table 10. This salt bath is capable of being operated at up to 400 °C (750 °F) and therefore can also be used for austempering.

Example in Table 11. Table 11 shows details of a salt martempering bath capable of cooling 210 kg/h (465 lb/h) from 845 to 260 °C (1550 to 500 °F). This specific installation is used exclusively for heat treating piston rings made of 52100 steel.

Example in Table 12. The equipment used in one installation for martempering aircraft landing-gear parts made of 4330 steel is detailed in Table 12. Following martempering, these parts are tempered at 425 °C (800 °F), which results in a hardness of 37 to 42 HRC.

Maintenance of Equipment

Lack of an established maintenance schedule may result in loss of process control, damage to the equipment, or both.

Salt System. Because martempering baths vary widely in design, shape, size, and method of operation, it is not feasible to set forth a standard maintenance schedule. Manufacturers' recommendations for specific equipment should be followed; however, typical schedules for maintaining a salt bath are as follows:

Each 8-h shift

- Check instruments and thermocouples against a standard
- Check neutrality of austenitizing bath (if salt containing cyanide is used for austenitizing, the cyanide content should be less than 2%)
- Remove sludge from martempering bath; mechanical separators (filter baskets or pans) eliminate the need for this operation
- Check salt level
- Check agitation of bath and adjust as needed

Weekly

- Lubricate all moving parts
- Remove sludge or contamination from the surface of the immersion heaters (radiant tubes or electrodes), and from the walls, bottom, and top of the furnace

Monthly

- Check operation of all moving parts, such as blowers and pumps; adjust belt tension and alignment of shafts
- Check electrical contacts of all contactors and relays, and repair as required; examine all electrical devices for proper operation
- Remove fallen parts or debris from the quench header or quench area to avoid fouling
- Check heating and cooling facilities

Semiannually or annually

- Remove the salt from the furnace and check the condition of the pot, pumps, and heating system

- Clean and repair all electrical parts, such as contactors, relays, motors, and motor starters (it is especially important to remove condensed salt from all terminals and transformers)
- Clean and repair all moving parts and lubricate as required

Oil System. Following is a typical procedure for maintaining a high-temperature (175 to 205 °C, or 350 to 400 °F) oil-quench system:

Daily

- Observe oil-temperature indicators every hour; verify the indicated temperature with a potentiometer each day
- Check oil level in sight gage to ensure proper level and function of the automatic makeup unit
- Check closed system frequently for proper pressure of the atmosphere blanket over the quenching oil; pressure of this blanket should be equal to furnace-atmosphere pressure
- Check oil agitation by either observing through sight doors and noting if the pump shaft is operating at the proper speed, or, preferably, by monitoring the load on the pump motor
- Check condition of oil on parts emerging from quench. Undue discoloration or varnishing may indicate deterioration of oil
- Visually check the performance of gas-fired immersion-heating tubes

Weekly

- Check condition of oil visually and by viscosity testing; record findings on graph to note trends
- Check speed of pump shaft with tachometer to ensure consistent oil flow
- Check performance of temperature-control devices through on-off range to ensure positive control
- Check thermocouple
- Check for proper operation and elevations of quenching mechanism or elevator
- Check and clean pilot lights
- Check and clean electrodes in ignition system of gas burners
- Check safety control on gas lines for heating tubes
- Check makeup oil supply
- Check motor-operated venting systems for proper operation and remove carbon buildup to prevent jamming

Semiannually

- Drain oil from, and clean, quench tank
- Operate, and inspect functioning of mechanical elements such as elevator, oil pumps, and adjustable oil deflectors
- Check gas-fired heating tubes
- Inspect V-belts for pump drive and agitators; replace if necessary
- Check condition of temperature-measuring system
- Determine condition of oil by physical and chemical testing of various properties

Racking and Handling

The techniques for handling parts to be martempered may be similar to those for conventional oil quenching. However, racking and fixturing can be simplified for some martempering applications because distortion is less.

Example 8: Elimination of Heavy Fixturing with Martempering.

Extensive fixturing was required during conventional oil quenching of shaftlike parts made of 52100 steel. These parts were about 180 mm (7 in.) long and had a major diameter of 25 mm (1 in.). The fixtures weighed about the same as the work load.

A change from conventional quenching to martempering for 5 min in salt at 245 °C (475 °F) eliminated the need for the heavy, expensive fixtures and made it possible to hold distortion within the required limits. For martempering, the parts were placed vertically in simple fabricated baskets. This practice also resulted in a greater "payload."

The manner in which workpieces enter the bath generally is less critical in martempering than in conventional oil quenching. For example, large flat parts do not dish as much when martempered. However, the shape of each part must be considered individually, and some trial and error often is necessary before an optimum handling technique can be developed.

Nesting of small parts can be a problem, and development of a handling method that will result in uniform quenching often requires experimentation. A technique that proved successful for one application is described below.

Example 9: Techniques to Improve Uniform Quenching during Martempering.

Flat blades that were not well suited to fixturing or wiring had a tendency to nest, which caused nonuniform quenching during martempering. This problem was overcome by use of a pump that directed a heavy flow of molten salt upward through a perforated metal basket, which kept the parts separated. This technique requires that the flow of salt be regulated to the floating characteristics of the workpieces.

For fixturing of parts, one of the following considerations may apply:

- Long, slender parts should be suspended
- Symmetrical parts, such as bearing races and cylinders, can be stacked and supported on a rack or grid
- Flat parts, such as circular saw blades, mower blades, and clutch plates, are best supported on horizontal slotted rods that provide the necessary separation
- Coils of wire are supported either vertically on a spider-type grid or horizontally on support rods
- Small parts can be loaded into a perforated ladle or basket and then dumped into the quench to obtain intimate quenching of all parts
- Fixture design should be simple, free of welds (if possible), and easy to maintain. For example, fixtures supporting vertical stacks of bearing races should be removable for periodic grinding to maintain flatness

Proper spacing of workpieces to permit good flow of the quenchant around each part is an important consideration in martempering. Also, the combined weight of workpieces and fixtures must be limited to the extent that the heat they contain is insufficient to cause a sharp increase in the temperature of the quenchant. In this regard, the size of a salt bath furnace is determined not only by the physical size of the work, but also by design requirements such as salt-separating systems, a means for agitation of the salt, and sufficient area for dissipation of heat through sidewalls.

Washing the Work

Regardless of the martempering medium used, the work load should not be washed until transformation is complete (all portions of workpieces should be near room temperature).

Martempering salts are completely water soluble, and any hot-water soaking tank or spray washer will remove all salt from accessible areas. Cold water can be used, but its washing action is much slower.

The speed of washing will depend on how much hot water unsaturated with salt flows over the salt-coated surface. Therefore, agitation will increase the washing action, and a device such as an open-impeller sump pump can be used in a soaking tank to direct a stream of hot water into recessed areas. Steam jets may be used as supplementary equipment to remove salt from sections of intricately shaped parts with difficult-to-reach recesses for which conventional washing equipment is inadequate.

Quenching oils often present washing problems. Martempering oil adheres more tenaciously to workpieces than does conventional quenching oil because of its higher viscosity, as high as 1200 Saybolt Universal Seconds (SUS) at 38 °C (100 °F), compared with 100 SUS at 38 °C for conventional oil.

Basically, the washing equipment is the same for both types of quenching oils, but a heavy-duty cleaner must be used to remove martempering oil. Several proprietary heavy-duty silicate-alkaline cleaners are available for cleaning parts martempered in hot oil. Vapor degreasing and steam cleaning without detergent may be used in special applications.

Austempering of Steel

Revised by John R. Keough, Atmosphere Group, Inc.; W. James Laird, Jr., The Metal Works Industrial Furnaces,Inc.; and A.D. Godding, Heatbath Corporation

Introduction

AUSTEMPERING is the isothermal transformation of a ferrous alloy at a temperature below that of pearlite formation and above that of martensite formation. Austempering of steel offers several potential advantages:

- Increased ductility, toughness, and strength at a given hardness (Table 1)
- Reduced distortion, which lessens subsequent machining time, stock removal, sorting, inspection, and scrap
- The shortest overall time cycle to through-harden within the hardness range of 35 to 55 HRC, with resulting savings in energy and capital investment

Table 1 Mechanical properties of 1095 steel heat treated by three methods

Specimen No.	Heat treatment	Hardness, HRC	Impact strength		Elongation in in 25 mm, or 1 in., %
			J	ft · lbf	
1	Water quenched and tempered	53.0	16	12	. . .
2	Water quenched and tempered	52.5	19	14	. . .
3	Martempered and tempered	53.0	38	28	. . .
4	Martempered and tempered	52.8	33	24	. . .
5	Austempered	52.0	61	45	11

Steel is austempered by being:

- Heated to a temperature within the austenitizing range, usually 790 to 915 °C (1450 to 1675 °F)
- Quenched in a bath maintained at a constant temperature, usually in the range of 260 to 400 °C (500 to 750 °F)
- Allowed to transform isothermally to bainite in this bath
- Cooled to room temperature

The process is described in detail by the inventors E.S. Davenport and E.C. Bain in U.S. Patent 1,924,099. The fundamental difference between austempering and conventional quenching and tempering is shown schematically in Fig. 1. For true austempering, the metal must be cooled from the austenitizing temperature to the temperature of the austempering bath fast enough so that no transformation of austenite occurs during cooling, and then held at bath temperature long enough to ensure complete transformation of austenite to bainite. Modifications of these procedures, constituting departures from true austempering, are discussed in the section "Modified Austempering" in this article.

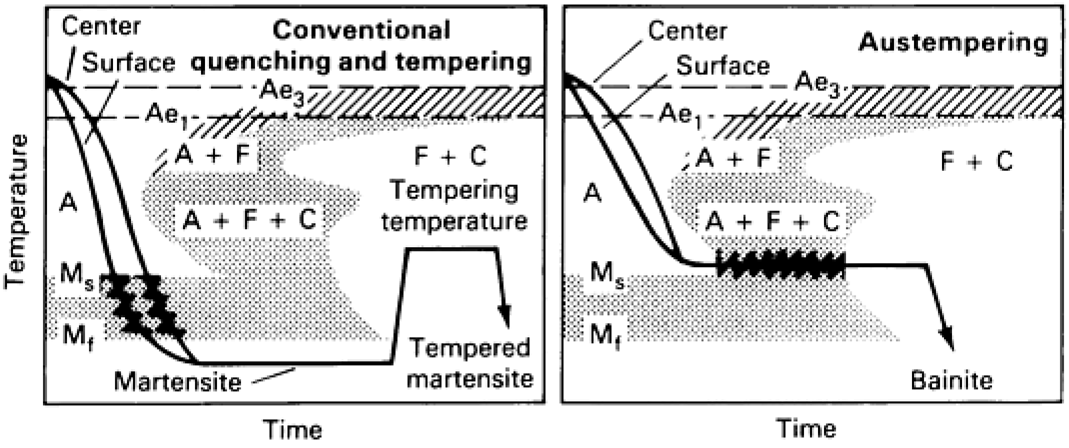

Fig. 1 Comparison of time-temperature transformation cycles for conventional quenching and tempering and for austempering

Austempering is also the isothermal transformation used to form a unique acicular matrix of bainitic ferrite and stable high-carbon austenite in hardenable cast irons. The process of austempering ductile iron (ADI) is described in detail in the article "Heat Treating of Ductile Iron" in this Volume.

Quenching Media for Austempering

Molten salt is the quenching medium most commonly used in austempering because:

- It transfers heat rapidly
- It virtually eliminates the problem of a vapor phase barrier during the initial stage of quenching
- Its viscosity is uniform over a wide range of temperature
- Its viscosity is low at austempering temperatures (near that of water at room temperature), thus minimizing dragout losses
- It remains stable at operating temperatures and is completely soluble in water, thus facilitating subsequent cleaning operations
- The salt can be easily recovered from wash waters by evaporative methods

Formulations and characteristics of two typical salt quenching baths are given in Table 2(a). The high-range salt is suitable for austempering only, whereas the wide-range salt may be used for austempering, martempering, and modifications thereof. Table 2(b) compares quench severity for salt quenches.

Table 2(a) Compositions and characteristics of salts used for austempering

	High range	Wide range
Sodium nitrate, %	45-55	0-25

Potassium nitrate, %	45-55	45-55
Sodium nitrite, %	. . .	25-55
Melting point (approx), °C (°F)	220 (430)	150-165 (300-330)
Working temperature range, °C (°F)	260-595 (500-1100)	175-540 (345-1000)

Table 2(b) Quench severity comparison for salt quenches

Numbers given are estimated Grossmann H-values as described in the article "Quenching of Steel" in this Volume.

Agitation	At temperature	
	180 °C (360 °F)	370 °C (700 °F)
Still and dry	0.15-0.20	0.15
Agitated and dry	0.25-0.35	0.20-0.25
Agitated with 0.5% water	0.40-0.50	0.30-0.40
Agitated with 2% water	0.50-0.60	0.50-0.60[a]

(a) Requires special enclosed quenching apparatus

Water Additions to Nitrate-Nitrite Salt. The quenching severity of a nitrate-nitrite salt can be increased significantly by careful addition of water. Agitation of the salt is necessary to disperse the water uniformly. Periodic water additions are needed to maintain required water content (see the article "Martempering of Steel" in this Volume). Water can be added with complete safety as follows:

- Water may be misted at a regulated rate into a vigorously agitated area of the molten bath
- In installations where the salt is pump circulated, returning salt is cascaded into the quench zone. A controlled fine stream of water may be injected into the cascade of returning salt
- The austempering bath may be kept saturated with moisture by introducing steam directly into a bath. The steam line should be trapped and equipped with a discharge to avoid emptying condensate directly into the bath
- Steam additions of water to ADI baths is done with operating temperatures above 260 °C (500 °F)

Addition of water to increase the quenching severity of salt usually is made by directing a stream of water onto the molten salt at the agitator vortex. A protective shroud surrounds the water spray to prevent spattering. The turbulence of the salt

carries the water into the bath without spattering or hazard to the operator. Water should never be added to a salt bath from a pail or dipper.

Water is continuously evaporating from the bath surface, and the rate of evaporation increases during quenching of hot work. Thus, it is necessary to add water periodically to maintain the water concentration and a uniform quenching severity. The amount of water to be added to an open salt bath varies with the operating temperature of the salt, as indicated by the following recommended concentrations:

Temperature		**Water concentration, %**
°C	**°F**	
205	400	$\frac{1}{2}$ to 2
260	500	$\frac{1}{2}$ to 1
315	600	$\frac{1}{4}$ to $\frac{1}{2}$

The numbers shown in this table represent the amounts of water soluble in salt baths maintained at atmosphere pressure. Some newer types of equipment with enclosed quenches have been reported to allow in excess of 10% water at 200 °C (400 °F) with a resultant increase in quench severity (see Table 2(b)).

Water additions are usually controlled at the discretion of the operator, who will add water as needed. On the basis of experience, however, it is possible to determine the need for water by freezing-point depression (Fig. 2); here, the addition of water may be simplified by use of timers that can be adjusted to time the frequency and duration of water additions.

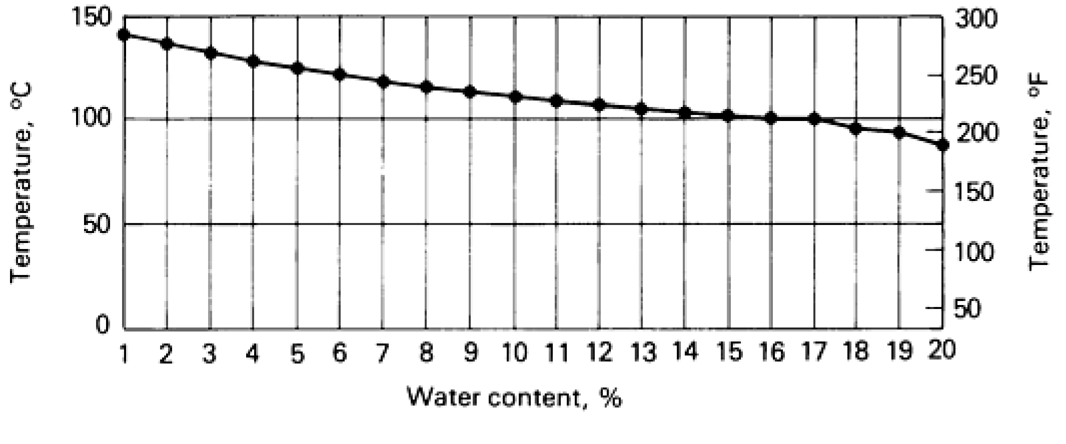

Fig. 2 Effect of water content on the freezing point of nitrate-nitrite salt bath

The presence of water is visually detectable by the operator because steam is released when the hot work is immersed in the nitrate-nitrite salt. The steam causes a visible mounding of the salt above the quench area, and there is a characteristic sizzling caused by the vapor phase.

Besides visual appearance, periodic hardness checks of the work will indicate the activity of the bath. Another determination can be made by removing a small quantity of the salt and weighing it accurately before and after dehydrating it by heating to 370 to 425 °C (700 to 800 °F).

Several other devices now exist for measuring quench severity and controlling water additions automatically. These devices are based on the slope of the cooling curve. In general, a heating element is placed in the bath and the time to cool between the initial temperature and a preset lower temperature is measured. If the cooling time is greater than the set point, water is automatically added. These devices aid the operator in maintaining a uniform quench severity and improve process capability.

Oil is sometimes used for austempering, but because of its chemical instability and resulting change in viscosity at austempering temperatures, its use is restricted to applications below 245 °C (470 °F). Because of its persistent vapor phase, oil is a slower quenchant than salt at elevated temperatures and presents a fire hazard.

Steels for Austempering

The selection of steel for austempering must be based on transformation characteristics as indicated in time-temperature transformation (TTT) diagrams. Three important considerations are:

- The location of the nose of the TTT curve and the speed of the quench being utilized
- The time required for complete transformation of austenite to bainite at the austempering temperature
- The location of the M_s point

As indicated in Fig. 3, 1080 carbon steel possesses transformation characteristics that provide it with limited suitability for austempering Cooling from the austenitizing temperature to the austempering bath must be accomplished in about 1 s to avoid the nose of the TTT curve, and thus prevent transformation to pearlite during cooling. Depending on the temperature, isothermal transformation in the bath is completed within a period ranging from a few minutes to about 1 h. Because of the rapid cooling rate required, austempering of 1080 can be successfully applied only to thin sections of about 5 mm (0.2 in.) maximum.

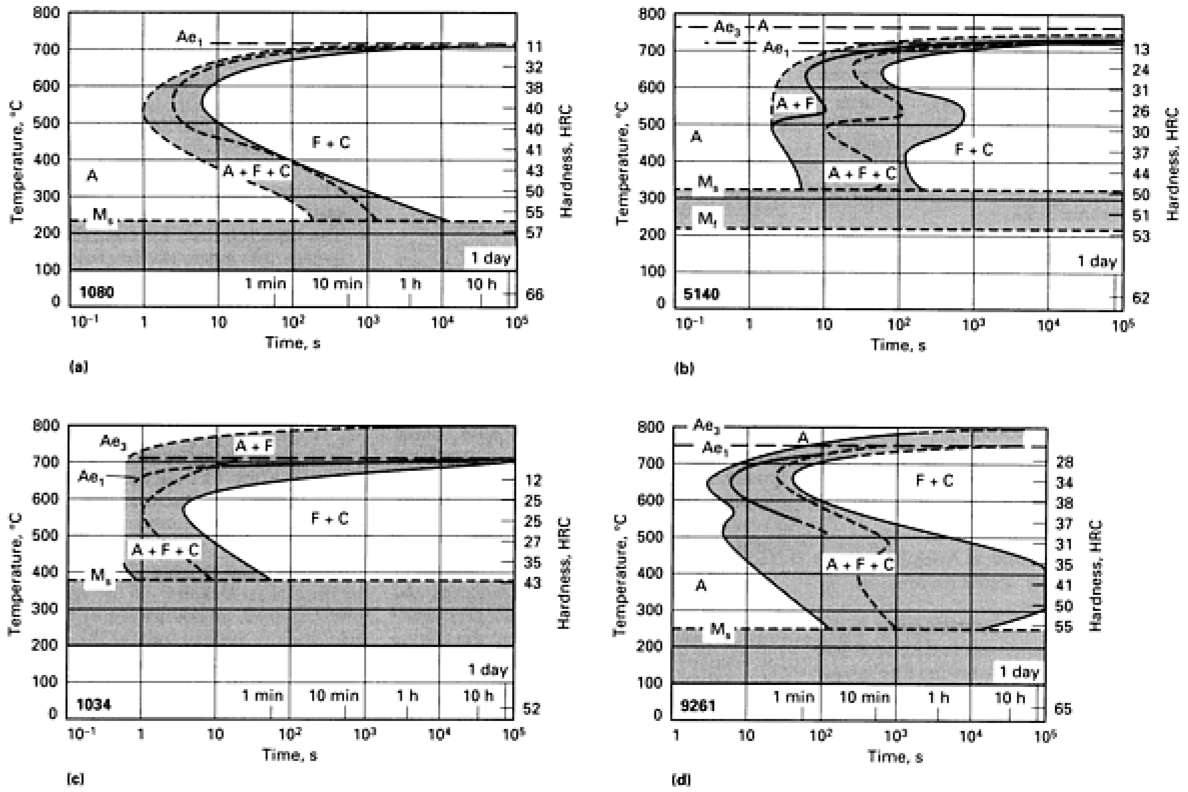

Fig. 3 Transformation characteristics of 1080, 5140, 1034, and 9261 steels, in relation to their suitability for austempering. 1080, limited suitability for austempering because pearlite reaction starts too soon near 540 °C (1000 °F); 5140, well suited to austempering; 1034, impossible to austemper because of extremely fast pearlite reaction time at 540 to 595 °C (1000 to 1100 °F); 9261, not suited to austempering because of slow reaction to bainite at 260 to 400 °C (500 to 750 °F). See text for discussion of steel selection.

5140 low-alloy steel is well suited to austempering, as indicated by the TTT curve for this steel shown in Fig. 3. Approximately 2 s are allowed in which to bypass the nose of the curve, and transformation to bainite is completed within 1 to 10 min at 315 to 400 °C (600 to 750 °F). Parts made of 5140 steel or of other steels with similar transformation characteristics are adaptable to austempering in larger section sizes than are feasible for 1080 steel because of the greater time allowed for bypassing the nose of the curve.

In addition to the steels previously indicated (1080 and 5140), steels adaptable to austempering include:

- Plain carbon steels containing 0.50 to 1.00% C and a minimum of 0.60% Mn
- High-carbon steels containing more than 0.90% C and, possibly, a little less than 0.60% Mn
- Certain carbon steels (such as 1041) with a carbon content of less than 0.50% but with manganese content in the range from 1.00 to 1.65%
- Certain low-alloy steels (such as the series 5100 steels) containing more than 0.30% C; the series 1300 to 4000 steels with carbon contents in excess of 0.40%; and other steels, such as 4140, 6145, and 9440

Some steels, although they have sufficient carbon or alloy content to be hardenable, are borderline or impractical for austempering because transformation at the nose of the TTT curve starts in less than 1 s, thus making it virtually impossible to quench other than thin sections in molten salt without forming some pearlite, or they require excessively long periods of time for transformation. A typical example of a steel belonging to the first category is 1034, whose transformation characteristics are shown in Fig. 3. Transformation characteristics for 9261 (also shown in Fig. 3) indicate no difficulty in quenching past the nose of the curve, but the time required for isothermal transformation to bainite (about 24 h) is excessive. Other alloy steels with excellent hardenability that require long transformation times include those in series 4300, 4600, and 4800.

The chemical composition of the steel is the major determinant of the martensite-start (M_s) temperature. Carbon is the most significant variable affecting the M_s. The direct effects of other alloying elements on the M_s point are much less pronounced than the effect of carbon. However, carbide-forming elements (such as molybdenum and vanadium) can tie up the carbon as alloy carbides and prevent complete solution of carbon. The approximate M_s temperature, in degrees Centigrade, of a completely austenitized steel can be calculated by means of the following formula:

$$
\begin{aligned}
M_s = 538 &- (361 \times \%C) \\
&-(39 \times \% Mn) \\
&-(19 \times \% Ni) \\
&-(39 \times \% Cr)
\end{aligned}
$$

Expressed in degrees Fahrenheit, the formula is:

$$
\begin{aligned}
M_s = 1000 &- (650 \times \% C) \\
&-(70 \times \% Mn) \\
&-(35 \times \% Ni) \\
&-(70 \times \% Cr)
\end{aligned}
$$

Austenitizing temperature has a significant effect on the time at which transformation begins. As the austenitizing temperature is increased above normal (for a specific steel), the nose of the TTT curve shifts to the right because of grain coarsening. In Fig. 3, for example, approximately $\frac{3}{4}$ s is allowed for quenching 1080 steel in order to avoid the nose of the curve. However, this is based on an austenitizing temperature of 790 °C (1450 °F); higher austenitizing temperatures move the TTT curve to the right, allowing more time before transformation begins.

Practical use is sometimes made of this phenomenon in order to process compositions or section sizes that would otherwise be borderline for austempering. However, the coarser grain sizes resulting from higher austenitizing temperatures may be detrimental to some desired properties. Therefore, it is recommended that standard austenitizing temperatures be given preference for austempering. If experience with specific compositions and parts proves that advantages can be gained from the use of a higher temperature and that no harm will be incurred from grain coarsening, higher austenitizing temperatures may be employed.

As the austenitizing temperature of a high-carbon steel increases, the M_s temperature decreases marginally because of more complete solution of carbon. This effect on the M_s temperature, however, is small compared to the effects of the chemical composition.

Section Thickness Limitations

Maximum thickness of section is important in determining whether or not a part can be successfully austempered. For 1080 steel, a section thickness of about 5 mm (0.2 in.) is the maximum that can be austempered to a fully bainitic structure. Carbon steels of lower carbon content will be restricted to a proportionately lesser thickness. Lower-carbon steels containing boron, however, can be successfully austempered in heavier sections. In some alloy steels, section thicknesses up to about 25 mm (1 in.) can be austempered to fully bainitic structures.

Nevertheless, sections of carbon steel significantly thicker than 5 mm (0.2 in.) are regularly austempered in production when some pearlite is permissible in the microstructure. This is demonstrated in Table 3, which lists section sizes of austempered parts made of various steels.

Table 3 Hardness of various steels and section sizes of austempered parts

Steel	Section size		Salt temperature		M_s temperature[(a)]		Hardness, HRC
	mm	in.	°C	°F	°C	°F	

1050	3[b]	0.125[b]	345	655	320	610	41-47
1065	5[c]	0.187[c]	[d]	[d]	275	525	53-56
1066	7[c]	0.281[c]	[d]	[d]	260	500	53-56
1084	6[c]	0.218[c]	[d]	[d]	200	395	55-58
1086	13[c]	0.516[c]	[d]	[d]	215	420	55-58
1090	5[c]	0.187[c]	[d]	[d]	. . .	. . .	57-60
1090[e]	20[c]	0.820[c]	315[f]	600[f]	. . .	. . .	44.5 (avg)
1095	4[c]	0.148[c]	[d]	[d]	210[g]	410[g]	57-60
1350	16[c]	0.625[c]	[d]	[d]	235	450	53-56
4063	16[c]	0.625[c]	[d]	[d]	245	475	53-56
4150	13[c]	0.500[c]	[d]	[d]	285	545	52 max
4365	25[c]	1.000[c]	[d]	[d]	210	410	54 max
5140	3[b]	0.125[b]	345	655	330	630	43-48
5160[e]	26[c]	1.035[c]	315[f]	600[f]	255	490	46.7 (avg)
8750	3[b]	0.125[b]	315	600	285	545	47-48

(e) Modified austempering: microstructure contained pearlite as well as bainite.

(f) Salt with water additions.

(g) Experimental value

The effects of section thickness on the hardness of austempered 1090 and 5160 steels are shown in Fig. 4. Hardness remains reasonably consistent to the center of a 17 mm (0.680 in.) diameter of 1090, but it becomes erratic when the diameter is increased to 21 mm (0.820 in.). A similar difference is evident for 5160 steel when the diameter is increased from 24.6 to 26 mm (0.967 to 1.035 in.).

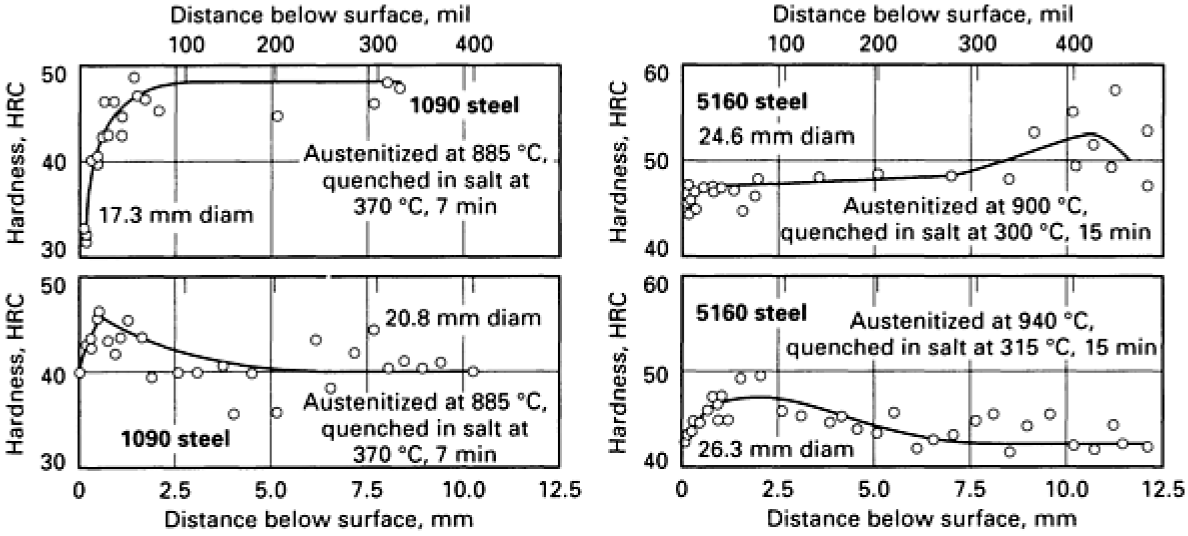

Fig. 4 Effect of section thickness on the hardness of austempered carbon and alloy steels. The 5160 steel was quenched in agitated salt containing some water. HRC values were converted from microhardness readings taken with a 100 g load. Low values of surface hardness result from decarburization. High hardness at center of 24.6 mm (0.967 in.) 5160 is due to segregation.

The lower surface hardnesses indicated for 1090 and 5160 were the result of surface decarburization and/or grain refinement. The high core hardness of the 24.6 mm (0.967 in.) diameter of 5160 is attributed to chemical segregation in the center portion of the bar and the absence of appreciable grain refinement.

Applications

Austempering usually is substituted for conventional quenching and tempering for the following reasons:

- To obtain improved mechanical properties (particularly higher ductility or notch toughness at a given high hardness). Figure 5 compares the fracture morphologies of austempered versus quenched and tempered 10B53 steel
- To decrease the likelihood of cracking and distortion
- To improve wear resistance for a given hardness
- To improve resistance to subsequent embrittlement

In some applications, austempering is less expensive than conventional quenching and tempering. This is most likely when small parts are treated in an automated setup wherein conventional quenching and tempering comprise a three-step operation--that is, austenitizing, quenching, and tempering. Austempering requires only two processing steps: austenitizing and isothermal transformation in an austempering bath.

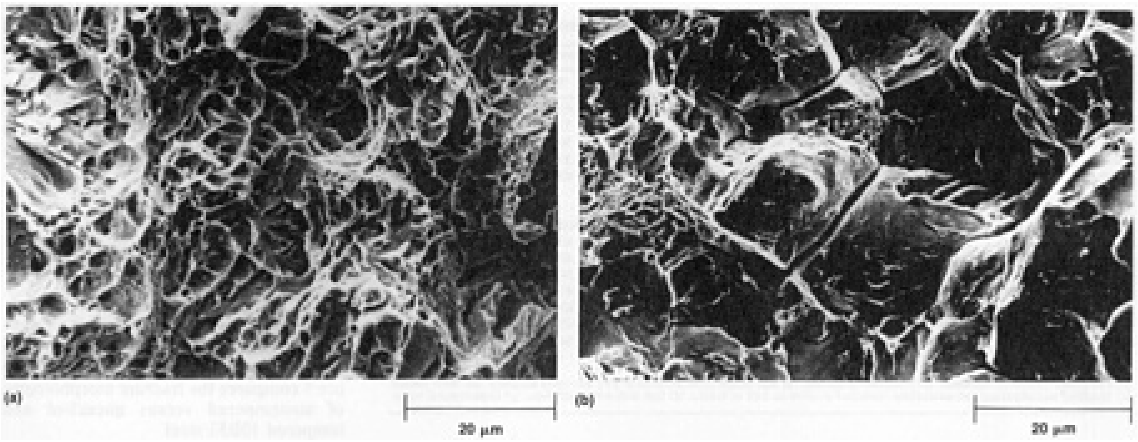

Fig. 5 Effect of heat treatment on the fracture appearance of 10B53 steel. (a) Ductile fracture surface of specimen austempered to 53 HRC. (b) Brittle fracture of specimen quenched and tempered to 53 HRC. Courtesy of Vermont America Corporation

The range of austempering applications generally encompasses parts fabricated from bars of small diameter or from sheet or strip of small cross section. Austempering is particularly applicable to thin-section carbon steel parts requiring exceptional toughness at a hardness between 40 and 50 HRC.

In austempered carbon steel parts, reduction in area is usually much higher than in conventionally quenched and tempered parts, as indicated in the following tabulation for 5 mm (0.180 in.) diam bars of 0.85% C plain carbon steel:

Austempered mechanical properties	
Tensile strength, MPa (ksi)	1780 (258)
Yield strength, MPa (ksi)	1450 (210)
Reduction in area, %	45
Hardness, HRC	50
Quenched and tempered mechanical properties	
Tensile strength, MPa (ksi)	1795 (260)
Yield strength, MPa (ksi)	1550 (225)

Reduction in area, %	28
Hardness, HRC	50

The mechanical properties of sway bars made of 1090 steel and hardened by these two processes are listed in Table 4 (see also Table 1).

Table 4 Comparison of typical mechanical properties of austempered and of oil-quenched and tempered sway bars of 1090 steel

Property[(a)]	**Austempered at 400 °C (750 °F)**[(b)]	**Quenched and tempered**[(c)]
Tensile strength, MPa (ksi)	1415 (205)	1380 (200)
Yield strength, MPa (ksi)	1020 (148)	895 (130)
Elongation, %	11.5	6.0
Reduction of area, %	30	10.2
Hardness, HB	415	388
Fatigue cycles[(d)]	105,000[(e)]	58,600[(f)]

(a) Average values.

(b) Six tests.

(c) Two tests.

(d) Fatigue specimens 21 mm (0.812 in.) in diameter.

(e) Seven tests; range, 69 050 to 137 000.

(f) Eight tests; range, 43 120 to 95 220

It is more important that austempered parts possess desired mechanical properties than that they have a 100% bainitic structure. In Table 3, it is evident from the hardness values indicated that several of the austempered steels have mixed structures. Higher-than-normal hardness indicates that some martensite has formed, and below-normal hardness indicates the presence of some pearlite. The formation of pearlite is more common and results from a quenching speed too slow for complete avoidance of the nose of the TTT curve.

In industrial austempering practice, a sizable percentage of applications are successful with less than 100% bainite. In fact, 85% bainite has been found to be satisfactory for some applications. Obviously, austempering is often "modified" to some degree in commercial application, and whether or not the metallurgical properties obtained conform to those obtained in true austempering is at least partially ignored if the treated parts meet service requirements. However, variations in hardenability from heat to heat may give rise to erratic results from variations in the amount of pearlite when borderline conditions are involved in modified austempering.

Table 5 presents processing data for a number of specific parts made of various plain carbon, alloy, and carburizing steels; these data are representative of austempering practice in at least a dozen different manufacturing plants.

Table 5 Typical production applications of austempering

Parts listed in order of increasing section thickness

Part	Steel	Maximum section thickness		Parts per unit weight		Salt temperature		Immersion time, min	Hardness, HRC
		mm	in.	kg^{-1}	lb^{-1}	°C	°F

(c) Case hardness

Equipment and Processing Procedures

Austenitizing prior to austempering can be performed in molten salt baths, in one of several types of standard heat-treating furnaces (including belt, batch, pusher, rotary retort, and shaker-hearth furnaces), or in other special types of furnaces that employ a protective gas atmosphere. In the types of austenitizing furnaces that employ a gaseous atmosphere, atmosphere control is extremely important because the formation of scale on parts will inhibit the rapid heat exchange that is essential in a successful austempering operation. Protective atmospheres do not contaminate the quench and are routinely controlled using oxygen probes, CO_2 analyzers, and continuous-reading dew-point devices in conjunction with a process controller.

Molten salt baths for austenitizing are widely used for batch-type operation; they can also be mechanized for continuous operation. Heating in salt for batch-type operation is advantageous because the film of adhering salt prevents scaling during transfer from the austenitizing operation to the austempering bath. Salt bath furnaces heated by either immersed or submerged electrodes are most common, although externally heated pots are also used.

Because most austempering is performed in molten salt, the salt bath used for austenitizing must be compatible with the austempering salt. Chloride salts are recommended for austenitizing; the composition and characteristics of a typical chloride salt bath for austenitizing are as follows:

Sodium chloride, %	45-55
Potassium chloride, %	45-55
Melting temperature. °C (°F)	650-675 (1200-1250)
Working temperature range, °C (°F)	705-900 (1300-1650)

Caution: Austenitizing salt baths should not contain cyanide because it reacts violently with quenching salts. Carbonate compositions and mixtures containing barium salts are not recommended because they are difficult to separate from quenching salts.

Shaker-hearth furnaces with atmosphere control are widely used for austenitizing, especially where large quantities of small parts are being processed. In a typical automated installation, the workpieces enter the shaker from a feeder, and after being heated to the austenitizing temperature, are dropped through a chute into the austempering bath, thus avoiding exposure in air and the possibility of scaling. The parts are transported through the austempering bath on variable-speed mesh or plate belt-type conveyors at a speed that allows complete transformation before they are automatically transferred to a constant-speed conveyorized washing and drying setup. These systems are relatively inexpensive to install and operate, but are restricted to a few hundred pounds per hour capacity.

Feeders for shaker-hearth furnaces vary widely in design, depending on the size, shape, and fragility of workpieces. In one type of equipment, parts are fed by gravity from the hopper onto a reciprocating hearth, on which they are transported through the shaker-hearth furnace and then into the austempering furnace. This mechanism is used for small round or flat parts that will not be distorted by the vibrating action. Other methods of feeding to the moving hearth include "Walmil"-style ram volumetric feeders, weigh loaders, and special magnetic conveyor-and-bin combinations that disentangle parts that bundle.

Rotary retort furnaces are widely used for products in the saw-chain, concrete, explosive drive, and air-driven nail industries and in similar applications where both hardness and ductility are prime factors in the end product, and reasonably large quantities of similar small parts are being processed without the threat of damage by the tumbling action of the retort. One of the advantages of the rotary retort, which advances the work by means of the internal spiral, is the absolute control of the retention time within the heated chamber. This control ensures uniformity of metallurgical properties of the product. Excellent atmosphere control is also attained because the work progresses through a sealed retort, is sealed at the quench chute by the quench media, and the process has a restricted part entry area. Consistent production rates and uniformity of results are obtained by controlling the loading rate with a weigh loader that is fed from a storage hopper by discharging the workpieces to a loading elevator that in turn transports the load through a chute into the partially sealed entry of the retort. These Systems are moderately expensive to install but inexpensive to operate and are capable of up to 200 to 500 kg (500 to 1000 lb) per hour of production.

Belt-type furnaces ensure controlled retention time for repeatability of metallurgical properties of the product. The integrity of the atmosphere is controlled by sealing the charge end of the furnace either mechanically or with a positive-atmosphere seal. The discharge chute into the molten salt also is sealed. Conveyorized transport through the austempering salt bath and wash tanks as described for shaker-hearth furnaces is also employed with both the rotary retort and belt furnace systems.

Belt furnaces may use either a cast-link or mesh-type part-carrier belt. In some belt furnace designs, the belt is totally enclosed in the austenitizing furnace. These units are loaded utilizing a charge conveyor or a shaker feeder. Belt units that use a positive-atmosphere seal allow the belt to return outside of the furnace, thus allowing either mechanical or hand loading outside of the furnace. The mesh-belt type of furnace is primarily used to process relatively thin sheet metal stampings that would become distorted if loaded directly onto a heavy cast-link belt or would become tangled or distorted if processed through a rotary retort.

Continuous automated parts feeding may be accomplished by use of specialized magnetic conveyor feeders. These feeders strip the parts that tend to tangle from one edge of the pile in the feeding bin and carry them up to a vibratory trough. The trough in turn feeds the workpieces to the hearth that enters the furnace.

The cast-link belt types are used to handle heavier parts that would not be subject to distortion upon loading onto the hot cast-link belt. Continuous feeding is accomplished with Walmil volumetric feeders, charge conveyors, automated orienters, or simple bin and vibratory trough types, depending upon part configuration. Each feeding system delivers parts to the hearth, which enters the furnace.

Direct-fired tunnel-type furnaces are employed for heat treating large quantities of similar parts that must be hung from hooks or fixtures to minimize distortion. In a typical installation, the hooks or fixtures carrying the work travel in front of the operators and can be easily loaded. The work is conveyed through the tunnel-type heating zone, automatically removed after heating and dropped into the austempering bath, and then conveyed to washing and drying. During austenitizing, parts are in a protective atmosphere provided by the controlled gas-to-air ratio of the burners. The entire operation is automatic except for the hand loading of parts onto hooks.

Austempering Lines. Simple salt baths, either fuel-fired or electrically heated, are suitable for low-production austempering Circulation can be provided by a propeller-type mixer. Most of these furnaces have no provision for cooling and depend on heat losses to equal the heat input acquired from workpieces.

Sufficient production quantities warrant the use of salt lines specifically designed for austempering. These furnaces usually provide for automatic handling. The salt bath units are heated with immersion heaters, immersed electrodes, or gas-fired immersion tubes. To maintain a constant temperature, heat is dissipated by forced air that cools the pot sidewall or by immersed plate coils. Both heating and cooling are automatically controlled. A salt-separating system is required to separate chloride salts dragged over from the austenitizing furnace. Chlorides, scale, and other contaminants are removed by:

- *Gravity separation:* Providing a separate chamber for the suspensions to settle; settled solids are then removed by manual desludging or sludge pans
- *Continuous filtration:* Suspended contaminants are continuously passed through filter baskets; the baskets are periodically removed and dumped
- *Solubility separation:* The temperature of the entire quench bath is periodically dropped, or the separating chamber is held at a lower temperature by insulating or cooling to drop chlorides (hardening salt) out of solution (Fig. 6) where they can be removed by manual desludging or through the use of sludge pans

An analysis for the amount of chloride in quench baths can also be made (Table 6). To provide uniform quenching, one or more propeller agitators are used to agitate the salt.

Table 6 Titration procedure for determination of chloride in quench baths

Reagents
1. 0*N* NaOH, 5% acetic acid, 0.1*N* $AgNO_3$, saturated potassium chromate, and phenolphthalein indicator
Procedure
1. Weigh out about 0.1-0.2 g sample and transfer into a 600 ml beaker
2. Add about 250 ml of distilled H_2O. Dissolve
3. Add 2 drops phenolphthalein (if pink, go to Step 5)
4. Add 1.0*N* NaOH dropwise until pink
5. Add 5% acetic acid until clear
6. Add 7-10 drops potassium chromate
7. Titrate with 0.1*N* $AgNO_3$ until orange color persists

Calculations

$$Chloride = \frac{Milliliters\ \text{of 0.1N AgNO}_3\ \text{x 0.3546}}{\text{Sample weight in grams}} = \%Cl$$

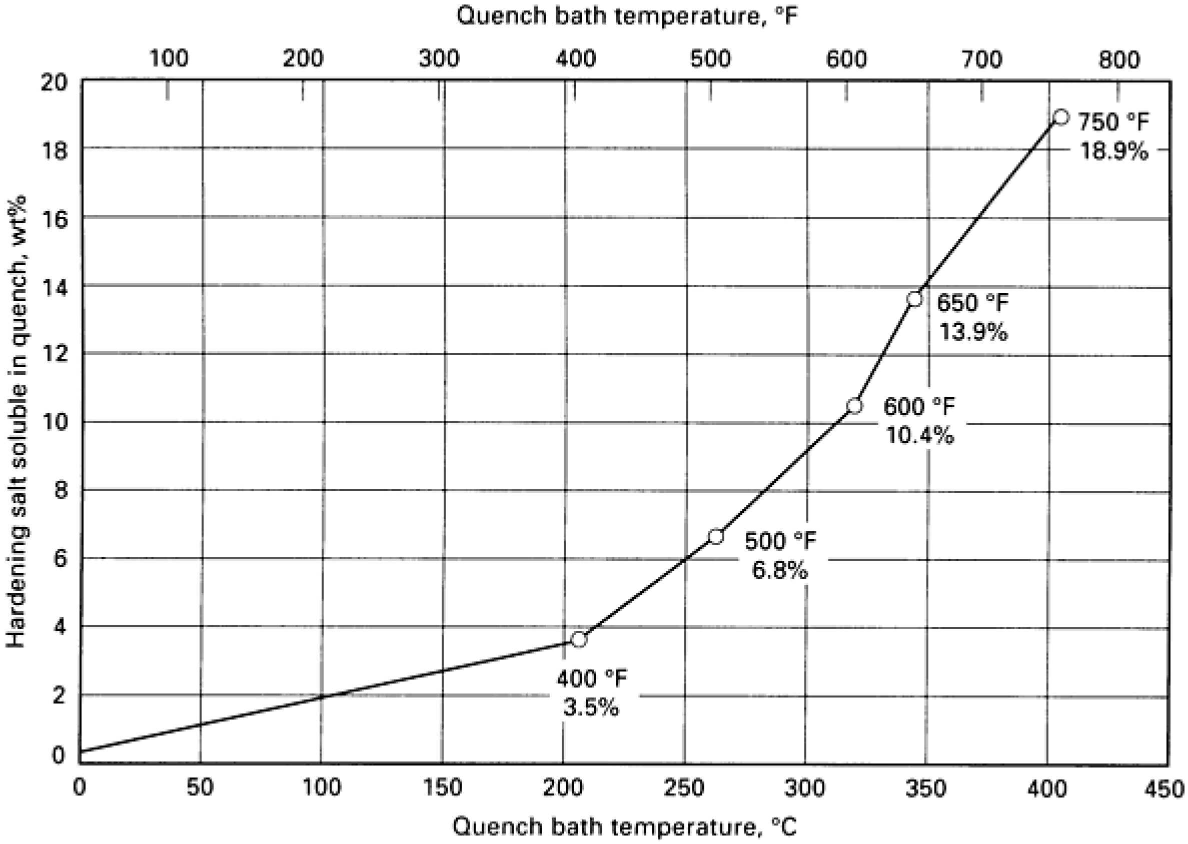

Fig. 6 Solubility of hardening salt in quench salt

Pusher-type furnaces utilize special alloy baskets or trays for holding the workpieces. The time at temperature and in the quench is controlled by the indexing time. Each time a basket exits the line, a basket of green parts is charged. These types of units are used extensively to austemper gears, shafts, heavier stampings, and forgings that are hand racked.

Pusher furnaces are relatively expensive to install and are suited best to processing large volumes (up to 900 kg, or 2000 lb, per hour) of parts that have the same austempering cycle. For high volumes, they are relatively inexpensive to operate, but as volumes drop and cycles are varied (that is, differing austenitizing and austempering temperatures and times), the effectiveness of the pusher furnace is reduced.

A pusher furnace can be fitted with a special, enclosed salt quench for adding larger amounts of water, thus realizing quench severities as fast as those for oil at room temperature.

Batch furnaces with either integral hot oil or salt quenches are used to process parts similar to those run in pusher furnaces. As with pusher furnaces, parts are racked in trays or baskets prior to being charged in the furnace. In the case of salt quenches, either open or enclosed quenches may be utilized. With hot oil quenches, an enclosed quench is utilized.

Batch furnaces are moderately expensive to install, but have the flexibility to change cycles, a feature that is lacking in pusher furnaces. For austempering high volumes of heavier stampings, forgings, and machined parts with a variety of cycles, the batch furnace is a cost-effective option. In addition, an enclosed batch salt-quench can be fitted with an enhanced water-addition system to through harden parts that could not be run in continuous or salt-to-salt systems.

Specialty Equipment Applications. Many specially designed types of austempering equipment have, and are utilized for, specific applications. Some examples include:

- *Gantry furnaces* are used to austemper long parts such as rollers, shafts, and tubes
- *Fluidized bed furnaces* are used to austemper small lots of highly alloyed parts such as tool bits, gun

components, and small, complex castings

- *Induction heating systems* are used in conjunction with hot oil or salt quenches to austemper parts in localized areas. These systems are used to locally harden parts requiring improved fatigue strength and/or wear resistance with minimum distortion
- *Multiple-quench batch-type systems* utilize one furnace servicing several quenches which may include salt, water-based, oil, or gas quenches
- *Carboaustempering systems* provide a carburizing atmosphere in conjunction with an austempering quench. Parts processed in systems with this capability have a high-carbon bainitic core and exhibit excellent fatigue and wear resistance with minimum distortion. These systems are used to process gears, rollers, and other wear parts

Racking and handling procedures for austempering are not necessarily different from those used for other heat-treating operations. Racking or other means of keeping parts separated are often essential to the process. To minimize distortion, delicate parts must be handled with particular care.

For heating in tunnel-type or other special furnaces, a standard form of racking (Fig. 7) is usually employed. (Provision must also be made for lowering of parts into the austempering bath.) Parts similar to those illustrated in Fig. 7 may be batch treated by using fixtures such as those shown in Fig. 8(a). Another common type of rack, useful for handling disks or rings, is shown in Fig 8(b). The well-known Christmas tree type of rack is used for parts that can be hung. Some parts are strung on wires that can be suspended into the austenitizing and quenching media. Heavier parts, or parts that cannot be hung, may be placed in baskets, provided that rapid and uniform quenching can be obtained. Parts must not be stacked together because this will result in nonuniform quenching.

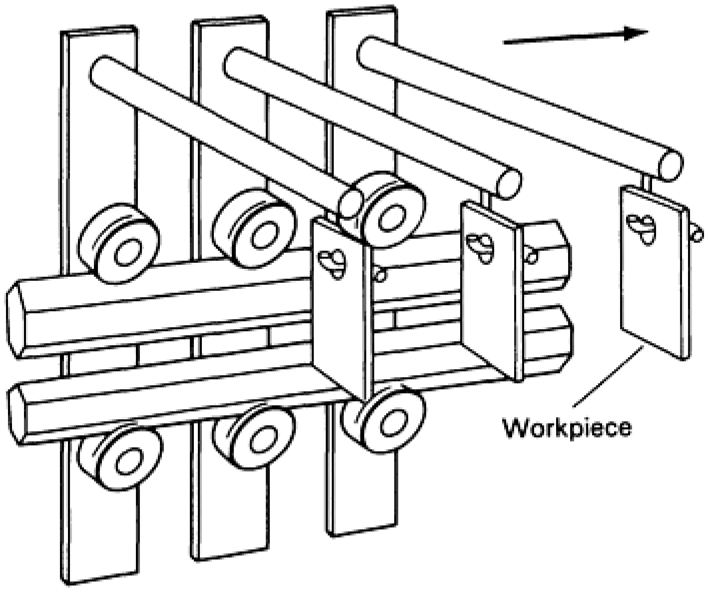

Fig. 7 Method of continuously transporting parts on fixtures through an austenitizing furnace and into an austempering bath

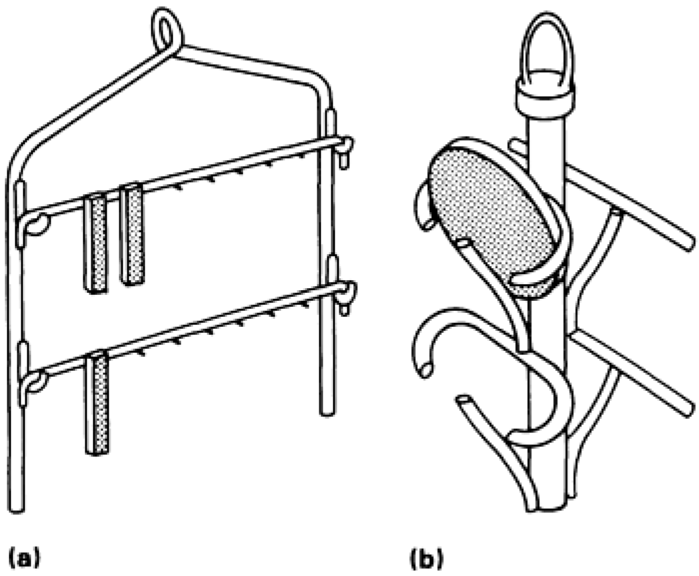

Fig. 8 Racking for batch-type austempering. See text for discussion of these two types of racks.

Racks, baskets, and other fixtures may be made of carbon steel, but if they are expected to last for many cycles it is usually more economical to make them of a heat-resisting alloy such as 35Ni-18Cr or another nickel-base alloy (see the article "Heat-Resistant Materials for Furnace Parts, Trays, and Fixtures" in this Volume).

Washing and Drying. Salts used in the austempering bath are water soluble, and no special equipment is needed for their removal. Normal practice is to use clean, hot water, with agitation, for dissolving and removing salt from austempered parts. Cold water may be used, but its dissolving action is much slower. Hot water may not suffice to dissolve all salt from parts with deep blind holes, small crevices, laps, hidden corners, or ledges. If it is not completely removed, salt may bleed from such crevices or joints long after heat treating. Quenching into hot water directly from the austempering salt bath is often used to blow out trapped salt. Large parts may be cleaned with high-pressure steam. However, rapid cooling may cause distortion.

Equipment requirements for specific austempering operations are detailed in the three production-base examples that follow.

Example 1: Two Methods of Austenitizing and Austempering Small Steel Parts.

Table 7 compares equipment required for two different methods of austenitizing and austempering small mechanical stops and levers. Parts of this type weighing 0.007 kg (0.015 lb) were processed at the rate of 4000/h by being austenitized at 845 °C (1550 °F) in an electrically heated salt-pot furnace and austempered in salt at 370 °C (700 °F). Parts weighing 0.002 kg (0.005 lb) were processed at the rate of 3700/h by being austenitized at 870 °C (1600 °F) in a controlled-atmosphere shaker-hearth furnace and austempered in salt at 360 °C (680 °F).

Table 7 Equipment requirements for two methods of austenitizing and austempering mechanical stops and levers

Requirements	Method 1	Method 2
Production requirements		
Weight of each piece, kg (lb)	0.007 (0.015)	0.002 (0.005)

Weight of each load, kg (lb)	12 (27)	[(a)]
Number of pieces per hour	4000	3700
Equipment requirements		
Type of austenitizing furnace	Salt pot[(b)]	Shaker hearth[(c)]

(j) Blower between pot and furnace wall, pyrometer controlled

Example 2: Austempering 1.8 kg (3.9 lb) Parts at 1500 Pieces per Hour.

Table 8 gives details of equipment required for austempering parts made of 1080 steel at the rate of 1500/h. These parts, which varied in weight from 1.1 to 1.8 kg (2.4 to 3.9 lb), were austenitized at 925 °C (1700 °F) before being austempered.

Table 8 Equipment for austempering parts made of 1080 steel

Parts austenitized at 925 °C (1700 °F)

Production requirements	
Weight of each piece, kg (lb)	1.1 to 1.8 (2.4 to 3.9)
Production per hour	1500 pieces
Equipment requirements	
Austempering furnace	Submerged fuel-fired salt pot
Size of furnace, m^3 (ft^3)	6.6 (233)
Nitrate-nitrite salt, kg (lb)	11,340 (25,000)
Temperature, °C (°F)	345-360 (650-675)
Agitation	Pump, directed at delivery chute
Cooling	Forced air through burner tube

Example 3: Equipment for Austempering with Manually Operated Monorail Line.

Table 9 lists details of the equipment comprising a manually operated monorail line for preheating, austenitizing, austempering, washing and rinsing, and corrosion protection, and indicates production capacities for processing tubes, plates, and disks made of 1035 and 1060 steels.

Table 9 Equipment requirements for austenitizing, austempering, and corrosion protection of parts made of 1035 and 1060 steels

Equipment comprises a manually operated monorail heat-treating line.

Production requirements			
Part	Fabricated disk	Rectangular tube	Rectangular plate
Steel	1035	1060	1060
Section thickness, mm (in.)	12.5 (0.492)	1.4 (0.055)	0.8 (0.032)
Weight of part, kg (lb)	1.1 (2.5)	0.2 (0.425)	0.01 (0.024)
Load weight (gross), kg (lb)	163 (360)	35.7 (78.75)	7.3 (16)
Number of pieces per h	432	720	3900

Austenitizing, °C (°F); min	845-870 (1550-1600); 10	830 (1525); 10	830 (1525); 10
Austempering, °C (°F); min	425 (800); 10	345 (650); 6	330 (630); 6
Equipment requirements			
Preheating furnace	Immersed-electrode salt bath, 0.45 by 0.6 by 1.6 m (18 by 24 by 62 in.)		
Amount of chloride salt, kg (lb)	590(1300)		
Austenitizing furnace	Immersed-electrode salt bath, 0.45 by 0.6 by 1.6 m (18 by 24 by 62 in.)		
Amount of chloride salt, kg (lb)	590 (1300)		
Austempering furnace	Gas-fired salt bath, 0.6 by 1.2 by 1.8 m (24 by 48 by 72 in.)		
Amount of nitrate-nitrite salt, kg (lb)	2270 (5000)		
Heat input, kJ (Btu) per h	740,000 (700,000)		

Agitation	Two 150 mm (6 in.) impellers
Two washing and rinsing tanks	Gas-fired, hot water; each 0.5 by 0.9 by 1.2 m (20 by 36 by 48 in.)
Capacity, each tank	570 L (150 gal)
Heat input, each tank, kJ (Btu) per h	316,000 (300,000)
Tank for corrosion protection, m (in.)	0.5 by 0.9 by 1.2 (20 by 36 by 48)

Control of Process Variables

The achievement of desired results from austempering processes depends on control of the bath temperature and the immersion time of the work being processed, and on agitation of the bath.

Temperature control of austempering baths is important because:

- Bath temperature determines the hardness and other properties obtained in the part being heat treated
- Unintended freezing of a salt bath can result in unwarranted expense
- At temperatures exceeding 455 °C (850 °F), nitrate-nitrite salt mixtures will cause pitting attack of steel pots, and more importantly, steel workpieces
- *Caution: Local temperatures above 595 °C (1100 °F) anywhere in a nitrate-nitrite salt bath can cause violent exothermic reactions inthe salt that may result in fire or explosion even after the source of furnace heat has been shut off.* Equipment manufacturers should be consulted as to their recommendations regarding safe *average* bath temperatures

The potential hazard of nitrate-nitrite salt mixtures overheating as the result of failure of a thermocouple or control instrument must be recognized, and appropriate safeguards must be provided. A second instrument and thermocouple are recommended. These may be set 28 °C (50 °F) higher than the desired operating temperature and arranged to take over in the event of malfunction.

Usually, a variation in bath temperature of ±6 °C (±10 °F) is permissible. However, variations greater than ±6 °C have been known to cause unacceptable variations in the hardness of austempered parts.

Time in the bath should be sufficient to allow complete transformation. Allowing parts to remain in the bath for longer than the required time will increase the cost of the operation, but it is not harmful to mechanical properties (Table 10). In one instance, parts that had fallen from racks were unintentionally held at 265 °C (510 °F) for several months. Subsequent tests revealed that their properties were not harmed by the prolonged immersion.

Table 10 Effect of austempering time on hardness of three steels

Steel	Austempering temperature		Rockwell hardness[a] after austempering times of						
	°C	°F							
			30 min	60 min	90 min	120 min	240 min	300 min	360 min

1095[(b)]	230[(c)]	450[(c)]	91	90	90	90	90	90	90
	265[(d)]	510[(d)]	90	89	89	89	89	89	89
			1 min	2 min	5 min	10 min	20 min	40 min	80 min
8735[(e)]	260[(f)]	500[(f)]	51	51	49	49	48	48	47
	315[(f)]	600[(f)]	49	45	46	46	46	46	46
	370[(f)]	700[(f)]	40	39	38	38	38	38	37
8750[(g)]	260[(f)]	500[(f)]	58	56	53	51	52	52	51
	315[(f)]	600[(f)]	58	52	48	47	47	47	47
	370[(f)]	700[(f)]	54	42	39	39	39	38	39

(a) Rockwell 15-N hardness values for the 1095 steel; Rockwell C hardness values for the 8735 and 8750 steels.

(b) Steel contained 0.90% C; specimen thickness, 0.25 mm (0.010 in.). Each hardness value is an average of 12 specimens; range of test values did not exceed one point on Rockwell 15-N scale.

(c) Time for 100% transformation was 170 min.

(d) Time for 100% transformation was 85 min.

(e) Steel contained 0.37% C; specimen size, 16 by 32 by 2 mm (0.622 by 1.250 by 0.087 in.).

(f) Time for complete transformation was 5 to 10 min.

(g) Steel contained 0.49% C; specimen size, 25 by 25 by 3 mm (1 by 1 by $\frac{1}{8}$ in.)

Bath agitation can be a significant variable in austempering because it affects quenching speed. Quench rates can be two to three times greater for thinner parts as linear flow rates are increased from 0 m/min (0 ft/min) to 15 m/min (50 ft/min). Mechanical stirring, pumping, and air agitation have all proved successful for specific operations. Pumping provides the greatest amount of salt movement, although it requires a more expensive installation. In many applications, the other methods have provided a sufficiently rapid quench. The suitability of stirring as compared to pumping is indicated in the following example.

Example 4: Redesign of Salt-Bath Quenching System from Mechanical Stirrers to Pump Flow Agitation.

Mechanical stirring devices were originally used in the quenching system of a rotary retort furnace used for austempering (Fig. 9a). Although the pattern of agitation could be varied by changing the location and altitude of the impellers, this did not provide for displacement of the static salt within the chute; consequently, parts failed to quench adequately because the static salt allowed parts to remain in clusters. Changing the angles of the mechanical stirrers failed to eliminate inadequate quenching.

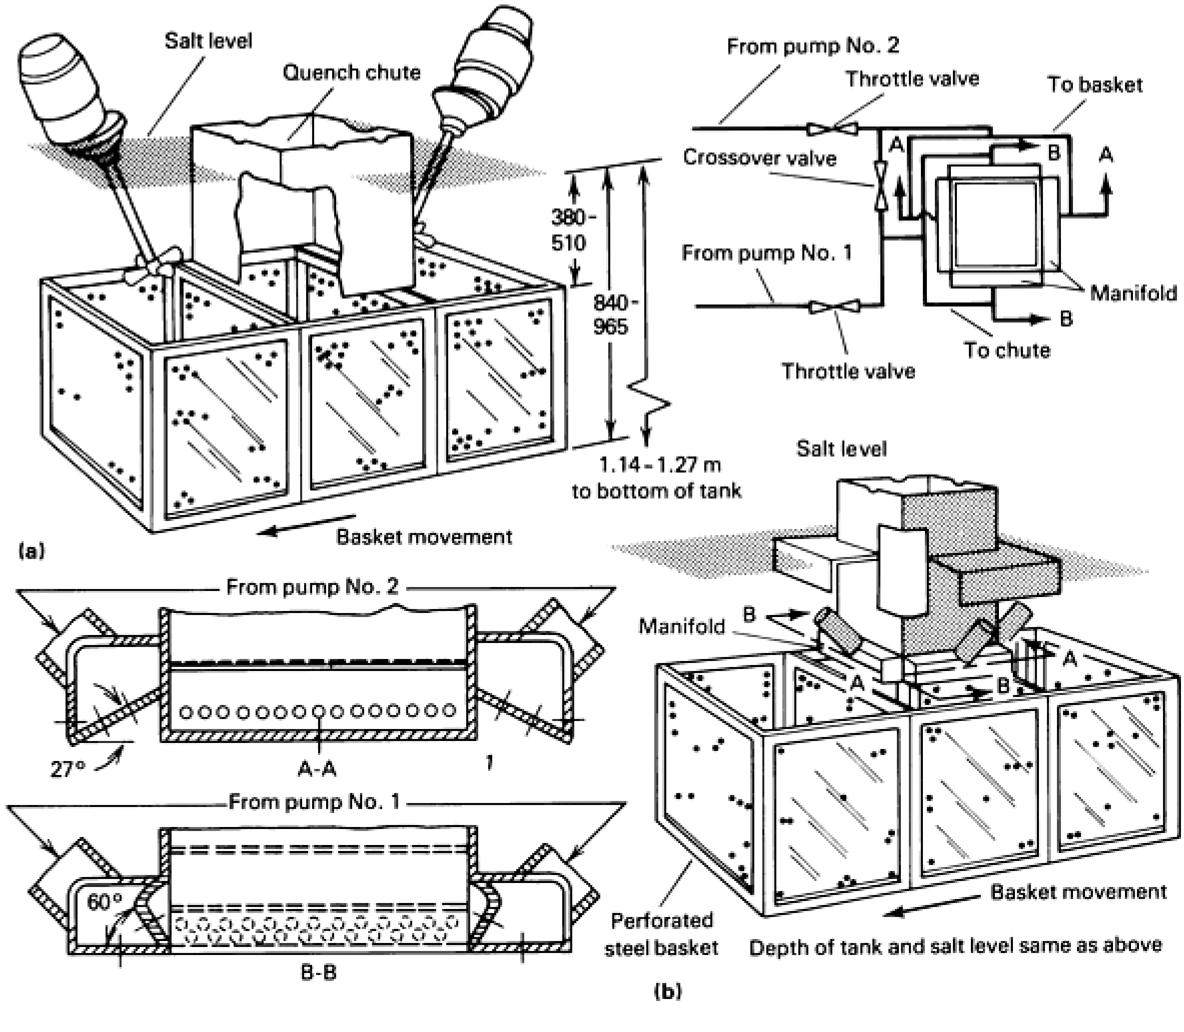

Fig. 9 Mechanical and pump methods of agitation discussed in Example 4. (a) Mechanical stirring. (b) Pump agitation. This example illustrates a problem of salt bath quenching efficiency in which extensive redesign of the quenching system proved to be necessary. After redesign, the system could be used at full flow for heavier parts 3 mm (0.125 in.) thick and at about half flow for parts about half this thickness. Accompanying text indicates methods of adjusting the pump throttle valve for control.

The lower section of the quench chute was redesigned for pump agitation (Fig. 9b). The output of a 950 L/min (250 gal/min) pump was directed upward into the chute at an angle of 60° above the horizontal from two oppositely inclined multiple orifice plates located at the bottom of the chute. Salt entering the chute was returned to the bath through a perforated section of the chute located just below the normal salt level. A skirt, extending outward from the chute above the perforated section and draped on all sides to a level below the salt level, maintained the atmosphere seal.

The output of a second 950 L/min (250 gal/min) pump was directed downward into the receiving basket at an angle of 27° below the horizontal. The salt entering the basket was returned to the bath through the perforated bottom and walls of the basket and over the top rim of the basket. A throttle valve was installed in the discharge line of each pump to control

the discharge velocity at the orifice plates. A crossover line with shutoff valve made it possible to supply salt to the two pairs of orifice plates, independently, from either or both pumps. The degree of agitation could then be adjusted for maximum quenching to match the mass of the parts being processed.

Experience has proved that the output from one pump to all four orifice plates provides adequate agitation for all parts being treated. Full flow is used for heavier parts 3 mm (0.125 in.) thick, and an estimated half flow is used for lighter parts 1.5 mm (0.060 in.) thick. Rough adjustment of the pump throttle valve is made by observing the stream of salt discharged from a hole drilled in the manifold piping (this hole serves primarily to drain these lines when the pumps are shut off). Final adjustment is based on the contour of the surface of the bath as formed by the parts in the baskets. A markedly dished (concave) contour, with the parts sloped upward against all sides and corners of the basket, indicates that agitation is sufficient to avoid clustering of parts. A feathering of the parts to an acute angle against the sides of the basket indicates excessive agitation that could result in loss of parts over the basket rim.

Dimensional Control

Parts can usually be produced with less dimensional change by austempering than by conventional quenching and tempering. Austempering may be the best way to hold close tolerances without extensive straightening or machining after heat treatment. The data in Fig. 10 and 11 indicate the degree of improvement in dimensional stability attainable by austempering as compared to water or oil quenching and tempering.

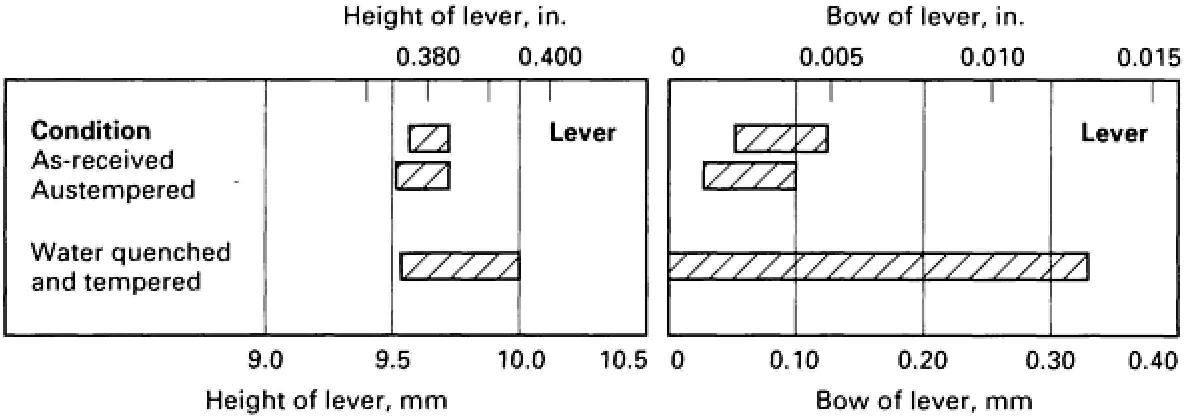

Fig. 10 Variation in dimensions of 3 mm (0.125 in.) thick levers after austempering and after water quenching and tempering. Horizontal bars represent groups of ten samples.

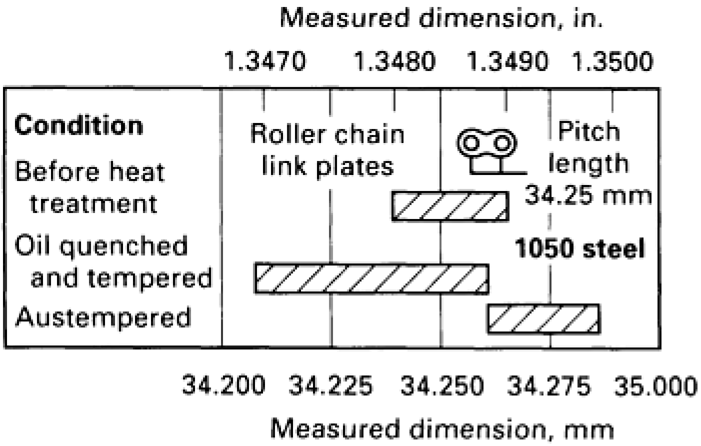

Fig. 11 Variation in pitch length of 2 mm (0.080 in.) thick link plates after austempering and after oil quenching and tempering. All link plates were austenitized at 855 °C (1575 °F) for 11 min; austempered link plates were held in salt at 340 °C (640 °F) for approximately 1 h, a time dictated by convenience in processing

but not required to attain complete transformation.

Example 5: Reduced Distortion in U-Bolts by Austempering.

In one application, a U-shape part was formed from 1095 steel strip, 0.25 mm (0.010 in.) thick. The open end of the U varied within 0.25 mm (0.010 in.) after forming. When these parts were oil quenched from 800 °C (1475 °F) and tempered at 260 °C (500 °F), the open end of the U varied over a range of 1.3 mm (0.050 in.). However, when the parts were austempered for 90 min at 265 °C (510 °F), the dimensional spread was decreased to about 0.8 mm (0.030 in.).

Example 6: Reduction in Straightening Operations with Austempering.

Table 11 compares the dimensional changes that occurred in stabilizer bars as a result of oil quenching and tempering with those that resulted from austempering. About 20% of these bars require straightening when oil quenched. This percentage is sharply reduced when austempering is used. With a new die setup, about 1 to 5% will require straightening for the first 3000 pieces while the dies are being trimmed for precise fit. Once the correct fit and setup are established, straightening will drop to less than $\frac{1}{2}$%. This will carry through until the die wear becomes appreciable (approximately 40,000 pieces), at which point the amount of straightening required begins to increase.

Table 11 Effects of oil quenching and tempering and of austempering on dimensions of stabilizer bars

Austempering Problems and Solutions

Problems encountered in austempering, together with their solutions, are discussed in the following examples.

Example 7: Normalizing before Austenitizing and Austempering to Achieve Carbide Solution and Adequate Ductility.

Threaded fasteners made of 1060 steel, designed to be embedded in concrete by explosive discharge, exhibited insufficient ductility after austempering. These parts were hardened by being heated to 845 °C (1550 °F) and quenched in a salt bath at 290 °C (550 °F) for 30 min. The lack of ductility was attributed to insufficient carbide solution. Parts with acceptable ductility after austempering were obtained by normalizing before final austenitizing and austempering.

Example 8: Austempering Procedure for a Steel with Borderline Hardenability.

Lawn mower blades, approximately 3 mm ($\frac{1}{8}$ in.) thick and made of 0.50 to 0.60% C steel, exhibited low hardness after austempering. Low hardenability due to lower-than-normal manganese content proved to be the cause. The manganese content desired for this application should be near the high side of the allowable range (0.60 to 0.90%), but the steel for these blades contained less than 0.50% Mn.

The problem was solved by first quenching the blades in a lower-temperature bath (just above M_s) for $\frac{1}{2}$ min and then transferring them to the normal austempering bath at 315 °C (600 °F) and holding for $\frac{1}{2}$ h. This technique has been successfully applied to many carbon steels that were borderline for austempering because of low hardenability in relation to the section being quenched.

Example 9: Use of Pump Agitation in Quenching Part Clusters.

A small percentage of parts made of medium-carbon and low-alloy steels had low hardness after austempering. The parts had been heated in a rotary retort furnace. Microscopic examination disclosed high-temperature transformation products caused by underquenching.

Investigation disclosed that this condition resulted when the parts were quenched in clusters rather than in a continuous sequence. Clustering resulted in a slow cooling rate at the center of the clusters. The problem was solved by redesigning the submerged portion of the quench chute to allow for high-velocity multiple jets of molten salt that could be directed upward into the chute and downward into the receiving basket (see Example 4 and Fig. 9).

Example 10: Reduced Salt Bath Temperature to Eliminate Nonuniform Quenching from Chloride Contamination.

Nonuniform hardness was found in some parts hardened in an automated austempering cycle. The parts, made of 1050 steel, were 13 mm ($\frac{1}{2}$ in.) wide, 125 mm (5 in.) long, and 1 mm (0.040 in.) thick. Heat treatment consisted of austenitizing at 845 °C (1550 °F) in a neutral salt, followed by quenching at 345 °C (650 °F) and holding for 15 min. The problem was traced to chloride contamination of the nitrate-nitrite quenching bath, a condition that caused the quenching bath to be sluggish. Inspection of the filtering screens indicated that they were not functioning adequately.

The problem was solved by establishing a procedure for reducing the bath temperature to 290 °C (550 °F) twice a week and thus precipitating the chlorides to a screen at the bottom of the bath for removal. This procedure eliminated the need for filtering screens and provided uniform quenching.

Example 11: Prehardening Treatment to Dissolve the Abnormally Large Carbides Produced during Spheroidization.

Chain saw components made of low-alloy Cr-Ni-V steel containing 0.65 to 0.75% C exhibited excessive brittleness in a torque test. The parts had been austenitized in a shakerhearth furnace at 830 °C (1525 °F) and quenched in an agitated salt bath at 290 °C (550 °F). Examination disclosed excessive martensite and undissolved carbides in the microstructure. Overspheroidization prior to hardening was determined to be the cause of brittleness. This resulted in the formation of abnormally large carbides that were not dissolved during the 11-min furnace cycle, thus lowering the carbon content of the matrix and raising the M_s temperature. This caused partial transformation to martensite instead of 100% lower bainite. The problem was solved by prehardening and tempering prior to the regular heat-treating cycle.

Modified Austempering

As mentioned previously, modifications of austempering practice that give rise to mixed structures of pearlite and bainite are quite common in industrial practice. The amounts of pearlite and bainite may vary widely in different modifications of processing.

Patenting, a treatment used in the wire industry, is a significant and useful form of modified austempering, in which austenitized wire or rod is continuously quenched into a bath maintained at 510 to 540 °C (950 to 1000 °F) and held in the bath for periods ranging from 10 s (for small wire) to 90 s (for rod). Patenting provides a combination of moderately high strength and high ductility. As indicated in Fig. 12 by the line designated Modified practice, the process varies from true austempering in that the quenching rate, instead of being rapid enough to avoid the nose of the TTT curve, is sufficiently slow to intersect the nose, which results in the formation of fine pearlite.

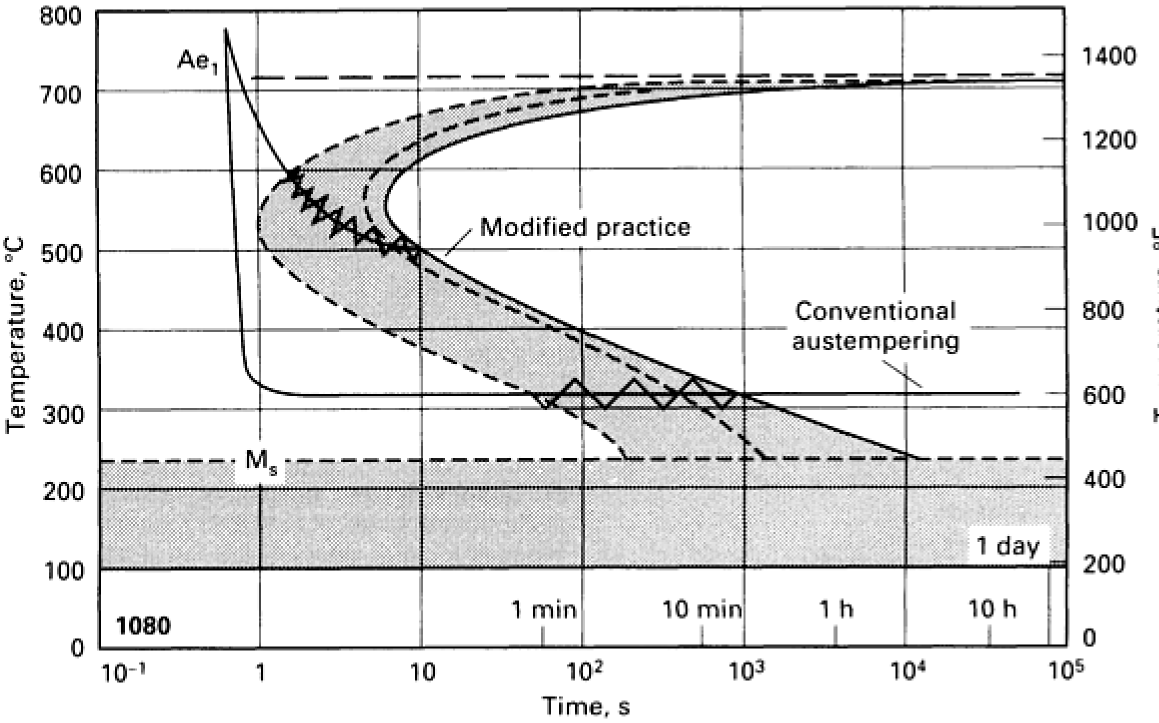

Fig. 12 Time-temperature transformation diagram for 1080 steel, showing difference between conventional and modified austempering. When applied to wire, the modification shown is known as patenting.

Similar practice is usefully employed in applications involving plain carbon steels when a hardness between about 30 to 42 HRC is desirable or acceptable. The hardness of plain carbon steel quenched at a rate that intersects the nose of the TTT curve will vary with carbon content (Fig. 13).

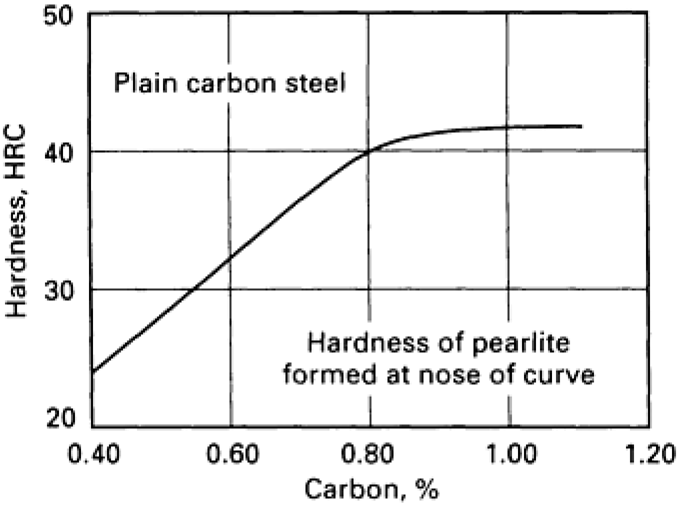

Fig. 13 Effect of carbon content in plain carbon steel on the hardness of fine pearlite formed when the quenching curve intersects the nose of the time-temperature diagram for isothermal transformation

Modified practices can be applied to parts having sections thicker than are normally considered practicable for austempering. These practices, however, also are subject to certain metallurgical limitations, such as the following that apply to the modified austempering of 1080 steel:

- The part to be quenched must be of sufficient mass or weight that cooling to the quench bath temperature cannot be accomplished in the time (about $\frac{3}{4}$ s) allowed for avoiding the nose of the TTT curve; otherwise, the part will undergo true austempering and may be harder than desired. The temperature of the quenching medium should not be raised above 370 °C (700 °F) in an effort to retard the cooling rate, or temper brittleness may result. For small parts, isothermal annealing at 565 °C (1050 °F) is preferred to austempering for obtaining hardness in the range of 30 to 42 HRC
- The part to be quenched is subject to a maximum, as well as a minimum, weight limit. If more than about 20 s is required for the center of the part to transform, or if there is a rise in bath temperature, some upper bainite may form, resulting in a variable hardness and mixed structure
- The lower temperature limit of the quench bath depends on the weight of the part. For pieces weighing 1 to 2 kg (2 to 4 lb), the lower limit of bath temperature is about 330 °C (625 °F)

From the above it is evident that modified practices are limited by several critical factors and that some trial and error is necessary in developing an optimum cycle for parts of specific composition and section thickness.

Another form of modified austempering also entails the use of a special technique but produces results that are similar to those obtained in true austempering. This modification is employed for parts that, because of their size and the type of steel from which they are made, are difficult to quench rapidly enough to avoid the nose of the TTT curve before transformation begins. In such applications, the cooling rate can be increased by first quenching the part into a bath that is slightly above the M_s temperature. For 1080 steel, this is about 260 °C (500 °F), as shown in Fig. 12. The part is held at this temperature for only the brief time necessary to obtain temperature equalization throughout the section, and is then transferred to the austempering bath at a higher temperature and allowed to transform isothermally in the normal manner (see Example 8).

Washing and Drying

Plain water, preferably warm or hot, is most suitable for cleaning austempering salts from parts. A single overflowing tank can be used. In automated systems, it is common practice to use two conveyorized tanks, the first heated by incoming parts and the second separately heated. Fresh water is added to the second tank, with the overflow going to the

first tank. In some cases, the concentrated salt solution is pumped back to the salt tank with available salt-recovery systems to recover both the salt and the water. This recovery reduces salt and water consumption and alleviates the disposal problem. The parts should be dried by warm forced air or treated with a rust preventative immediately after washing.

Safety Precautions

In operating an austempering installation, the same precautions should be taken that are appropriate for operation of any other hot liquid bath. These include the wearing of gloves and face masks. Several other special precautions are unique to operation of nitrate-nitrite baths:

- *Caution: Local temperatures above 595 °C (1100 °F) anywhere in a nitrate-nitrite salt bath can cause violent exothermic reactions in the salt that may result in fire or explosion even after the source of furnace heat has been shut off.* (Overheating might be caused by instrument failure or by overloading of the bath with hot workpieces.) Equipment manufacturers should be consulted for their recommendations regarding safe *average* bath temperatures
- *Caution: Nitrate-nitrite mixtures are oxidizing and should not be intermixed with materials that are readily oxidized. Cyanide and cyanide-bearing salts are especially incompatible with nitrate-nitrite salt mixtures.* Austempering should never be done directly from an austenitizing bath containing cyanide. When it is desirable to austemper cyanided or liquid carburized parts, they should first be immersed in a bath of neutral salt. This bath should be operated at the desired austenitizing temperature and controlled to prevent the accumulation of more than 2% sodium cyanide or potassium cyanide
- When austempering is carried out in the same area where cyanide-containing salts also are used, the salt pots and salt containers should be color coded. Yellow, orange, or red are commonly used for identification of nitrite and nitrite-containing salts. Cyanide-containing materials may be identified by white, blue, or gray. *Caution: Anyone handling these materials should be made aware that explosions can occur if they are intermixed*
- Finely divided carbonaceous materials should not be used. For example, it is common practice to use graphite, coal, or powdered coke as an insulating cover on lead baths. *Caution: Under no circumstances should these be employed as coverings for nitrate-nitrite salt baths.* Accidental contamination of austempering baths with accumulations of carbon black, which may build up at the discharge end of gas carburizing or carbonitriding furnaces, must also be avoided. Where work is to be austempered directly from such furnaces, an opening for frequent cleanout should be provided.

Introduction

INDUCTION HEATING is a method of heating electrically conductive materials by the application of a varying magnetic field whose lines of force enter the workpiece. In this process, the varying magnetic field induces an electric potential (voltage), which can then create an electric current depending on the shape and the electrical characteristics of the workpiece. These so-called eddy currents dissipate energy and produce heat by flowing against the resistance of an imperfect conductor.

Because all metals are fair electrical conductors, induction heating is applicable to several types of metal processing operations such as melting, welding, brazing, heat treating, stress inducement, zone refining, and heating prior to hot working (Table 1). The technique also lends itself to a variety of nonmetal applications including adhesive bonding, graphitizing carbon, drying, curing, and superheating glass. Of these applications, heat treating predominates in terms of the number of units used, with surface hardening of steel and cast iron being the most prevalent use. Compared to furnace techniques, induction heating can often provide energy savings and much higher heating rates than convection, radiation, conduction, or even flame-impingement processes. Other advantages of induction heat treating, which stem from this noncontact method and its generation of heat within the workpiece, are:

- Ease of automation and control
- Reduced floor space requirements
- Quiet and clean working conditions Suitability for integration in a production line or general work area due to the elimination of secondary or radiated heating

- Self-monitoring capability

Much of the material presented in this article was adapted from *Elements of Induction Heating--Design, Control, and Applications,* ASM International, 1988 and from *Induction Heat Treatment of Steel,* ASM International, 1986.

Principles of Induction Heating

The basic components of an induction heating system are an induction coil, an alternating-current (ac) power supply, and the workpiece itself. The coil, which may take different shapes depending on the required heating pattern, is connected to the power supply so that a magnetic field is generated from the current flow (Fig. 1a). The magnitude of the field depends upon the strength of the current and the number of turns in the coil.

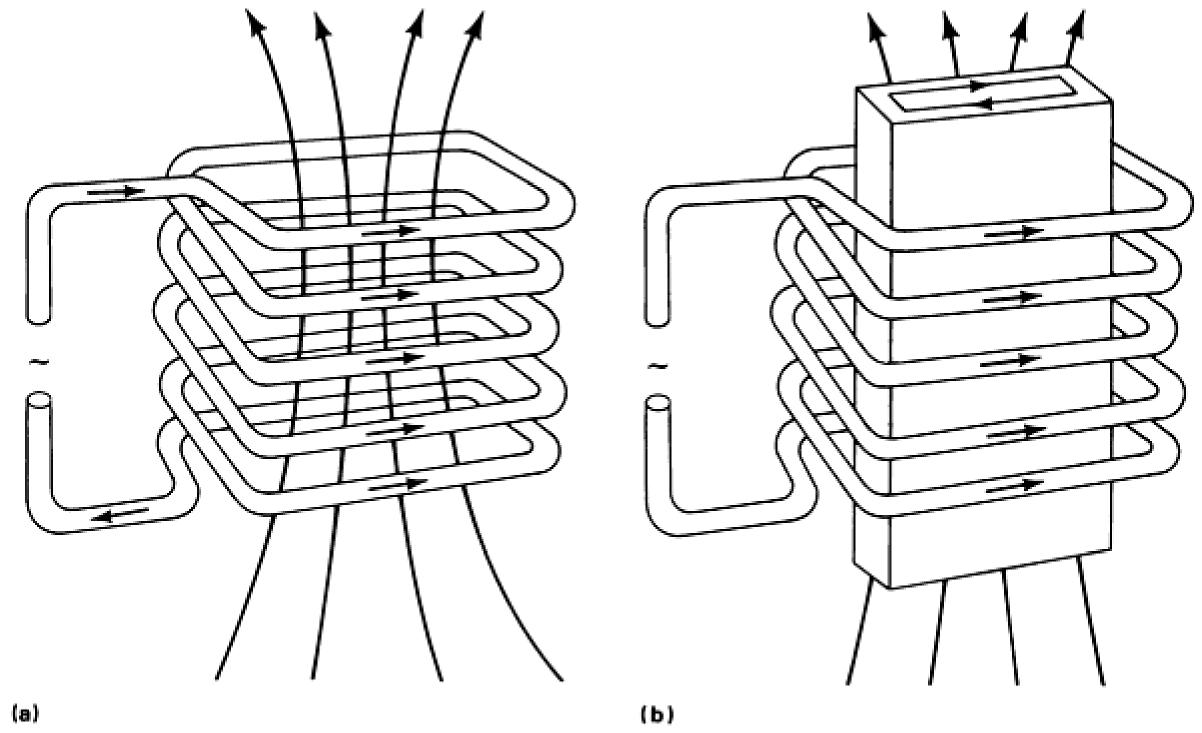

Fig. 1 Pattern of currents and the magnetic field in a solenoid coil (a). In (b), note that the induced eddy current in the specimen is opposite to that in the coil.

If an electrically conductive object is placed inside a coil with a varying current, the eddy currents are generated from the varying magnetic field within the object. These eddy currents are induced as a result of Faraday's law of electromagnetic induction:

$$e = -N\frac{d\Phi}{dt} \qquad \textbf{(Eq 1)}$$

which relates an induced voltage (e) to the time rate of change of the magnetic field (Φ) and the number of turns (N) in the coil. In effect, the coil acts in much the same manner as a primary winding of a transformer, with the workpiece acting as a single-turn (or short-circuited) secondary winding. Hence, the term "transformer action," which is sometimes used to describe the process (see the section "Coil Design" and the discussion of Fig. 31).

Eddy Current Characteristics. At any moment the direction of the induced current in the workpiece is approximately opposite to that in the inductor coil, and in general its flow pattern will describe a kind of "shadow image" of the coil conductors. The induced currents also generate their own magnetic fields, which are in opposition to the field generated by the coil and thereby prevent the field from penetrating to the center of the object (Fig. 1b). Therefore, the eddy currents are more concentrated at the surface and decrease in strength toward the center of the object (Fig. 2a). This phenomenon of the eddy currents travelling closer to the surface of a conductor is called the "skin effect."

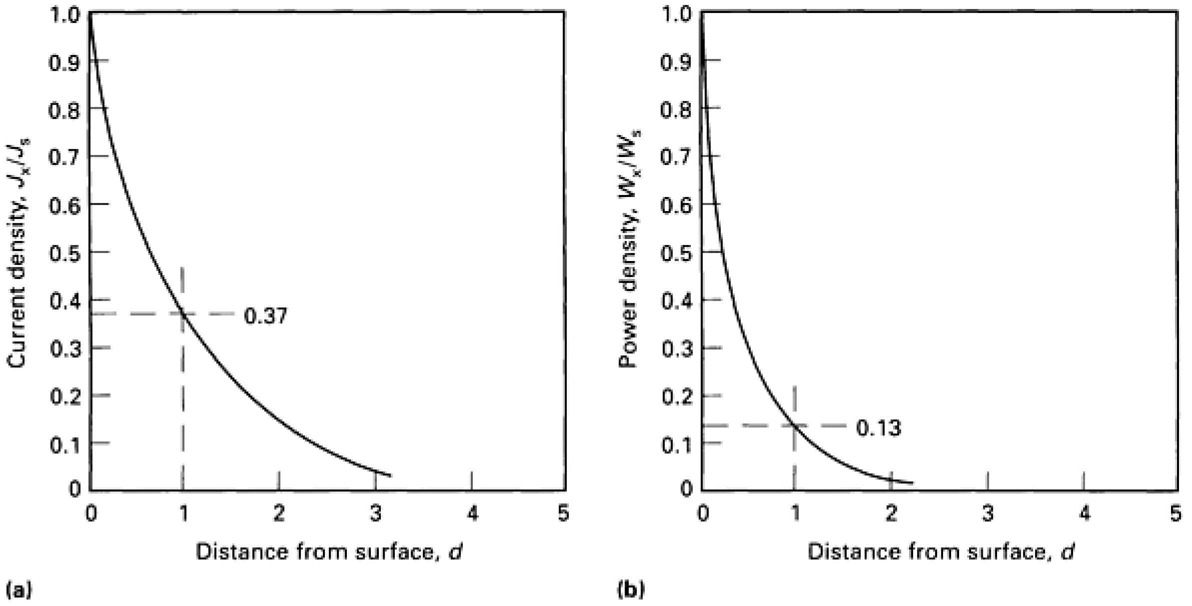

Fig. 2 Schematics showing current density (a) and power density (b) characteristics. In (a), $J_x = J_s\, e^{-x1d}$, where J_x is the current density at some distance, x, from the surface, J_s is the current density at the surface, and *d* is the reference depth as given in Eq 2. In (b) $W_x = W_s\, e^{-2x1d}$, where W_x and W_s represent the power density at some distance, x, from the surface and the surface power density, respectively.

Reference Depth. The mathematics needed to explain the skin effect involve a differential equation that has solutions in the form of Bessel functions. These solutions demonstrate that the induced current in a large planar object (that is, a plate much thicker than the expected eddy current penetration) decreases exponentially from the surface into the workpiece, or electrical load. This allows the definition of an "effective" depth of eddy currents known as the "reference depth" or "penetration depth," where the current density has dropped by 1/*e* (or 37%) of its surface value. The formula for this depth is given by:

$$d = \sqrt{\frac{r}{p m_0 m f}} \qquad \textbf{(Eq 2)}$$

where *d* is the reference depth; ρis the resistivity of the workpiece; μ_0 is the magnetic permeability of the vacuum; μ is the relative magnetic permeability of the workpiece (dimensionless); and *f* is the frequency of the alternating magnetic field of the work coil. If the current is squared, a curve that relates to the heating effect of the eddy currents (Fig. 2b) is obtained. At the depth of penetration, *d,* the heating effect therefore drops to $1/e^2$, or 14% of its value at the surface.

Figure 3(a) presents plots of penetration depth at various frequencies as a function of electrical resistivity. Figure 3(a) also illustrates different frequency requirements for a given penetration depth during various steel processing methods. These variations occur for any given material, because the resistivity of conductors varies with temperature. Furthermore, for ferromagnetic metals, the relative permeability varies with temperature, decreasing to a value of one (relative to free space) at the so-called Curie temperature. Also, as the power density is increased, steels may become magnetically saturated, leading to decreased permeability and hence increased reference depth (Fig. 3b). Because of these effects, the reference depth in nonmagnetic materials may vary by a factor of two or three over a heat-treatment temperature range, whereas for magnetic steels it can vary by a factor of 20.

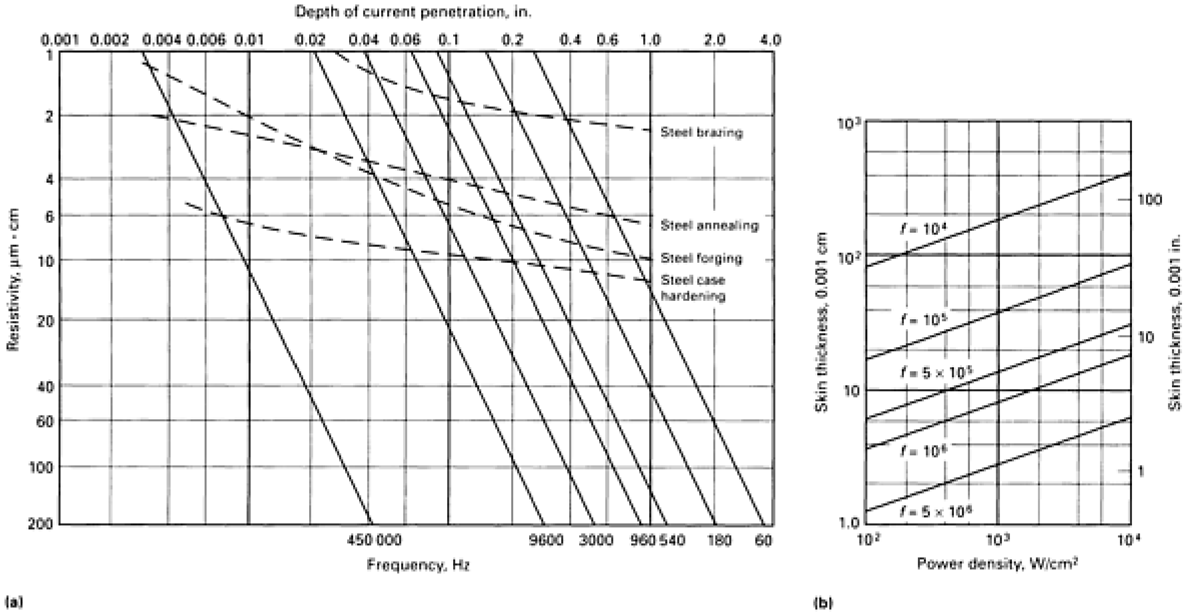

Fig. 3 Plots of penetration depth at various frequencies as a function of electrical resistivity. (a) Curves of current penetration versus frequency for induction heating with longitudinal flux. The dashed lines represent the reference depth for ferromagnetic steel below the Curie temperature for various operations. (b) Reference (skin) depth for magnetic steel as a function of power density

Current Cancellation. As previously noted, current density decreases exponentially (Fig. 2a) if the dimensions of the part are sufficiently large. However, if eddy currents in the inner regions of an object overlap each other, then the currents cancel each other. This effect is illustrated in Fig. 4(a) for various ratios of object thickness (*a*) and reference depth (*d*). The dashed lines show exponential decay from either side, while the solid line gives the net current from the summation of the two dashed lines. Net heating curves (Fig. 4b) are obtained by squaring the net current density.

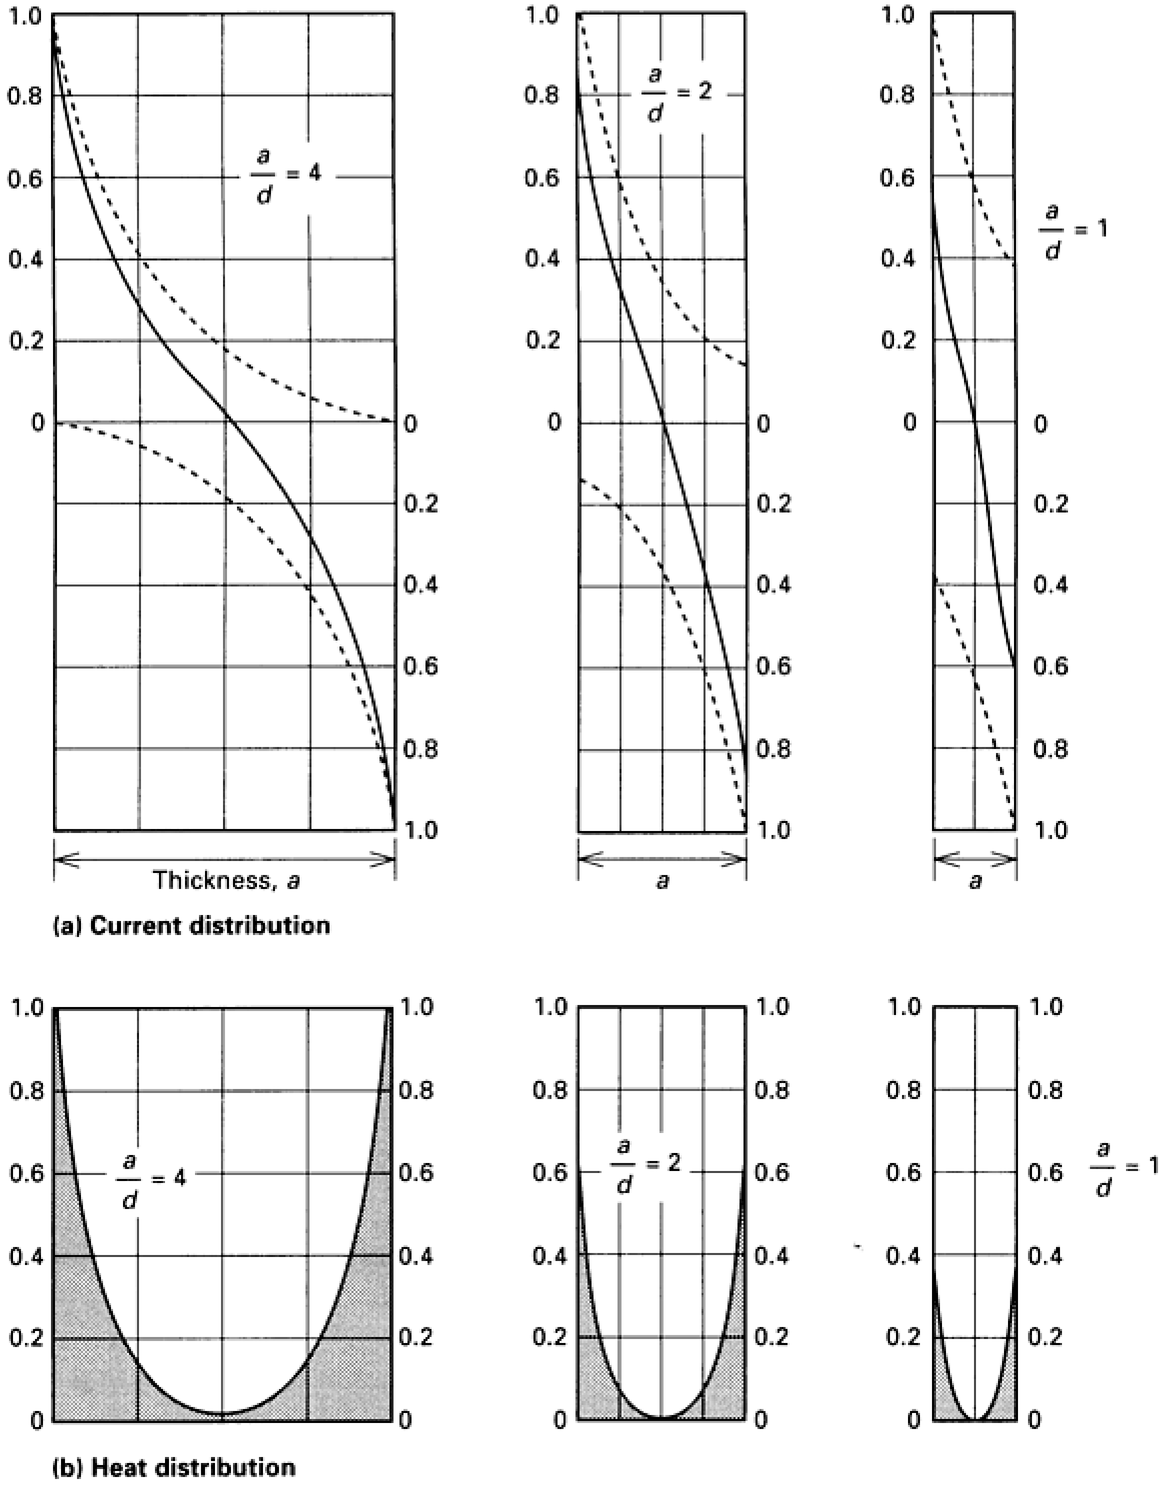

Fig. 4 Schematics showing current distribution (a) and heat distribution (b) for specimens of varying thicknesses. See the discussion of current cancellation for details.

Because current cancellations reduce the efficiency of heating, the rule of thumb for good efficiency is to have the reference dimension of the part at least 3 times greater than the reference depth (*d*). The reference dimension is the diameter of round objects or the thickness of rectangular objects such as strips or slabs.

Heat Generation. The primary mechanism of heat generation occurs from the flow of eddy currents in the workpiece. A second mechanism of heat generation occurs in ferromagnetic materials when energy is dissipated during the reversal of magnetic domains. This effect in ferromagnetic materials is usually ignored in induction heating calculations, because

the effect is small for the typical strength levels of magnetic fields for induction heating. Therefore, the rate of heating in units of power (watts) is largely a function of I^2R, or Joule heating.

The heating rate is affected by several variables such as:

- Field strength (expressed in units of ampere-turns of the work coil)
- Proximity of the workpiece to the coil conductors
- The electrical and magnetic properties of the material such as resistivity (ρ) and magnetic permeability (μ)

Heating rates are typically controlled by the coil voltage, because the field strength (or coil current) is roughly proportional to coil voltage.

The desired rate of heating varies with the application, and the mathematical analysis of induction heating processes can be quite complex for all but the simplest of workpiece geometries. This is because of the effects of nonuniform heat generation through the workpiece, heat transfer, and the fact that the electrical, thermal, and metallurgical properties of most materials exhibit a strong dependence on temperature. For this reason, quantitative solutions exist for the most part only for the heating of round bars or tubes and rectangular slabs and sheets. Nevertheless, such treatments, if properly applied, may provide useful insights into the effects of coil design and equipment characteristics on heating patterns in irregularly shaped parts. This information, coupled with knowledge generated through years of experimentation in both laboratory and production environments, serves as the basis for the practical design of induction heating processes.

Coupling and Flux Shaping. The degree of coupling between the workpiece and the magnetic field of the coil is determined by the number of magnetic flux lines that enter the workpiece. This flux density (number of lines of force) is proportional to the coil current, and the amount of energy transferred is proportional to the square of the number of flux lines intercepted by the workpiece. The frequency of coil currents also influences the pattern of induced currents, because flux lines tend to stay closer to the coil conductors as frequency is increased.

Flux leakage refers to the flux that does not thread through the heated material. The degree of flux leakage depends, in part, upon the electrical gap between the coil conductors and the workpiece. This so-called air gap is of greater concern as frequency increases, because flux lines tend to stay closer to the surface of coil conductors as frequency is increased. The factors influencing the air gap distance are discussed in the section "Coil Design" in this article (see the discussion on coupling distance).

Flux leakage can also be influenced by the use of flux concentrators, which are ferromagnetic materials purposely placed on or near the coil assembly. These devices, which are described in the section "Coil Design" in this article, provide a path of low magnetic reluctance and facilitate the concentration of flux lines in desired regions.

Induction Heat-Treating Equipment

An induction heating system typically consists of a power supply, a workstation, an inductor (heating) coil, controls, and workpiece handling units. When a steel or cast iron is being hardened, the system may also include a quenching system, depending on the hardenability of the particular grade.Some annealing practices may also be enhanced by accelerated cooling. It is common practice to include other auxiliary equipment such as line starters, electrical disconnects, and equipment cooling systems as part of an induction heating package.

The basic architecture of an induction heating system includes a workstation (or heat station), which contains load matching components such as output transformers and capacitors, plus high-frequency contactors, protective devices, cooling-water manifolds, and quench valves. The principal function of the workstation is to provide the proper electrical impedance match between the output of the power supply and the inductor (induction heating coil) for optimum power transfer into the heated load. The coil is normally mounted on the front of and close to the workstation. Workstation components may sometimes be installed in the power supply enclosure, as is often the case in small solid-state, medium-frequency heaters, and in many of the vacuum-tube oscillator units. Here the only external component that may be needed for load matching is an output transformer that may be positioned up to several feet from the power supply.

Power Supplies

Besides the induction coil and workpiece, the power supply is probably the most important component of an overall induction heating system. The function of the power supply is to accept power from a line at 60 Hz (50 Hz or other utility frequency in other parts of the world) and to deliver ac electrical energy through the load matching circuit to the inductor coil circuit at a useful voltage and frequency. Over the years, three basic frequency ranges have evolved for the classification of ac induction heating systems:

- Low-frequency systems (50 or 60 Hz line-frequency systems)
- Medium-frequency systems (150 or 180 Hz triplers or converters up to about 10 kHz)
- High-frequency systems (10 kHz and up)

Medium- and high-frequency power supplies suggest the need for conversion of line-frequency power, preferably three phase, to a single phase of higher frequency. Typical power ratings as a function of frequency are shown in Fig. 5.

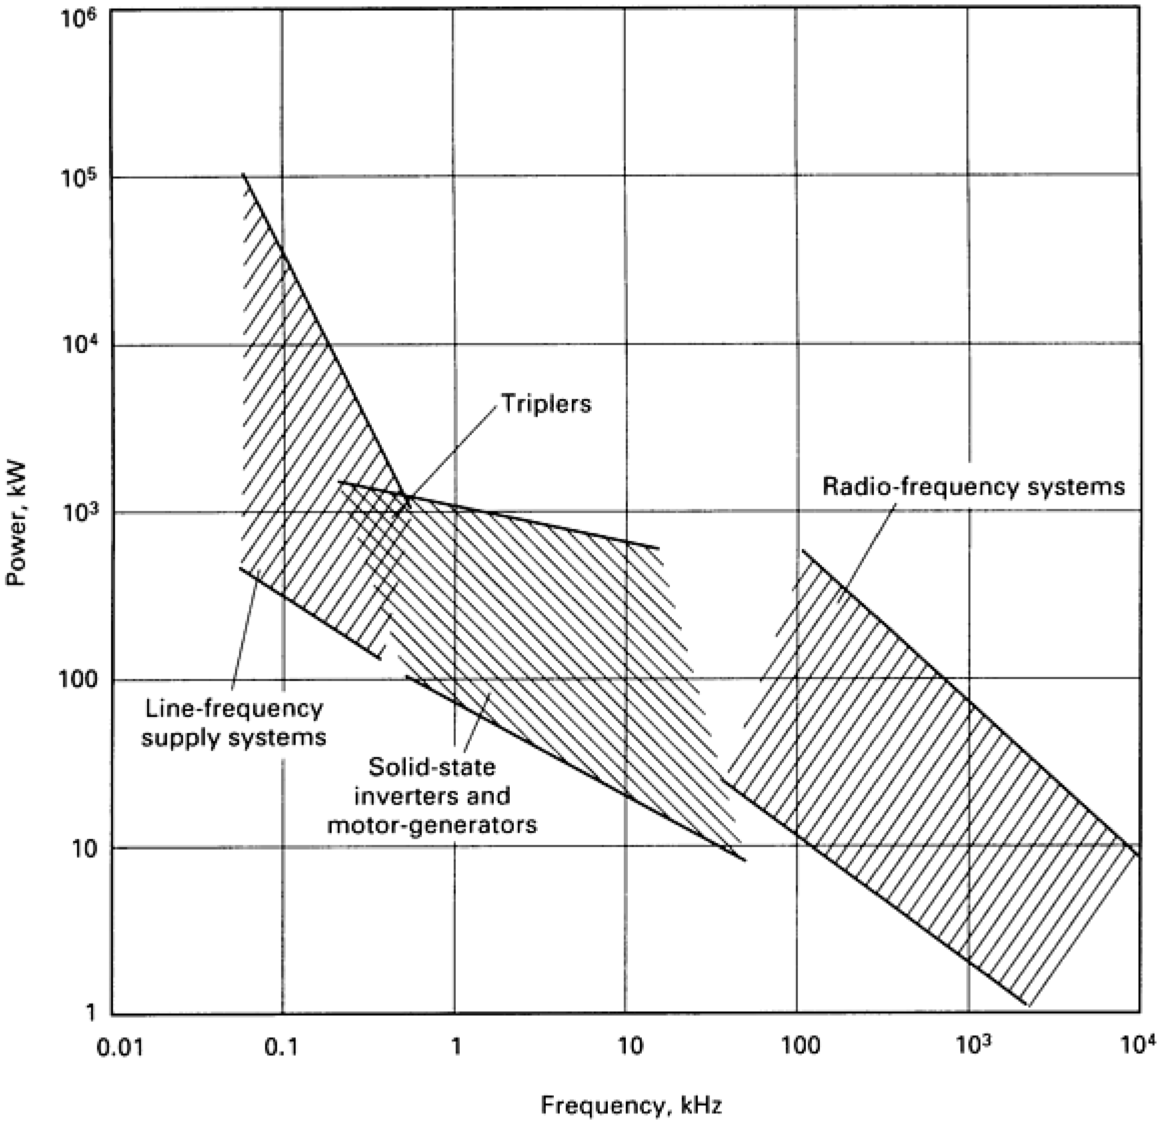

Fig. 5 Ranges of power ratings and frequencies for various induction power systems

There are essentially six different types of power supplies for ac induction heating applications, each designed to supply ac power within a given frequency range. These six types are line-frequency systems, frequency multipliers, solid-state (static) inverters, motor-generators, spark-gap converters, and radio-frequency (RF) power supplies. At the present time, the spark-gap oscillator is no longer manufactured, and the static, solid-state power supply has all but replaced rotating

machines or motor-generators. Table 2 gives the frequency and power ranges, approximate efficiencies, and other features of four major induction heating power sources.

Table 2 Characteristics of the four major power sources for induction heating

Power source	Frequency range	Power range	Efficiency %	Features
Line frequency	60 Hz	100 kW to 100 MW	90-95	High efficiency; low cost; no complex equipment; deep current penetration
Motor-generator	500 Hz to 10 kHz	10 kW to 1 MW	75-85	Low sensitivity to ambient heat; low sensitivity to line surges; fixed frequency; low maintenance cost; spares not needed
Solid state	180 Hz to 50 kHz	1 kW to 2 MW	75-95	No standby current; high efficiency; no moving parts; needs protection outdoors; no warmup time; impedance matches changing loads
Vacuum tube	50 kHz to 10 MHz	1 kW to 500 kW	50-75	Shallow heating depth; localized heating; highest cost; impedance matches changing loads; lowest efficiency

Choice of a power source depends primarily on the desired frequency, although there is often considerable overlap of application capability for any given unit in its frequency range. The frequency required for efficient induction heating is determined by the material properties (that is, resistivity and relative magnetic permeability) and the workpiece cross-sectional size and shape (see, for example, the previous discussions of Fig. 4). In a great many cases, a suitable frequency may also be impacted by the application requirements such as case depth in surface hardening of steels or the allowable temperature gradient for through hardening. In general, however, equipment cost per kilowatt increases with frequency, so a power supply of the lowest possible frequency that will accomplish the job efficiently is usually the best place to start when considering equipment. However, there is a trend away from 60 Hz even where they can be used, because they may not always be the most economical in initial cost when compared to solid-state supplies. Typical frequency selections for a number of specific applications are summarized in the section "Frequency Selection" in this article.

Power requirements for induction heating are also dependent on the specific application. For through heating applications, the power needed is generally based upon the amount of material processed per unit of time, the peak average temperature, and the material's heat capacity at this temperature. A power determination for localized heating and other operations, such as surface hardening of steel, is not as simple because of the effects of heat conduction to the adjacent metal and/or unhardened core. Nevertheless, guidelines in such situations are available (see the section "Power Density and Heating Time" in this article).

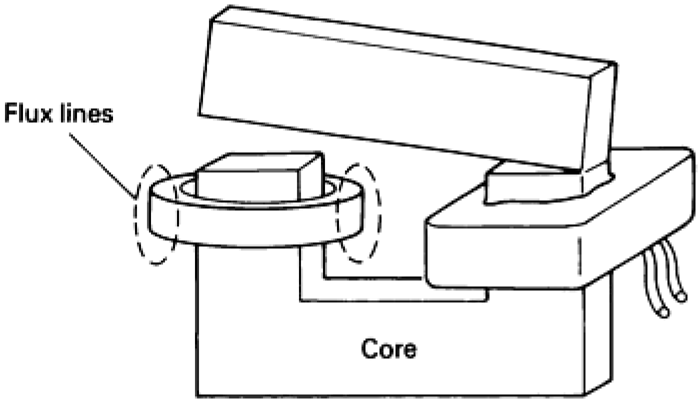
Line-frequency power supplies are considered low-frequency (50/60 Hz) and apply the local utility frequency to the coil, so no frequency conversion is needed. From an application viewpoint, the primary use for line-frequency induction equipment is through heating or very deep heat treating. Because most requirements in through heating applications call for some reasonable degree of surface-to-core temperature uniformity, these frequencies are more applicable than the higher ones. Line-frequency heating also works well for deep hardening large-diameter parts such as mill rolls. A line voltage of 220 or 440 V is acceptable for supplies rated to about 300 kW, whereas ratings to 1000 kW might operate from a 2300 or 4160 volt line, depending on how the electric utility services the plant and the internal power distribution system. Primary voltages of 6 kV or more are used with solid-state switching in higher power ratings up to 20 MW.

A major advantage of this type of system is the fact that there is no frequency conversion. Power losses and maintenance costs are therefore low because of the absence of rotating machinery or complex electronic equipment. Switchgear, power-factor correction capacitors, control components, and so forth, may often be standard catalog items. Equipment cost is generally less than that of medium- or radio-frequency units, although sometimes a standard medium-frequency solid-state power supply will prove the exception. Low-frequency induction heating with conventional water cooled longitudinal coils have been limited to deep case hardening and to quench-and-temper operations for steel cross section thickness of 125 mm (5 in.) and larger. It may be somewhat difficult to apply because of high mechanical forces and stray field effects, but it can provide more uniform temperatures from the surface to the required depth.

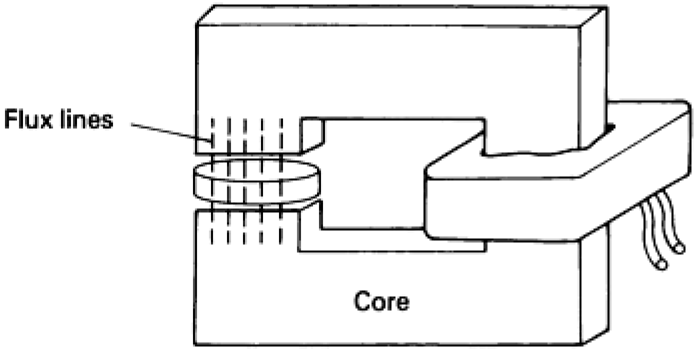
When high power levels are involved, balanced three-phase systems are often required to meet the electric utility or the plant requirements for power distribution. These may be achieved by the use of a three-phase coil or three separate coils, with each part energized by a different phase. Such arrangements yield a reasonably balanced load, provided that the coils are filled with a workpiece. If one coil or coil section is only partly filled, one phase becomes out of balance. For this reason, it is good practice to avoid a neutral wire in the supply line, which could carry an excessive current. Another option is to use a three-to-single-phase load balancer. Sometimes, the higher temperatures required for heating steel above the Curie temperature (at which $\mu = 1$) are more efficiently achieved with medium frequencies; so in a dual-frequency progressive heating system, a number of 60-Hz coils can be used such that each can be energized separately by a single phase. This produces a well balanced three-phase load to the line. Thus, three or any multiples of three small single-phase coils can be loaded on a three-phase supply.

Portable line-frequency power supplies designed specifically for pipe preheating and postheating are available in single-phase ratings to 150 kVA (150 kW with a power factor of 1). These consist of movable transformer modules, generally supplied with a temperature sensing thermocouple and control instrument, and with insulated cables to be wrapped around the work and connected to the secondary winding output. Portable units used in the field on construction sites may obtain power from a diesel generator.

Core-Type Induction Heater. Another type of self-contained line-frequency power supply is the core-type heater. In this device, the workpiece is placed in or around the core of a power transformer instead of being heated in a coil. Air or water cooled primary windings are placed around a laminated silicon-steel transformer core, 75 mm × 75 mm (3 × 3 in.) or larger cross section. A ring-shaped workpiece such as a ring gear, bearing, or wheel may be placed around a movable section of the core in which case the part becomes a short-circuited single-turn secondary winding of a true core-type transformer (Fig. 6a). If a solid workpiece is sandwiched between a split section of core (Fig. 6b), the metal will be inductively heated through transverse flux. Heaters of this type are used extensively to preheat parts, to stress relieve, and they may be capable of heating some parts to supercritical temperatures. In general, however, standard core-type heaters and those using coils made of thermally insulated cable wrapped around a cylindrical load are limited to preheating, stress relieving, and post-welding treatments.



(a)



(b)

Fig. 6 Core-type inductor heater arrangements. (a) Split-yoke arrangement for heating a ring with longitudinal flux lines. (b) Arrangement for heating a solid object with transverse flux lines

Single-phase line-frequency heaters may be acceptable to a utility up to some power level, particularly if other single-phase loads are available to balance the incoming three-phase system. Three-phase power may be considered for any line-frequency heater where three, or multiple of three, heating coils are employed, or where two coils can be energized from a Scott-connected transformer.

Balancing the load on a three-phase line when connected to a single winding coil may also be accomplished with a phase-balancing network using an inductive reactor and capacitors. These are commonly applied to induction melting furnaces up to several thousand kilowatts, but use in heat treating is quite limited.

Load matching apparatus for a line-frequency heater starts at the power transformer which may be equipped with primary and/or secondary voltage-adjusting taps, plus power factor correction capacitors to supply leading reactive current to offset the lagging inductive reactance of the load. To meet most electric utility requirements and/or to minimize rate penalties for low power factor, the heater should be corrected to a 0.85 power factor or better.

Heating Coils for Low-Frequency (50/60 Hz) Heaters. Because low-frequency induction heaters operate with low volts-per-turn and high current, the electromagnetic forces are greater than at higher frequencies. At high power and current levels, forces in the coil must be considered in determining the rigidity of coil construction. For some low-power-density coils used in heating ferromagnetic metals, forces in the coil may not be a serious concern. Core heater coils are somewhat typical and may have fiberglass wrapped turns with varnish or epoxy as a binder. Stud board construction may be used for high-power coils with spaced turns, and turn-to-turn insulation with the entire assembly clamped under pressure is appropriate for close wound coils.

Work Handling Equipment for Low-Frequency (50/60 Hz) Heaters. Because electromagnetic forces exist between the coil and the load, low frequencies also have a greater tendency to physically move parts and cause vibration. Positive clamping or containment may be needed in fixtures, and greater driving force may be required to enter an energized low-frequency coil.

Controls and auxiliary equipment for low-frequency (50/60 Hz) induction heaters will be similar to those used in higher-frequency systems. Voltage regulation and/or power control may come from a line-side saturable core reactor, a rotary induction regulator, an on-load tap switch, or from a solid-state thyristor switching system. Simple on-off cycles can be initiated and terminated by an electromechanical line contactor or a solid-state switch. When power-factor correction capacitors are used, one should be cautious of high inrush currents and potential problems with harmonics of thyristor switching. Auxiliary devices for line-frequency systems might also include a three-to-single-phase balancer and some electrical protection devices such as a fused disconnect and/or a circuit breaker.

Frequency multipliers are used to obtain multiples of the line supply, most often 180 and 540 Hz. Like line-supply installations, they are used primarily for large heating and melting applications.

The 180 Hz supply, also known as a tripler because it is derived directly from 60 Hz line current, is composed of three saturable reactors, each of which is connected between one leg of a Y-connected secondary and a single-phase load. The voltages from the secondaries are 120° apart. Passing them through a single-phase output, therefore, produces three pulses in the same time period as that in which a normal 60 Hz system would produce one waveform. Accordingly, the frequency is essentially tripled. The 180 Hz system is similar to the 60 Hz heater in that the circuit containing the load must be turned to the frequency of the power supply--namely, 180 Hz. Systems may be cascaded to produce other multiples of the line frequency, such as 540 Hz.

Solid-State Systems. Medium-frequency power supplies using solid-state frequency conversions make up the vast majority of induction heating and melting power supplies in use today. These systems, which utilize high-power silicon-controlled rectifiers (SCRs) having rapid turn-on/turn-off times, have largely replaced motor-generator sets for medium-frequency conversion. As compared with motor-generator sets, the basic advantages of solid-state power supplies are their improved efficiency (Fig. 7), low initial cost and maintenance, and availability in a multitude of sizes and frequencies.

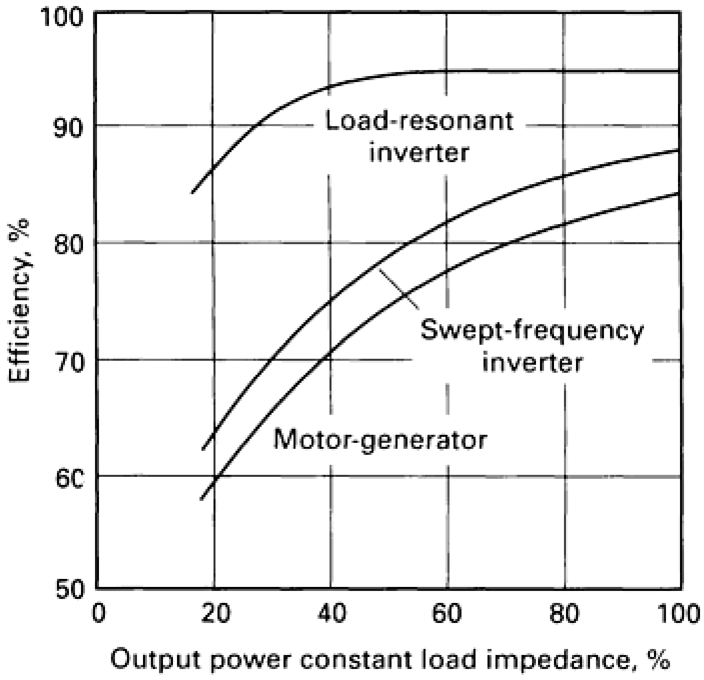


Fig. 7 Comparison of the overall system efficiency of a typical motor-generator, swept-frequency inverter, and load-resonant (constant-current) inverter

With the exception of an ac-to-ac solid-state converter, which does not have wide usage in heat-treating applications, all of the commercial medium-frequency solid-state inverters for induction heating use a two-step conversion in which 60 Hz ac is changed to dc and the dc changed back to ac at the desired frequency. Diodes or thyristors first rectify three-phase line frequency to produce direct current, and solid-state logic then converts dc into ac by one of the two methods discussed below. In both types of solid-state inverters, the system frequency is tuned to the load, whereas in motor-generator circuits the load is tuned to the fixed frequency of the generator. This greatly simplifies load matching when the electrical characteristics of the load change during a heating cycle.

Constant-Voltage (Swept-Frequency) Inverter. The first development in solid-state frequency conversion for induction heaters was based on the swept- (or variable-) frequency inverter. With this system (Fig. 8a), line voltage is converted to direct current and then is applied by means of a capacitive voltage divider to an SCR (dc-to-ac) inverter circuit. The system utilizes internal commutation to turn off the SCR's in the inverter circuit. A feedback circuit from the resonant tank, together with power- and voltage-control signals, is fed to a local oscillator whose output signal then controls the inverter firing rate. The system then operates at a frequency along the straight portion of the tank's resonant-frequency curve, but not at the resonant frequency.

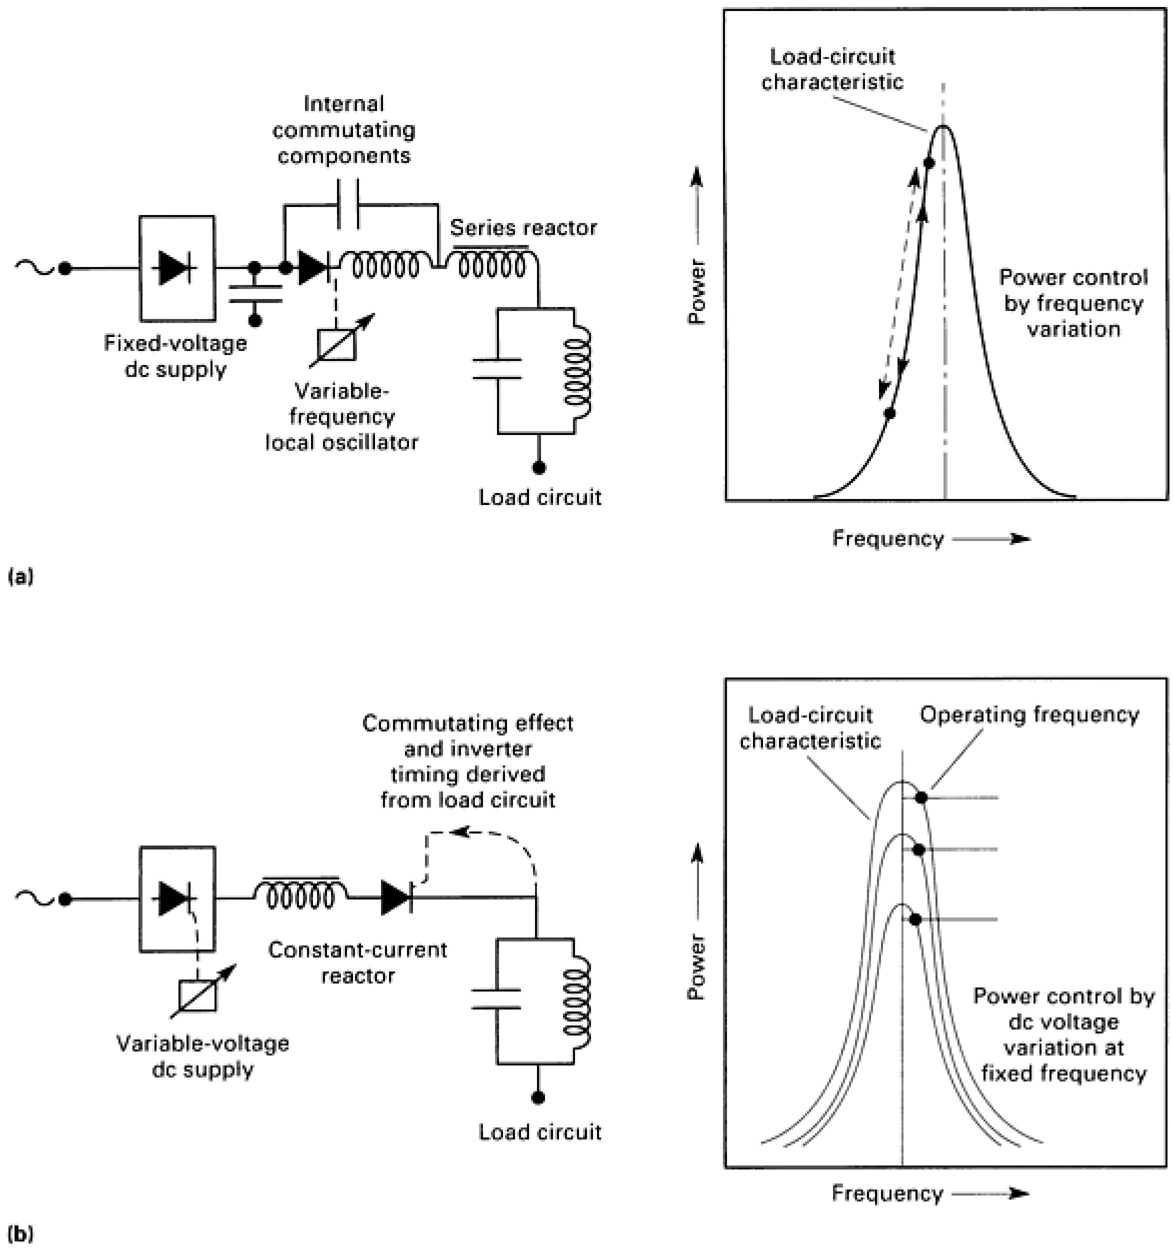

Fig. 8 Circuit schematics for (a) a swept-frequency inverter and (b) a load-resonant or constant-current solid-state inverter

By offsetting the firing rate of the oscillator from the resonant frequency of the tank, the unit can be made to operate along the power curve (Fig. 8a). The frequency from the local oscillator can thus be shifted by the resonant frequency of the tank circuit (or heat station), and the power supply (if set for constant output at the load) can shift its frequency as the load is heated. Nevertheless, it is necessary first to tune the system so that the tank frequency is within the frequency band of the local oscillator. Once the tank is tuned within the range of the local oscillator, it too will provide a constant output as the resonant frequency of the tank shifts, especially when the temperature passes through the Curie point during heating of magnetic steels.

Constant-Current (Load-Resonant) Inverter. The other common solid-state inverter, known as the load-resonant or current-fed inverter (Fig. 8b), also utilizes a dc power source. However, this inverter is provided with an SCR for voltage control. The SCR inverter uses no local oscillator but derives its commutating effect directly from the resonant tank circuit. Thus, it is load-resonant. In actuality, for reasons based on the operational characteristics of the SCR's, the system is usually operated with a slightly leading power factor and thus an operating frequency slightly higher than the load-resonant frequency (Fig. 8b).

Because the frequency is dependent on the tank-resonant conditions, changes in the coil inductance (such as when a magnetic material passes through the Curie temperature) will shift the frequency of operation without any change in power output. If it is desired to select a specific frequency, depending on the application, capacitor taps can be adjusted to meet this requirement. Because the system always operates at the resonant frequency of the tank circuit, its power factor is usually close to unity, and therefore impedance matching by means of a transformer-tap change is the only routine adjustment that need be made to secure optimum power output. This procedure is the same as that for tuning a fixed-frequency motor-generator system.

Ratings. Solid-state power supply ratings vary with design. Output power ratings vary with frequency (Fig. 5), and conversion efficiencies can be higher than 90%. Except for power output above 500 kw, most power ratings are based on a three-phase, 480 V line-frequency input. Above 500 kw, higher nonstandard input voltages may be appropriate, and a special input transformer may be used.

Because solid-state inverters were initially designed to replace motor-generators, the frequency and power ratings of these systems were based on standard motor-generator rating techniques with power rated at the terminals neglecting the losses in the heat station, coil, and so forth. However, solid-state power supplies are really not frequency limited, because they are either load-resonant or the frequency is controlled by a local oscillator. Thus, a frequency can be selected which is optimum for the application. In effect, all solid-state generators are actually variable-frequency inverters, generally designed to operate within some reasonable frequency range.

Motor-Generator Sets. As the name implies, a motor-generator set is a rotating machine in which a driven generator uses electromagnetic induction to produce higher-frequency current. The motor and the generator can be individual units with a mechanical coupling and a common base, or they can be constructed on a single shaft in a common housing. Both horizontal and vertical types have been used. A cooling system is used to remove the heat dissipated by the current flowing in the windings and the hysteresis losses that develop in the structure and motor laminations. Early motor-generator systems utilized forced air cooling, but later water-cooled, finned copper tubing heat exchangers were built within the unit shell and have since become standard. Frequencies generated by motor-generators are determined by rotational speed (usually 3600 rpm) and the number of poles in the generator. Frequencies that are low multiples of a supply frequency (such as 180 Hz from 60 Hz) can be produced with motor-generator sets using a standard induction or synchronous motor driving an ac generator.

A more widely used subclass of motor-generator is the inductor-alternator with no windings on the rotor. In this instance, both the field (or excitation) winding and the output windings are on the stator; therefore, no centrifugal forces act on the output windings, and the rotor can be an extremely robust package of silicon steel punchings. Such designs permit higher frequencies and higher power capacity to be obtained from the motor-generator class of equipment. Inductor-alternators are available with output frequencies of 180 Hz, 360 Hz, 400 Hz, 1 kHz, 2 kHz, 3 kHz, 10 kHz, 12 kHz (European) and 20 kHz. Kilovolt-ampere ratings range from $7\frac{1}{2}$ to 1800 kVA with output voltages of 220, 400, or 800 volts. Conversion efficiencies are 75 to 85%, with lower efficiencies at the higher frequencies. Because the power needed to spin the heavy rotor is the same at light load or full power, system efficiency (Fig. 7) is low when the generator is loaded lightly (that is, when only a fraction of its rated power is drawn). Moreover, some power is consumed when the load is completely removed.

Radio-Frequency (RF) Power Supplies. For frequencies above 150 kHz, frequency conversion can be performed by either vacuum-tube or solid-state systems. Vacuum-tube systems are the most widely used type at the present time, and they can attain frequencies up to about 2 MHz for induction heating. Solid-state systems presently produce RF heating energy in the frequency range 20 to 200 kHz. Frequencies higher than 2 MHz are used for dielectric heating (of nonconductors) instead of induction heating.

Vacuum-tube radio-frequency induction heaters, like most solid-state inverters, use ac/dc/ac conversion stages. Radio-frequency energy is similarly developed in tuned tank circuit and then transferred to the workpiece. The work coil can be placed in series with the tank coil (Fig. 9a) or connected to the secondary of an RF output transformer (Fig. 9b). The series-connected system, usually utilizing a tapped tank coil, is often referred to as a DTL (direct tank loaded) technique, simply because the work coil becomes a functioning part of the tank-circuit inductance. On the other hand, in transformer coupled output circuits, the primary winding is a part of the tank, and the work coil is isolated from both the transformer primary and the tank circuit. The work coil may be center or midpoint grounded to minimize voltage potential and, therefore, arcing from coil to ground.

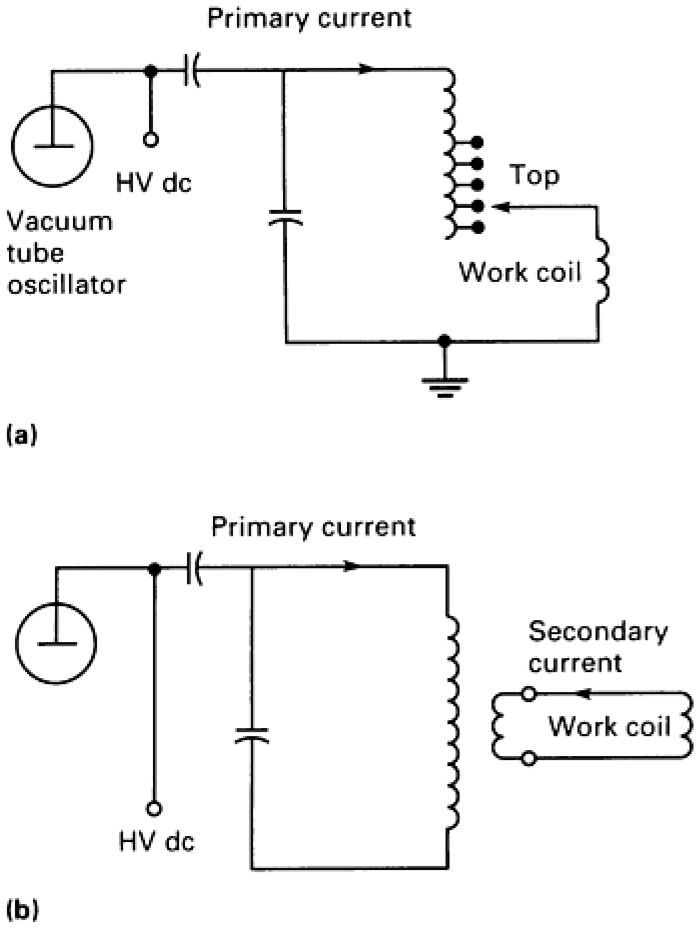

Fig. 9 Output tank circuits of common high-frequency inductor generators (a) direct tank loaded and (b) transformer coupled

It is also possible to locate the entire tank circuit (capacitance and inductance) remotely in a way similar to heat stations running off low- or medium-frequency power supplies. In this case, the remote tank and work coil (either DTL or transformer circuit) is connected to the oscillator by means of semiflexible coaxial cable. Moving the tank circuit itself rather than the coil involves much lower current at impedance levels that are more forgiving. The feedback necessary for oscillation is generally obtained from the tank circuit with a pick-up coil. An RF output transformer can be used a short distance from the power-supply enclosure, but if a fairly low-impedance heating coil is used some distance from the generator, significant power losses can occur. To minimize voltage drop, RF should be designed for low impedance. This is particularly true for leads from a transformer to a coil. Moreover, in the case of a remote output station or a DTL system, personnel must be protected from the high voltages from these lines. Radio-frequency interference can also develop from unshielded high-voltage leads. Grounded aluminum or shielded coaxial cable should be used for energy transmission. According to FCC regulations, all RF generators (10 kHz and above) must be type certified to be below allowable radiation levels.

Vacuum-Tube RF Generators. The first methods used to generate radio frequencies for induction heating utilized spark gap and vacuum-tube oscillators. In general, vacuum tube frequency conversion process starts with one-phase (to 5 kW) or three-phase line current being changed to direct current (dc). The dc is then almost universally applied to a class C oscillator, which produces RF energy for heating. Rectifiers for the initial ac-to-dc conversion can be mercury vapor two-element or three-element tubes (the latter for variable dc voltage and power control). In recent years, solid-state diodes or thyristors are being used for the same purpose. Oscillator tubes are forced air cooled up to 10 kW maximum, while larger oscillator tubes have water-cooled anodes. Guaranteed life is in the range of 5000 to 10 000 h. Tube output ratings vary from 1 to 200 kW with effective overall conversion efficiency of 60 to 75%. Tank circuits and other losses account for conversion efficiency of 50 to 60%.

Solid-state RF power supplies also now operate at 20 to 200 kHz in a wide range of power outputs. Unlike the inverters used at 20 kHz and below, these units do not have SCR's, but are instead powered by MOSFET (metal-oxide semiconductor field-effect transistor) output devices.

A solid-state RF power supply is similar to an SCR inverter in that line voltage enters the system through an isolation transformer and is then changed to a dc voltage, the level of which is adjustable through thyristor rectifiers. This filtered dc output is the input for the solid-state RF supply's power boards. The MOSFETs on each board and the boards themselves are connected in parallel. Frequency sensing from the tank circuit feeds the tank resonant-frequency signal back to the microprocessor. The MOSFETs in turn are driven at this frequency by the microprocessor. The software will also change the system operating frequency in response to changes in tank resonant frequency. As does the load-resonant inverter, the solid-state RF system operates at the peak of the resonant curve, and its efficiency is therefore similar.

Similarly, the software for these microprocessor-driven systems can be modified to provide constant current, constant power, or constant voltage, depending on the conditions required for the particular application. The software also permits interrogation of the system through a computer-keyboard interface.

Spark-Gap Converters. Although no longer produced commercially, the spark-gap converter was one of the earliest means of providing high-frequency ac power in the radio-frequency region. It was initially developed for metal melting, but has been used in a wide variety of heat-treating applications. It is almost obsolete because of high maintenance, difficulty in maintaining repetitive application of power, and the potential for RF interference.

In its simplest form, the spark-gap converter includes a step-up transformer to increase the line voltage to a few thousand volts, which is impressed across the spark gap. In operation, as the voltage rises in each half-swing of the 60-Hz line current, the voltage across the gap also rises until it discharges at the breakdown level, thus firing the tuned load. Frequencies generated by this system are generally in the range of 20 to 40 Hz for the quenched gap type and 80 to 200 kHz for the mercury hydrogen type. However, many frequency components are produced simultaneously so that the output is not purely sinusoidal, and a damped wave output has the disadvantage of a high peak voltage for a much lower average voltage. Efficiency of these systems is rather low--on the order of 15 to 50% line-to-load.

Induction Heat Treating of Steel

Peter A. Hassell, Hassell Associates; Nicholas V. Ross, Ajax Magnethermic Corporation

---

Inductor Coils

The inductor (or heating) coil is the device that shapes the electromagnetic field around and into the part or material being heated. The resulting magnetic flux achieved by an inductor can be classified as one of two modes:

- Longitudinal flux
- Transverse flux (sometimes called proximity heating)

Longitudinal flux induction heating is by far the most widely used mode of application, typified by the coil turns surrounding the load with flux lines flowing longitudinally in the direction of part movement (Fig. 1b). When the air gap between the coil and workpiece is reasonable for the frequency and load conditions involved, heating can be quite efficient because the flux lines tend to be confined, with a large percentage of them coupled to the workpiece. However, because eddy current cancellation occurs when the thickness of the object becomes small in comparison with the reference signal (Fig. 4), longitudinal flux heating of thinner parts requires higher frequencies than transverse flux.

Transverse flux heating means the field flux is applied at right angles to the axis or movement of the part. Because current flows at right angles to the flux (right hand rule), it will then produce an image pattern of the coil on one face of the part. The term proximity heating implies that the coil is only placed in proximity to the work, rather than surrounding it. Additional information on transverse flux heating can be found later in this article (see the section "Coil Design").

Coil Design

Coil design is influenced by many factors including the dimensions and configuration of the workpiece, the number of parts to be heated, the temperature required, the pattern of heat desired, and whether the workpiece is to be heated at one time or progressively. The applied frequency and the level of power also enter into coil design.

In a sense, coil design for induction heating is built upon a large store of empirical data whose development has sprung from theoretical analyses of several rather simple inductor geometries such as the classical solenoidal coil. Because of this, coil design is generally based on experience. In this section, the fundamental electrical considerations in design of inductors are reviewed and some of the most common coils in use are described. The actual construction of coils and the selection of power-supply leads are also discussed.

Design Considerations. In many texts on induction heating as well as in the section "Principles of Induction Heating" in this article, an analogy between a transformer and an inductor/workpiece combination has been described. The inductor is similar to the transformer primary, and the workpiece is equivalent to the secondary (Fig. 10). Therefore, several of the characteristics of transformers are useful in the development of guidelines for coil design.

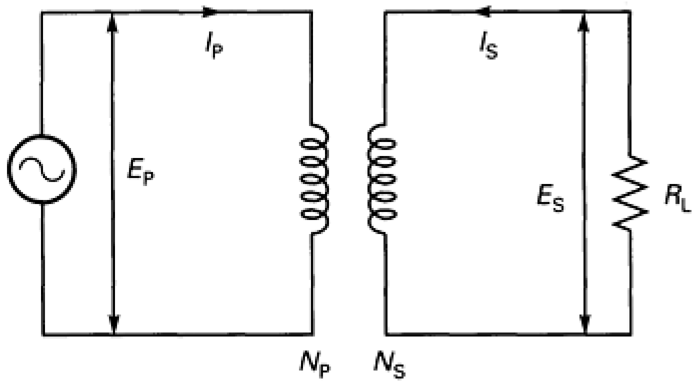

Fig. 10 Electrical circuit illustrating the analogy between induction heating and the transformer principle. E_p = primary voltage (V); I_p = primary current (A); N_p = number of primary turns; I_s = secondary current (A); N_s = number of secondary turns; E_s = secondary voltage (V); R_L = load resistance (Ω)

One of the most important features of transformers lies in the fact that the efficiency of coupling between the windings is inversely proportional to the square of the distance between them. In addition, the current in the primary of the transformer multiplied by the number of primary turns is equal to the current in the secondary multiplied by the number of secondary turns. Because of these relationships, there are several conditions that should be kept in mind when designing any coil for induction heating:

- The coil should be coupled to the part as closely as feasible for maximum energy transfer. It is desirable that the largest possible number of flux lines intersect the workpiece at the area to be heated. The denser the flux at this point, the higher will be the current generated in the part
- The greatest number of flux lines in a solenoid coil are toward the center of the coil. The flux lines are concentrated inside the coil, providing the maximum heating rate there
- Because the flux is most concentrated close to the coil turns themselves and decreases farther from them, the geometric center of the coil is a weak flux path. Thus, if a part were to be placed off center in a coil, the area closer to the coil turns would intersect a greater number of flux lines and would therefore be heated at a higher rate, whereas the area of the part with less coupling would be heated at a lower rate; the resulting pattern is shown schematically in Fig. 11. This effect is more pronounced in high-frequency induction heating
- At the point where the leads and coil join, the magnetic field is weaker; therefore, the magnetic center of the inductor (along the axial direction) is not necessarily the geometric center. This effect is most apparent in single-turn coils. As the number of coil turns increases and the flux from each turn is added to that from the previous turns, this condition becomes less important. Due to this phenomenon and the impracticability of always centering the part in the work coil, the part should be offset slightly toward this area. In addition, the part should be rotated, if practical, to provide uniform exposure
- The coil must be designed to prevent cancellation of the field of magnetic induction by opposite sides of the

inductor (Fig. 12)

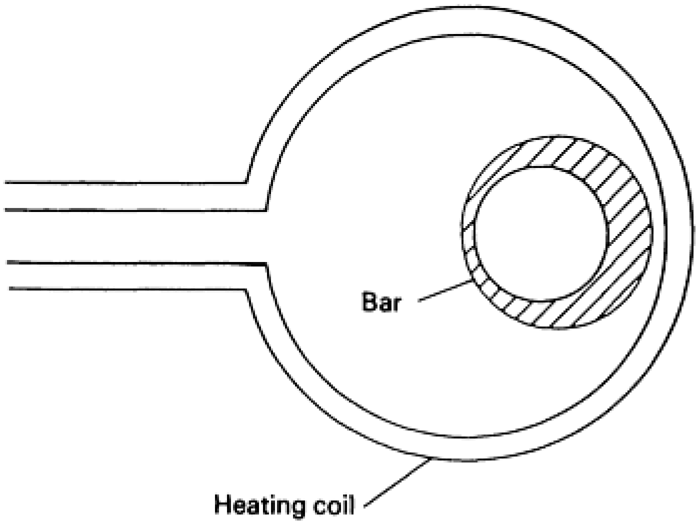

Fig. 11 Induction heating pattern produced in a round bar placed off center in a round induction coil

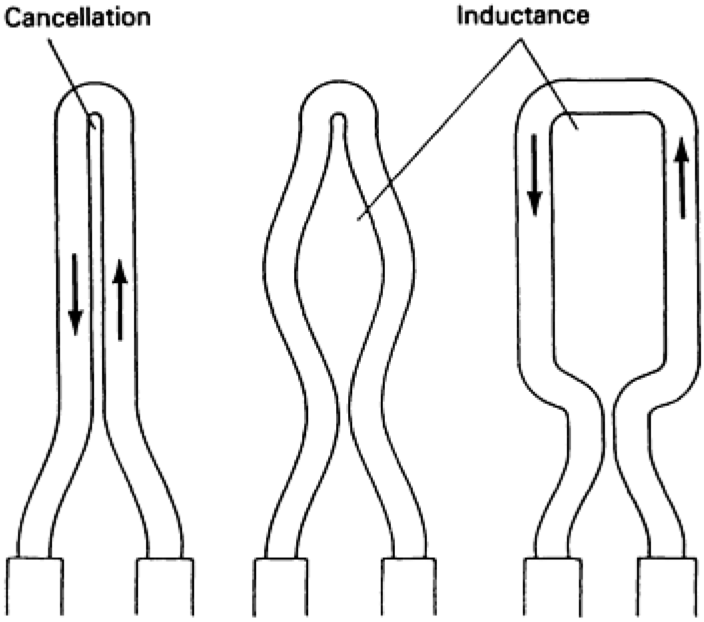

Fig. 12 Effect of coil design on inductance. The coil on the left has no inductance because the opposite sides of the inductor are too close to each other. Putting a loop in the inductor (center coil) will provide some induction. The coil will then heat a conducting material inserted in the opening. The design at the right provides added inductance and is more representative of good coil design.

Because of the above principles, some coils can transfer power more readily to a load because of their ability to concentrate magnetic flux in the area to be heated. For example, three coils which provide a range of heating behaviors are the following:

- A helical solenoid with the part or area to be heated located within the coil and thus in the area of greatest magnetic flux
- A pancake coil where the flux from only one surface intersects the workpiece

- An internal coil for bore heating, where only the flux on the outside of the coil is utilized

In general, helical coils used to heat round workpieces have the highest values of coil efficiency and internal coils have the lowest values.

Besides coil efficiency, design considerations with regard to heating pattern, part motion relative to the coil, and production rate are also important. Because the heating pattern reflects the coil geometry, inductor shape is probably the most important of these factors. Quite often, the method by which the part is moved into or out of the coil can necessitate large modifications of the optimum design. The type of power supply and the production rate must also be kept in mind. If one part is needed every 30 s but a 50-s heating time is required, it is necessary to heat parts in multiples to meet the desired production rate. Keeping these concurrent needs in mind, it is important to look at a wide range of coil techniques to find the most appropriate one.

Low-Frequency Heating Coils. Low-frequency induction heating is generally desired for through heating of metals, particularly those with large and relatively simple cross sections. Typical applications are round or round-cornered square (RCS) stock for forging or extrusion and slabs for hot rolling. In these cases, coil design is often quite simple, usually consisting of a solenoid coil or a variation of it that matches the basic workpiece cross-sectional shape (for example, square, rectangular, trapezoidal, and so forth).

Low-frequency coils often have many turns. Accordingly, the coil usually forms the total tank inductance, and an autotransformer may be used to match the coil impedance to that of the induction generator. In any case, the coil or transformer inductance must be high in order to reduce the number of tank capacitors needed to tune the resonant circuit at the operating frequency. Generally, the lower the frequency, the larger the coil or the greater number of turns. When low-inductance coils are occasionally required, isolation transformers can be used to match the coil impedance to that of the induction generator. However, these occasions are considerably fewer at the lower frequencies. In a practical sense, coils of this nature are generally purchased as part of an overall system, with total responsibility for operation resting with the system supplier.

Medium-to-High-Frequency Coils. Simple solenoid coils, as well as variations of them, are also often relied on in medium-to-high-frequency applications such as heat treatment. These include single- and multiple-turn types. Figure 13 illustrates a few of the more common types based on the solenoid design. Figure 13(a) is a multiturn, single-place coil, so called because it is generally used for heating a single part at a time. A single-turn, single-place coil is illustrated in Fig. 13(b). Figure 13(c) shows a single-turn, multiplace coil. In this design, a single turn interacts with the workpiece at each part-heating location. Figure 13(d) shows a multiturn, multiplace coil.

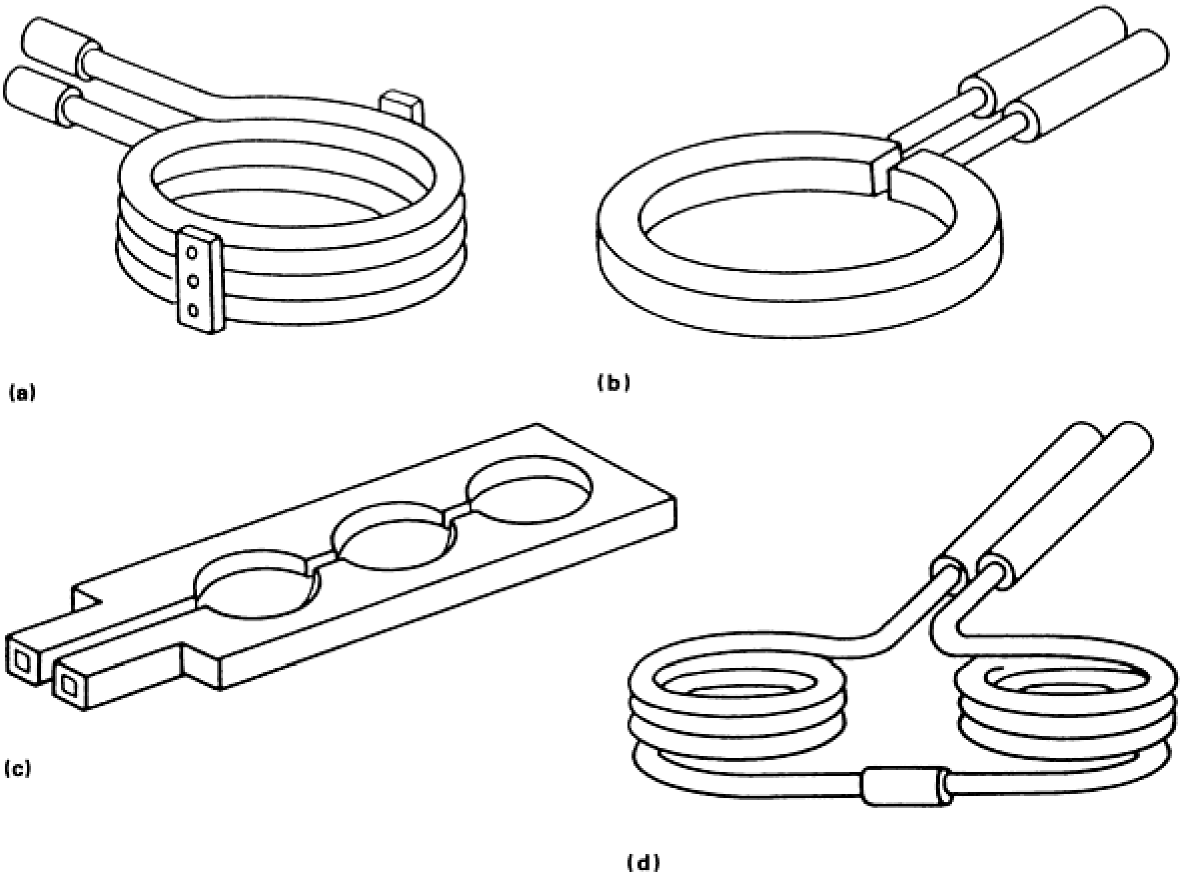

Fig. 13 Typical configurations for induction coils. (a) Multiturn, single-place. (b) Single-turn, single-place. (c) Single-turn, multiplace. (d) Multiturn, multiplace

More often than not, medium-to-high-frequency applications require specifically configured or contoured coils with the coupling adjusted for heat uniformity. In the simplest cases, coils are bent or formed to the contours of the part (Fig. 14). They may be round (Fig. 14a), rectangular (Fig. 14b), or formed to meet a specific shape such as the cam coil (Fig. 14c). Pancake coils (Fig. 14d) are generally utilized when it is necessary to heat from one side only or where it is not possible to surround the part. Spiral coils (Fig. 14e) are generally used for heating bevel gears or tapered punches. Internal bores can be heated in some cases with multiturn inductors (Fig. 14f). It is important to note that, with the exception of the pancake and internal coils, the heated part is always in the center of the flux field.

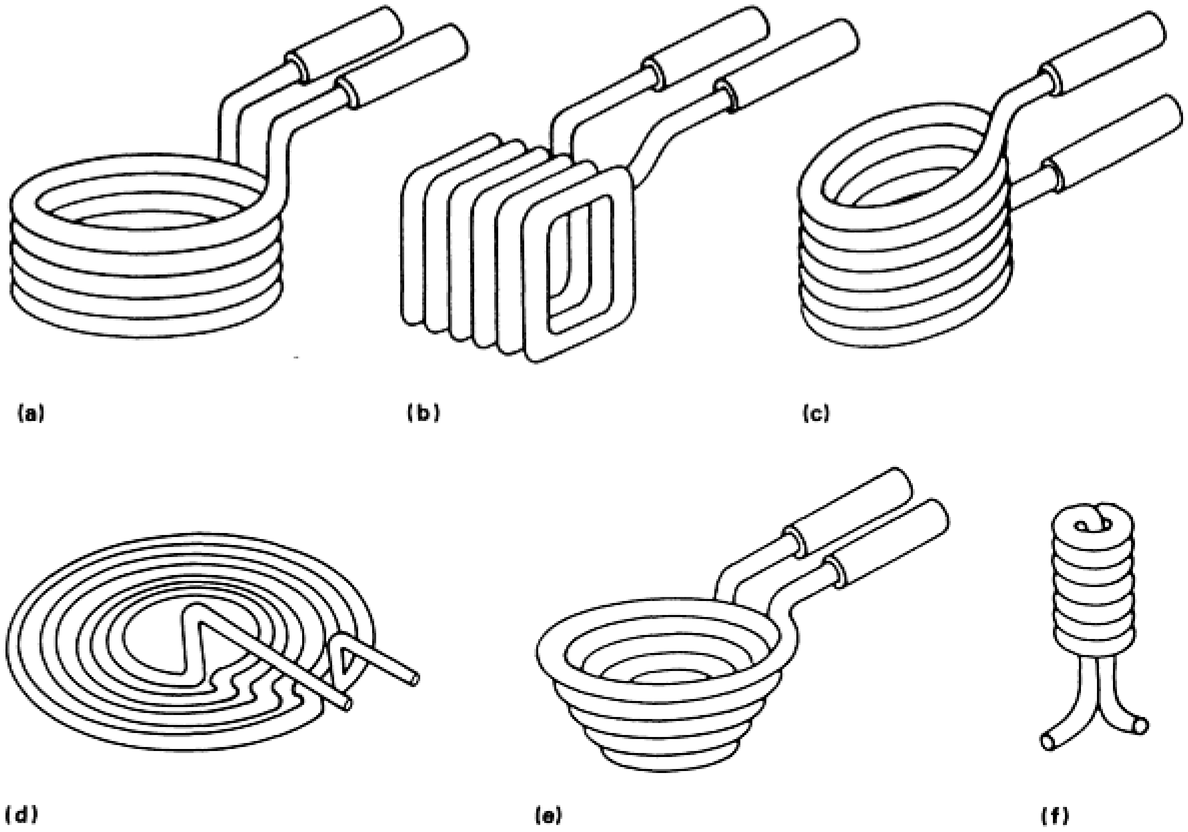

Fig. 14 Multiturn coils designed for heating parts of various shapes. (a) Round. (b) Rectangular. (c) Formed. (d) Pancake. (e) Spiral-helical. (f) Internal

Regardless of the final part contour, the most efficient coils are essentially modifications of the standard, round coil. A conveyor or channel coil, for example, can be looked at as a rectangular coil whose ends are bent to form "bridges" in order to permit parts to pass through on a continuous basis. The parts, however, always remain "inside" the channels where the flux is concentrated. Figure 15 illustrates similar situations in which the areas to be hardened are beside the center of the coil turns and thus are kept in the area of heaviest flux.

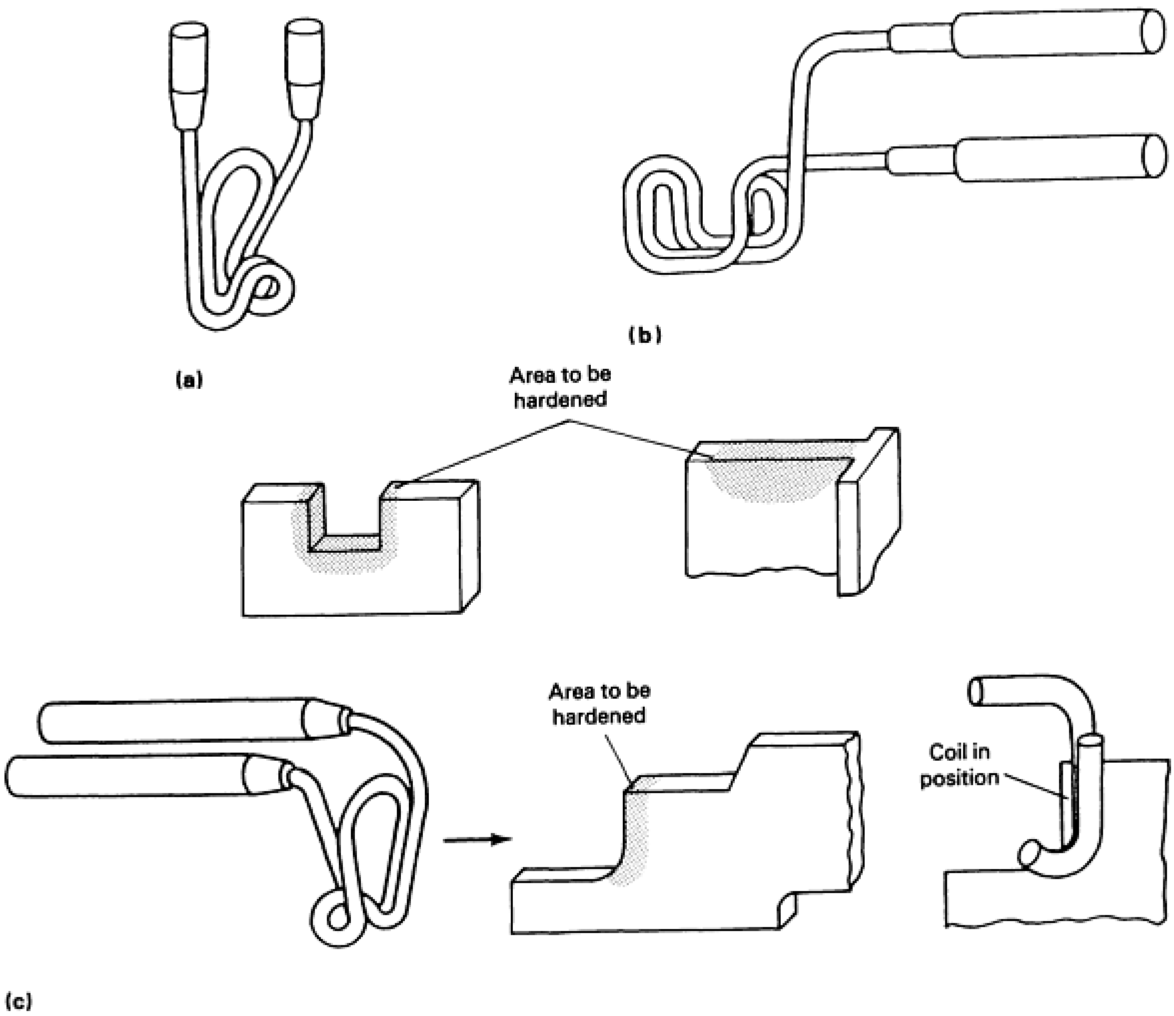

Fig. 15 Coil modifications for localized heating of three different parts

Internal Coils. Heating of internal bores, whether for hardening, tempering, or shrink fitting, is one of the major problems most commonly confronted. For all practical purposes, a bore with an approximately 10 mm (0.45 in.) internal diameter is the smallest that can be heated with a 450-kHz power supply. At 10 kHz, the practical minimum inside diameter is 25 mm (1 in.).

Tubing for internal coils should be made as thin as possible, and the bore should be located as close to the surface of the coil as is feasible. Because the current in the coil travels on the inside of the inductor, the true coupling of the maximum flux is from the inside diameter of the coil to the bore of the part. Thus, the conductor cross section should be minimal, and the distance from the coil outside diameter to the part (at 450 kHz) should approach about 1.5 mm (0.062 in.).

Internal coils, of necessity, utilize very small tubing or require restricted cooling paths. Further, due to their comparatively low efficiency, they may need very high generator power to produce shallow heating depths. Because of the high currents utilized during the heating cycle as well as the heat radiated from the workpiece surface, more cooling than can be obtained using the normal coil water supply is required here. It is best to provide a separate, high-pressure water supply for the coil to achieve a satisfactory flow rate.

Coil Characterization

Because magnetic flux tends to concentrate toward the center of the length of a solenoid work coil, the heating rate produced in this area is generally greater than that produced toward the ends. Further, if the part being heated is long, conduction and radiation remove heat from the ends at a greater rate. To achieve uniform heating along the part length,

the coil must thus be modified to provide better uniformity. The technique of adjusting the coil turns, spacing, or coupling with the workpiece to achieve a uniform heating pattern is known as coil characterization.

There are several ways to modify the flux field. The coil can be decoupled in its center, increasing the distance from the part and reducing the flux in this area. Secondly, and more commonly, the number of turns in the center (turn density) can be reduced, producing the same effect. A similar approach--altering a solid single-turn inductor by increasing its bore diameter at the center--achieves the same result. Each of these techniques is described and illustrated in this section.

In Fig. 16(a), the coil turns have been modified to produce an even heating pattern on a tapered shaft. The closer turn spacing toward the end compensates for the decrease in coupling caused by the taper. This technique also permits "through the coil" loading or unloading to facilitate fixturing. A similar requirement in the heat treatment of a bevel gear is shown in Fig. 16(b). Here, because of the greater part taper, a spiral-helical coil is used. With a pancake coil, decoupling of the center turns provides a similar approach for uniformity.

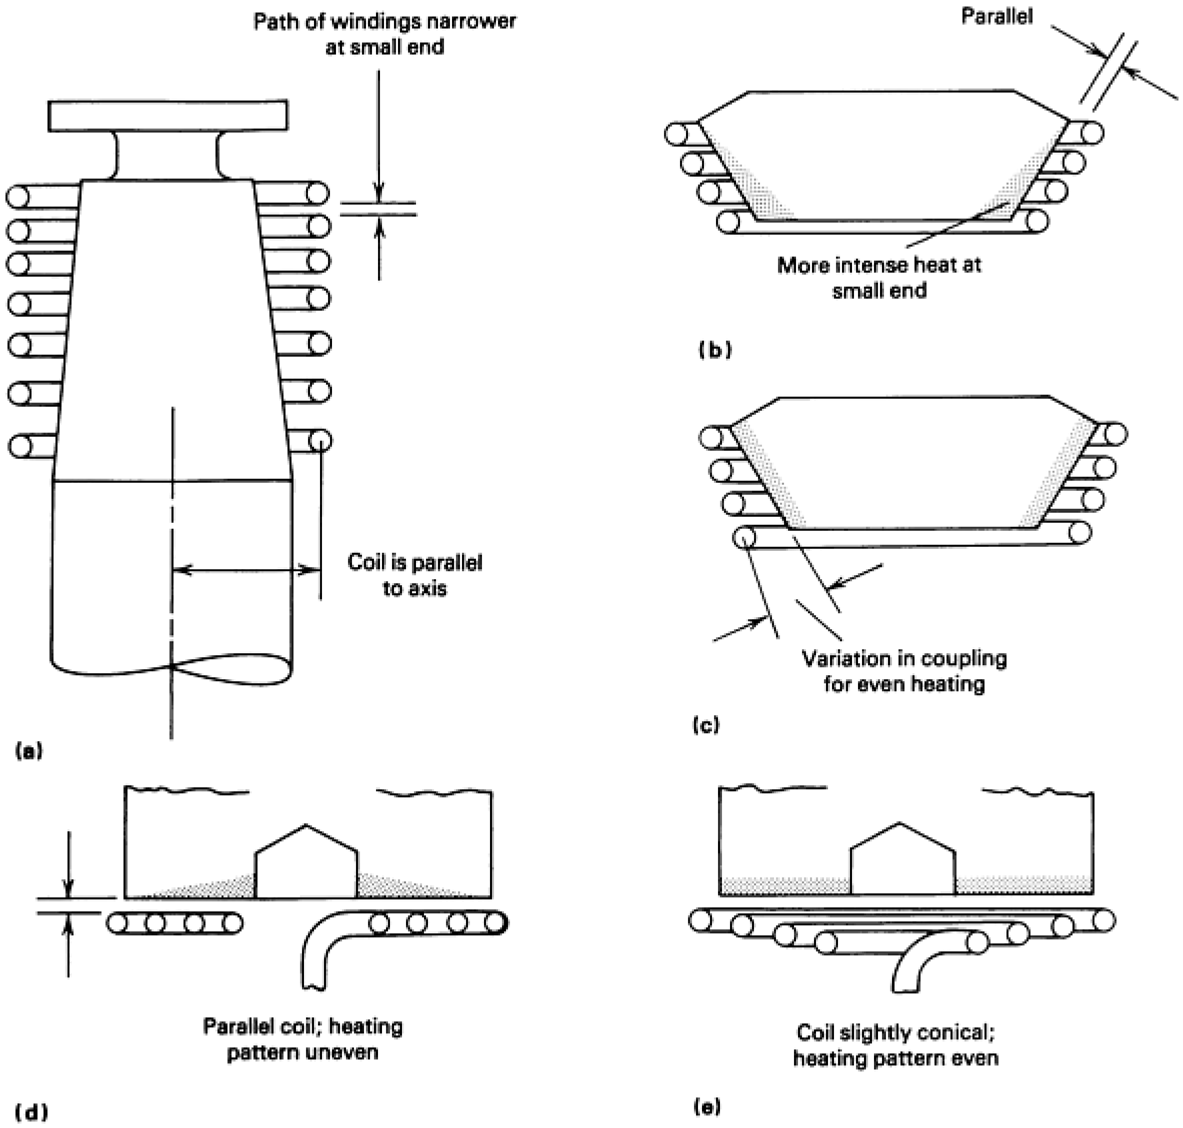

Fig. 16 Adjustment (coil characterization) of induction heating patterns for several parts by varying the coupling distance or turn spacing

Selection of Multiturn versus Single-Turn Coils. Heating-pattern uniformity requirements and workpiece length are the two main considerations with regard to the selection of a multiturn versus a single-turn induction coil. A fine-pitch, multiturn coil, which is closely coupled to the workpiece develops a very uniform heating pattern. Similar uniformity can be achieved by opening up the coupling between the part and the coil so that the magnetic flux pattern

intersecting the heated area is more uniform. However, this also decreases energy transfer. Where low heating rates are required, as in through heating for forging, this is acceptable. When high heating rates are needed, however, it is sometimes necessary to maintain close coupling. The pitch of the coil must be opened to prevent overloading of the generator.

Because the heating pattern is a mirror image of the coil, the high flux field adjacent to the coil turns will produce a spiral pattern on the part. This is called "barber poling" and can be eliminated by rotating the workpiece during heating. For most hardening operations, which are of short duration, rotational speeds producing not less than ten revolutions during the heating cycle should be used.

If part rotation is not feasible, heating uniformity can be increased by using flattened tubing, by putting an offset in the coil, or by attaching a liner to the coil. Flattened tubing should be placed so that its larger dimension is adjacent to the workpiece. The offsetting of coil turns (Fig. 17) provides an even horizontal heating pattern. Offsetting is most easily accomplished by annealing the coil after winding and pressing it between two boards in a vise. A coil liner is a sheet of copper that is soldered or brazed to the inside face of the coil. This liner expands the area over which the current travels. Thus, a wide field per turn can be created. The height (that is, axial length) of this field can be modified to suit the application by controlling the dimensions of the liner.

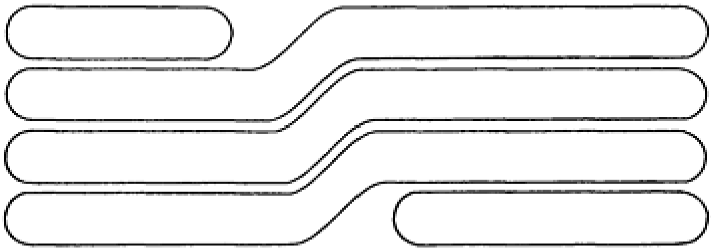

Fig. 17 Induction coil with an offset used to provide heating uniformity

When the length of the coil exceeds four to eight times its diameter, uniform heating at high power densities becomes difficult. In these instances, scanning the part with either a single-turn or multiturn coil is usually preferable. Multiturn coils generally improve the efficiency, and therefore the scanning rate, when a power source of a given rating is used. Single-turn coils are also effective for heating of bands which are narrow with respect to the part diameter, particularly for ferrous materials.

The relationship between diameter and optimum height (that is, axial thickness) of a single-turn coil varies somewhat with size. A small coil can be made with a height equal to its diameter because the current is concentrated in a comparatively small area. With a larger coil, the height should not exceed one-half the diameter. As the coil opening increases, the ratio is reduced--that is, a 50 mm (2 in.) inside diameter coil should have a 19 mm (0.75 in.) maximum height, and a 100 mm (4 in.) inside diameter coil should have a 25 mm (1.0 in.) height.

Single-Shot versus Scanning Techniques. When only one part at a time is placed in the coil and heated, the process is referred to as a *single-shot* process. Although handling of parts and conversion of the system for treatment of parts of different sizes are easy with this arrangement, such systems frequently are not economical to operate because the induction generator is not operated continuously at its rated power output. This type of system is not commonly used for long-time heating for through-heating, but it can be useful in surface hardening of gears (see the discussion of Fig. 48 later in this article). Modifications of single-shot techniques may also be employed for preferential hardening of only certain portions of gear teeth, such as tooth tips or flank regions.

The other class of technique, which allows high output in production environments (particularly for through-heating applications), is referred to as *induction scanning.* In this method, the workpiece is moved through a solenoid coil. Alternatively, a short coil may be moved along the workpiece length once (or several times), a common procedure when the workpiece is large and not easily moved. In this manner, the generator is operated continuously and, if its power output is low, smaller areas can still be heat treated, leading to progressive processing of the part.

For continuous or scan heat treating, the heating time is a function of scan rate so it must be accurately controlled through the drive system. Speed of travel may be sensed through a tachometer feedback system or some other sensing means so power can be adjusted to produce a desired heating result at varying speeds. Likewise, in continuous processing lines, material size (diameter, width, and so forth) can be sensed and the output power adjusted to suit the product. These are all possibilities and the response to changes by external control is rapid because as an electromagnetic process, induction heating has almost zero time lag and changes take place immediately within the product rather than at the surface.

Coupling distance refers to the space between the coil conductors and the workpiece, and the amount of this gap influences the degree of coupling and flux leakage (flux which does not thread through the workpiece). Although the coupling distance should be as small as possible to reduce flux leakage, the air gap dimensions are often dictated by process conditions, material handling requirements, and perhaps mechanical clearance for the electrical and/or thermal insulation of the coil.

Frequency is a major process condition that influences coupling distance. Because flux lines tend to stay closer to the coil conductor at higher frequencies, a larger air gap becomes more critical and less tolerable when frequency is increased. Coil current (and thus applied power) is also related to frequency. Coil currents at higher frequencies are lower, and thus coupling must be increased by a reduction in coupling distance or the use of flux shapers. With low and medium frequencies, coil currents are considerably higher, which thus allows a larger air gap and decreased coupling.

Preferred coupling distance also depends on the type of heating (single-shot or scanning) and the type of material (ferrous or nonferrous). In static surface heating, in which the part can be rotated but is not moved through the coil, a coupling distance of 1.5 mm (0.060 in.) from part to coil is recommended. For progressive heating or scanning, a coupling distance of 2 mm (0.075 in.) is usually necessary to allow for variations in workpiece straightness. For through heating of magnetic materials, multiturn inductors and slow power transfer are utilized. Coupling distances can be looser in these cases--on the order of 6.5 to 9.5 mm (0.25 to 0.38 in.). For nonferrous materials, coupling should be somewhat closer, usually between 1.5 and 3 mm (0.06 and 0.12 in.).

Coupling can also be influenced by the insulation around the coil. Heating coils used to austenitize tubulars in a continuous quench and temper operation, for example, are exposed to radiated heat from a high-temperature load for long periods of time and may serve better with thermal insulation at the hot face. This will add to the electrical gap because air space is still needed to accommodate expansion and distortion of the load, and still allow free movement. Hot face thermal insulation is used in coils up to about 3 kHz where sufficient electrical gap can be tolerated. More gap can be tolerated at lower frequencies, such as in the through heating of billet stock (prior to hot working). In this low-frequency application, coupling distance must be increased significantly because thick refractory materials, as well as electrical insulation, must be incorporated into the inductor design. In most cases, the distance increases with the diameter of the billet, typical values being 19, 32, and 45 mm (0.75, 1.25, and 1.75 in.) for billet-stock diameters of approximately 38, 100, and 150 mm (1.5, 4, and 6 in.), respectively.

To secure consistent results, constant coupling is necessary in induction hardening. For a given part and coil, the coupling will be determined primarily by the ability of the fixture to position the part consistently to provide a constant air gap between the coil and the part. Some variation in coupling can be tolerated when the inductor completely surrounds the workpiece by one or more turns. For face heating with a pancake-type coil or modifications thereof, the coupling is critical, and should be maintained within 0.4 mm ($\frac{1}{64}$ in.) if a highly restricted hardness pattern is required.

Effects of Part Irregularities on Heating Patterns. With all coils, flux patterns are affected by changes in the cross section or mass of the part. As shown in Fig. 18, when the coil extends over the end of a shaftlike part, a deeper pattern is produced on the end. To reduce this effect, the coil must be brought to a point even with or slightly lower than the end of the shaft. The same condition exists in heating of a disk or a wheel. The depth of heating will be greater at the ends than in the middle if the coil overlaps the part. The coil can be shortened, or the diameter at the ends of the coil can be made greater than at the middle, thereby reducing the coupling at the former location.

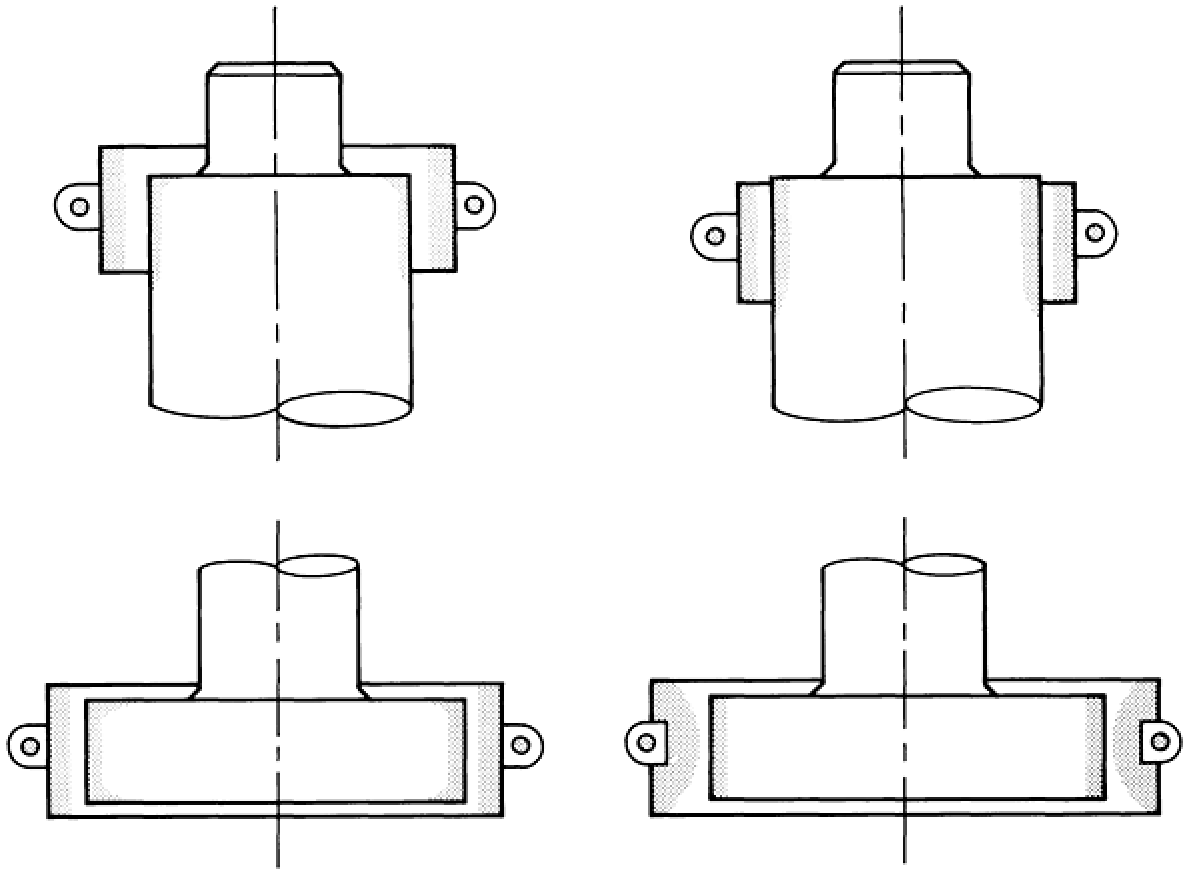

Fig. 18 Effect of coil placement on the heating pattern at the end of a workpiece. When the coil overlaps the edge (left), overheating will occur on the end surface. Coil placement should be slightly below the edge (right) for a more uniform heating pattern.

Just as flux tends to couple heat to a greater depth at the end of a shaft, it will do the same at holes, long slots, or projections (Fig. 19). If the part contains a circular hole, an additional eddy-current path is produced which will cause heating at a rate considerably higher than that in the rest of the part. The addition of a copper slug to the hole can be used to effectively correct or eliminate this problem. The position of the slug (Fig. 20) can control the resultant heating pattern. In addition, the slug will minimize hole distortion if the part must be quenched following heating. For slotted parts heated with solenoid coils, the continuous current path is interrupted by the slot, and the current must then travel on the inside of the part to provide a closed circuit. This is the basis for concentrator coils, which are discussed below. It is of interest to note, however, that with the slot closed, the applied voltage of the work coil causes a higher current to flow. This is due to the fact that the resistive path, now around the periphery of the part, is considerably shorter. The increase in current then produces a considerably higher heating rate with the same coil.

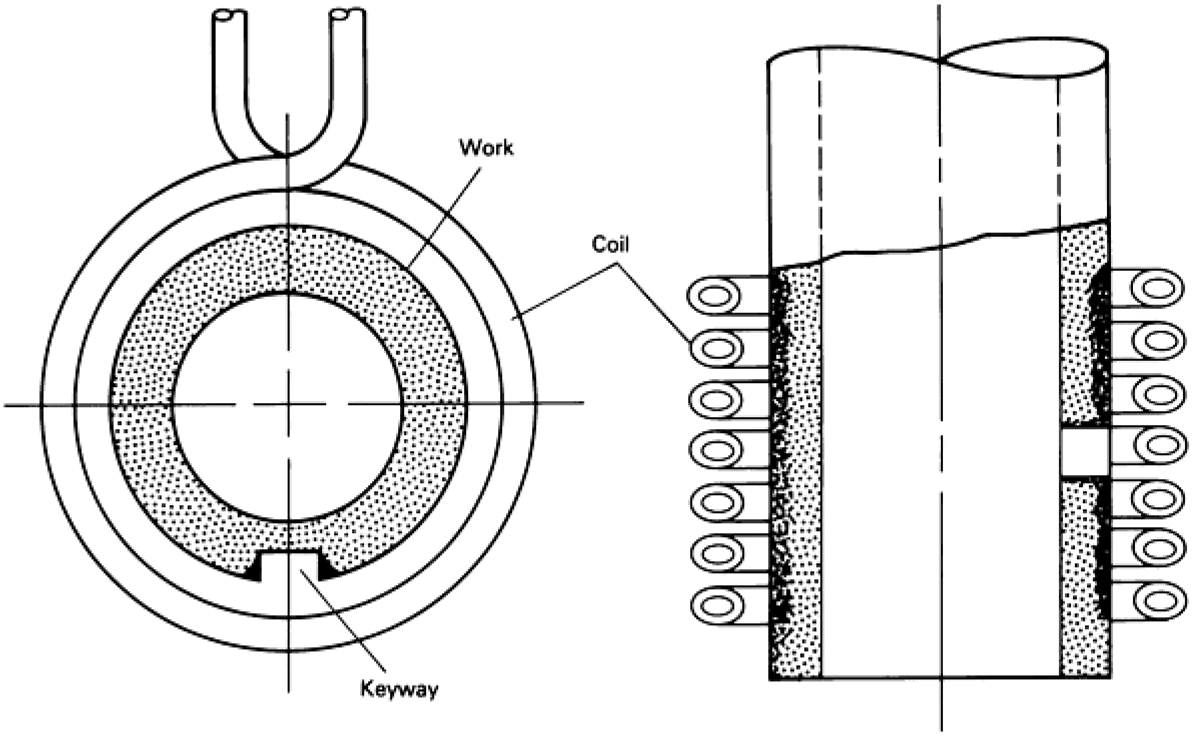

Fig. 19 Localized overheating of sharp corners, keyways, and holes most prevalent in high-frequency induction heating

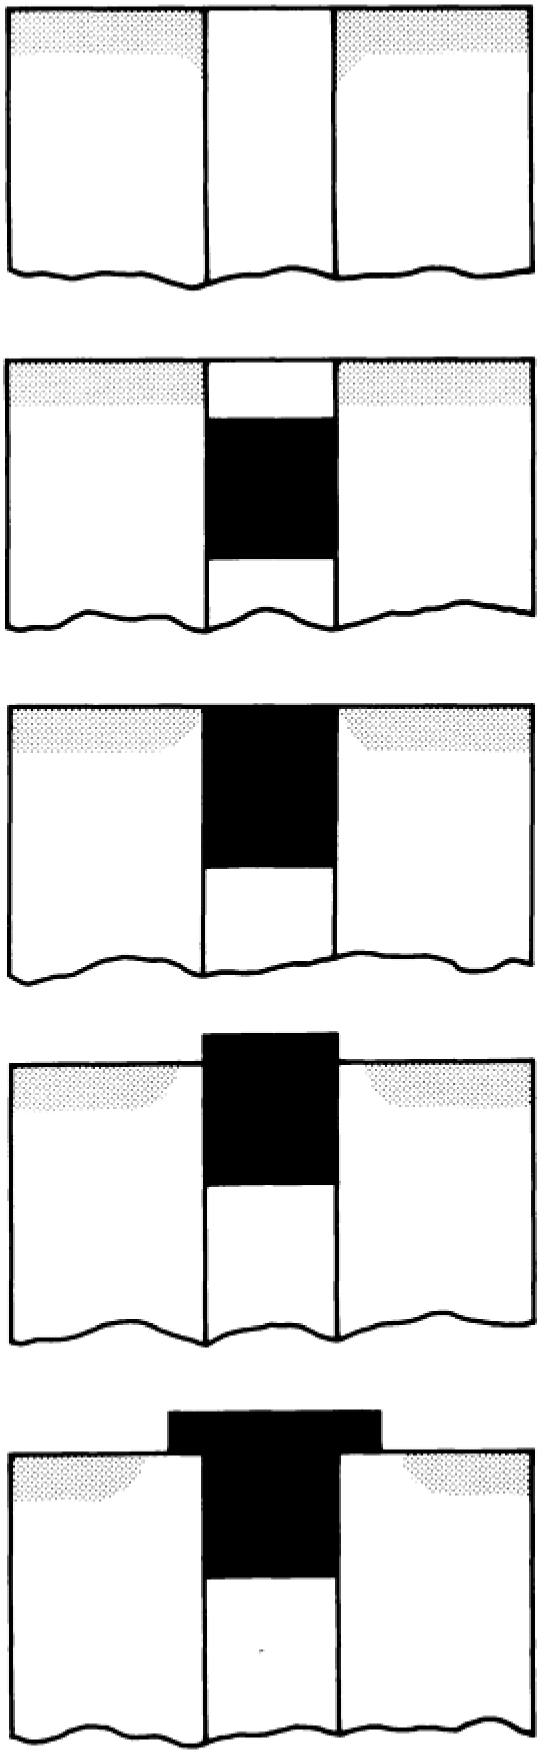

Fig. 20 Control of heating pattern at a hole through the use of copper slugs

Flux Diverters. When two separate regions of a workpiece are to be heated, but are close together (Fig. 21), it is possible that the magnetic fields of adjacent coil turns will overlap, causing the entire bar to be heated. To avoid this problem, successive turns can be wound in opposite directions. By this means, the intermediate fields will cancel, and the fields that remain will be restricted. It should be noted that, as shown in Fig. 21, lead placement is critical. Having the return inductor spaced far from the coil leads would add unneeded losses to the system.

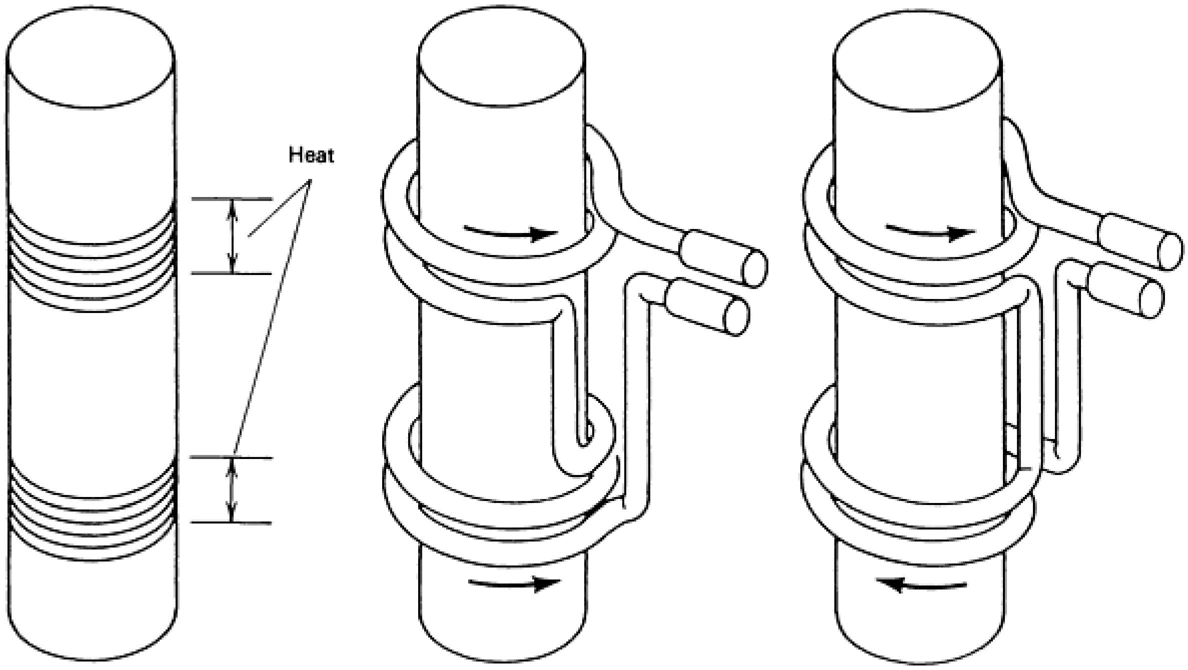

Fig. 21 Control of heating patterns in two different regions of a workpiece by winding the turns in opposite direction

Another technique that can be utilized in the above circumstances involves the construction of a shorted turn or "robber" placed between the active coil turns. In this case, the shorted loop acts as an easy alternative path for concentration of the excess flux, absorbing the stray field. It is therefore sometimes called a flux diverter. As for the active coil turns, the robber must be water cooled to dissipate its own heat (Fig. 22).

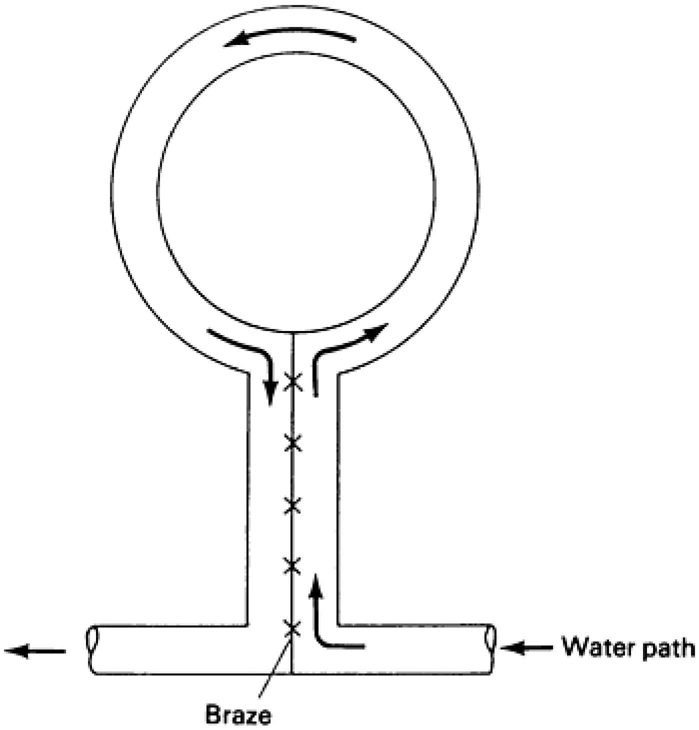

Fig. 22 Typical construction of a water-cooled flux robber

Flux robbers or flux diverters can also be used in fabricating test coils when it is desired to determine the optimum number of turns empirically. In these situations, a few additional turns are provided that can be added or removed as required.

Specialty Coils

As mentioned above, coil designs are based on the heating-pattern requirements of the application, the frequency, and the power-density requirements. In addition, the material-handling techniques to be used for production also determine to a large extent the coil to be used. If a part is to be inserted in a coil, moved on a conveyor, or pushed end to end, or if the coil/heat station combination is to move onto the part, the coil design must take the appropriate handling requirements into consideration. Accordingly, a variety of specialty coil designs have evolved for specific applications.

Master Work Coils and Coil Inserts. When production requirements necessitate small batches (as in job-shop applications) and a single-turn coil can be used, master work coils provide a simple, rapid means of changing coil diameters or shapes to match a variety of parts. In its basic form, a master work coil consists of copper tubing that provides both an electrical connection to the power supply and a water-cooled contact surface for connection to a coil insert. A typical design, shown in Fig. 23, consists of a copper tube that is bent into the form of a single-turn coil and soldered to a copper band which conforms to the slope of the coil insert and is recessed. Holes in the inserts which match tapped holes in the master coil securely clamp the inserts to the master coil, providing good transfer of electrical energy and heat removal. Inserts are machined from copper with a thickness that matches the required heating pattern and should be somewhat greater in thickness than the depth of the recess for easy removal. Special coil shapes are easily configured. It is important to note that, because of the less-than-optimal cooling technique, coil inserts are particularly well-adapted to processes requiring short heating times or those in which they are also cooled by the quenching medium.

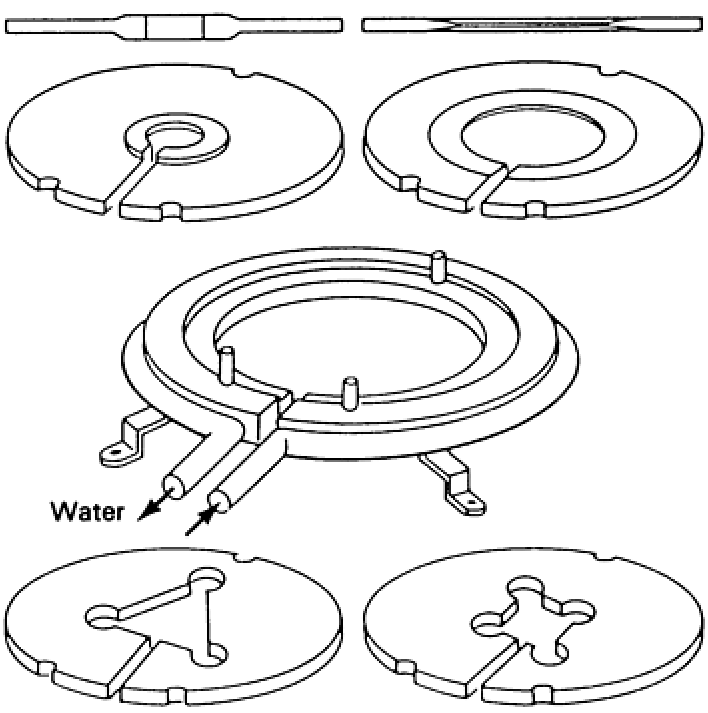

Fig. 23 The design of a master coil with interchangeable inserts

Coils for progressive hardening (scanning) are built using two techniques. The simpler of the two employs a simple single-turn or multiturn coil with a separate quench ring which can be mounted on the scanner (Fig. 24). For larger production runs, on the other hand, a double-chamber coil which incorporates both coil cooling and quenching capabilities is often the preferred choice. The scanning inductor shown in Fig. 24(b) is typical of the latter type of design. Cooling water flows through the upper, or inductor, chamber to keep the copper resistivity low. The quenchant is sprayed from perforations in the beveled face onto the workpiece as it exits from the inductor. The beveled face normally is at an angle of 30 ° to the vertical so that there is some soaking time between the end of induction heating and the quenching operation. This delay time helps to increase uniformity. Proper choice of the spray direction also reduces the amount of fluid runback on the shaft, which could cause variation in bar temperature and result in uneven hardness. Well-directed quench spray holes are required inasmuch as "barber poling" can occur due to erratic or misdirected quenchant that precools the part ahead of the main quench stream.

Split coils are generally utilized as a last resort for applications in which it is difficult to provide a high enough power density to the area to be heated without very close coupling and where part insertion or removal would then become impossible. Typical examples of such situations include hardening of journals and shoulders in crankshafts. In these cases, the split-coil design would also include the ability to quench through the face of the inductor.

It should be noted that with a split inductor good surface-to-surface contact must be made between the faces of the hinged and fixed portions of the coil. Generally, these surfaces are faced with silver or special alloy contacts that are matched to provide good surface contact. Clamps are used to ensure closure during heating. Often, high currents at high frequency pass through this interface, and the life of the contact is generally limited to both wear and arcing. Figure 25 illustrates a hinged split inductor.

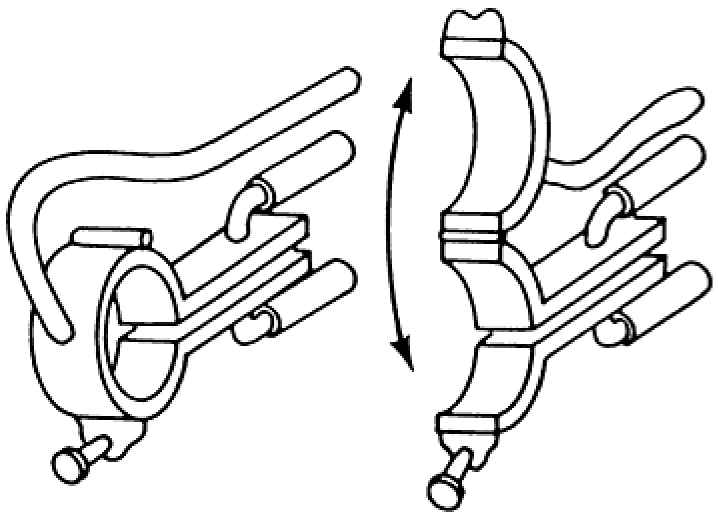

Fig. 25 A split inductor used for heating crankshaft journals

Coolant for the coil chamber of a split inductor is carried by flexible hoses that bypass the hinge so that excessive heating does not occur in the movable section during the cycle. The quench chamber is fed by a separate hose arrangement. The face of the quench chamber is closest to the work during heating and therefore carries most of the current. Accordingly, it must be sufficiently thick to preclude either melting or distortion during the heating cycle.

With split coils it is also frequently necessary to provide some means of locating the part in the coil to maintain the proper coupling distance. Ceramic pins or buttons are frequently secured to the face of the inductor. These pins contact the part during the heating cycle and establish rigid relative positioning between part and coil. However, they are subject to thermal shock during the heating and quenching cycles and suffer mechanical abuse as well. Therefore, they should be designed for simple replacement as required.

Butterfly Coils. One of the most difficult heating challenges is the creation of an even heating pattern at the end of a bar or shaft. Patterns developed with a pancake inductor produce a dead spot at the center due to field cancellation in this area.

The butterfly coil (Fig. 26), so named because of its appearance, utilizes two specially formed pancake coils. The current paths of the adjacent sides are aligned so that they are additive. The "wings" of the butterfly may be bent up to decouple their fields from the shaft, or if heat is required in this location, they may be coupled with the shaft itself. In winding this coil, it is important that all center turns be wound in the same direction so that they are additive. Further, only these turns should couple directly with the part to produce the desired pattern; part rotation is required to provide uniform heating on the end of the part.

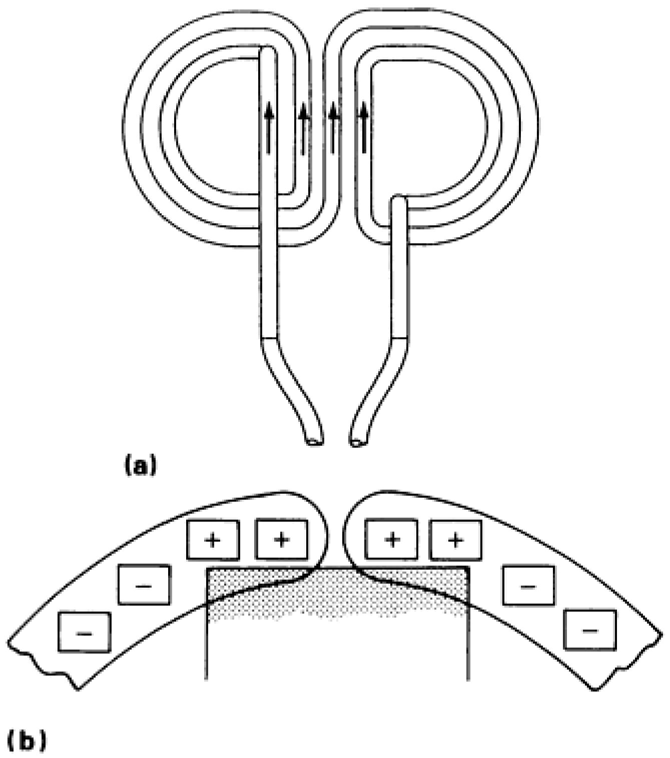

Fig. 26 Schematic of a butterfly coil. (a) Coil construction (arrows indicate reinforcing type of current flow in coil. (b) Coupling between the turns of the coil and the end of the workpiece to produce a uniform heating pattern

Split-Return Inductors. If a narrow band of heat is required and heating must be accomplished from one surface only as in weld-seam annealing, the split-return inductor offers distinct advantages (Fig. 27). With this design, the center runner of the work coil carries twice the current of each of the return legs. The pattern on the workpiece, being a mirror image of the coil, produces four times as much heat under the center leg as in each of the return loops. With proper balancing, the high-heat path can then be extremely narrow while the heat produced in each of the return legs is insufficient to affect the remainder of the part.

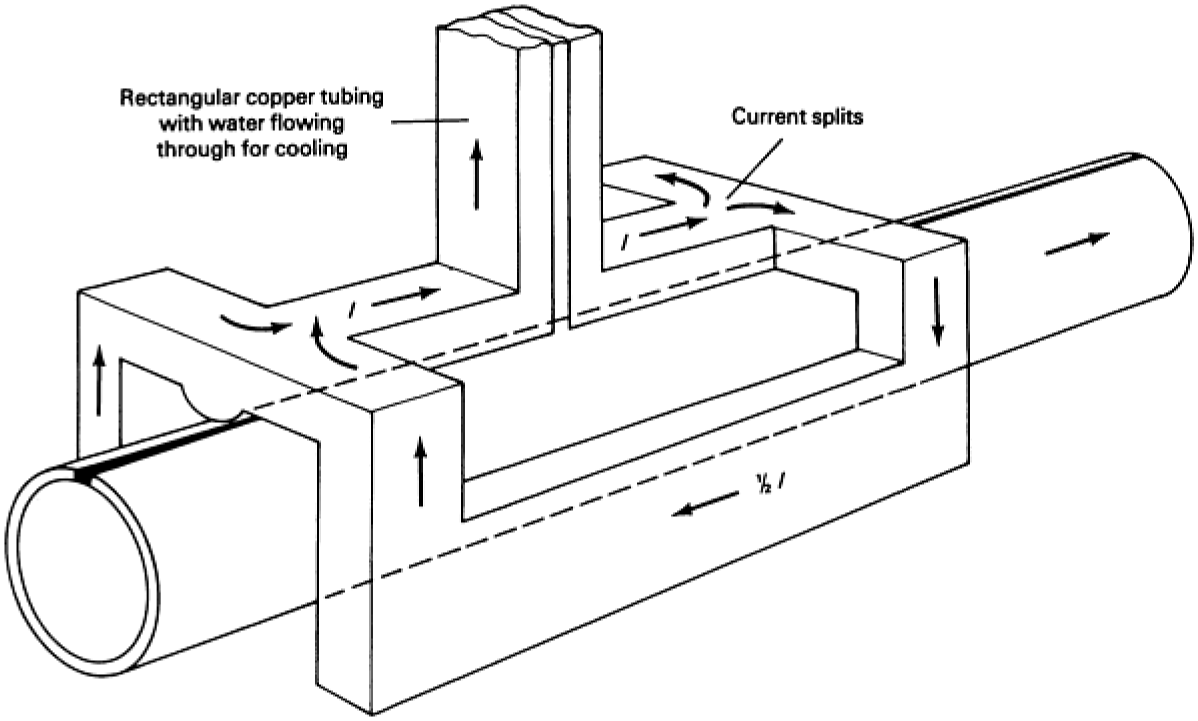

Fig. 27 Split-return coil for annealing of seam welds in pipe or tubing

Transverse-Flux Coils. In heating of parts that have a long longitudinal axis and a thin cross section, a circular coil wrapped around the workpiece produces a heating pattern (Fig. 28) that, due to coupling distances, is effective only at the edges. In transverse-flux heating, however, the coil is designed to set up a flux field which is perpendicular to the sheet or similar part. In this way, the path of the eddy currents is changed so that it is parallel to the major axis of the work. For example, in the manufacture of items such as hacksaw blades, the steel moves between the turns of the coil and the eddy-current path is a circular one across the flat of the blade. For heating of wide sheet materials, specially designed transverse-flux inductors have become available in recent years.

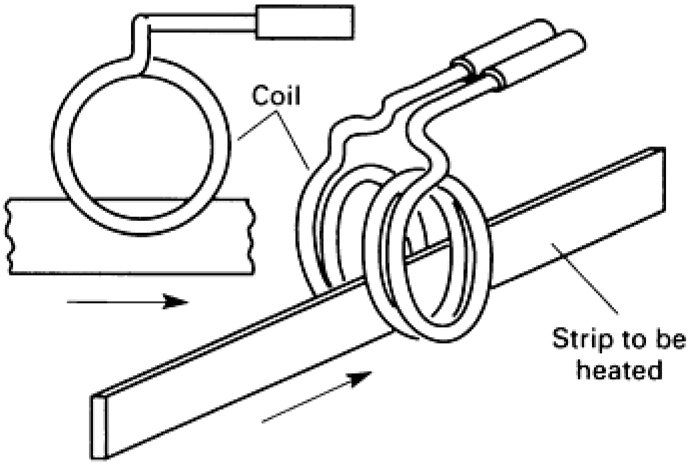

Fig. 28 Transverse-flux coil for heating thin sections

These inductors usually contain laminated iron cores with a series of windings along the length of the strip which induces a circulating current that flows across the width of the strip and returns on itself along the edges under adjacent pole faces. In this type of arrangement, coil sections are placed on both sides of the strip to force the magnetic flux to pass

transversely through the strip as opposed to the typical longitudinal flux pattern developed with a coil that encircles the strip.

Series/Parallel Coil Construction. It is sometimes desirable to have long work coils or coils with many turns connected in series. The current through each turn is identical and it is simple to balance the heating pattern. Furthermore, if an imbalance occurs in any one turn (for example, it is suddenly loaded more heavily), the other turns are affected equally. Thus, if a slow-down occurs in one location of a conveyor, the power along the whole line can be adjusted proportionally. In some situations, however, as the number of coil turns and resultant length increases, the voltage must also be increased to drive the current through the coil turns. This means that on long coils, the voltage between the workpiece and the coil can be extremely high, and arcing can occur. This may be a problem, for example, in the heating of continuous strip, in which speeds are high, and coils are therefore very long. In these situations, it becomes advantageous to use parallel coils, thereby reducing the applied voltage.

With parallel coils, the voltage required is limited to that needed to drive current through a single inductor. However, coil resistance and inductance in parallel inductors are such that extreme care must be taken to preclude all the current going through the inductor closest to the power supply.

The best method for parallel coil construction makes use of a wide bus arrangement. With identical coils mounted to the bus, this method permits rapid, simple replacement of individual sections as required, and fabrication of the individual sections is easily accomplished. A second technique which assures an even current distribution comprises the interwinding of several coils. An even current distribution is assured in that each coil receives its current from the same point in the bus.

Conveyor/Channel Coils. When power densities are low and heating cycles not extremely short, parts can be processed by means of a turntable or conveyor in a continuous or indexing mode. The coil must then be designed to permit easy entry and exit of the part. The simplest conveyor or channel coil used in these situations is a modification of the hairpin inductor. With the indexing technique, in which the part is at rest in the coil during the heating cycle, the ends of the hairpin can be decoupled to prevent overheating of the ends. The raised portions or bridges also facilitate the passage of the part through the coil. When a wide heat zone is to be produced on the part, coupling over a greater area can be effected through the addition of a liner to the coil turn, or more ampere turns can also be produced with a multiturn channel inductor. Channel coil liners may also be configured to produce specialized heat patterns where greater heat densities are required in specific areas.

During design of heating operations utilizing channel coils, there is a "fill factor" which must be considered from an efficiency standpoint. The unused portion of the coil appears as lead losses. Therefore, parts must be as close as possible to each other, without touching, to utilize the full capabilities of the inductor. Another important consideration when using a channel coil is the fact that those areas of the workpiece closest to the coil receive the greatest portion of the flux and therefore heat the fastest. If conduction through the part is slow, the part should be rotated while passing through the coil. Sufficient time (in an indexing conveyor or turntable) or speed variation (in a continuous motion device) must be provided to allow heat uniformity to occur in part areas furthest from the coil turns.

Flux Concentrators. If a ferromagnetic material with incomplete current paths is introduced into the coil field, it will provide a low-reluctance path for the flux (without dissipating energy). This low-reluctance path reduces the stray flux and tends to gather flux lines, thereby concentrating the field. This use of flux concentrators improves the load power factor and may thus reduce coil current requirements.

Flux concentrators can play a very important role in enhancing the induction heating process when they are properly applied in and around the induction coil. The major uses of flux concentrators are:

- Improve heating at coil ends
- Improve heating effect of internal coils
- Improve the heating effect of proximity or stray field coils
- Improve the general efficiency of any coil

For example, flux concentrators applied at coil ends will tend to make the heat pattern more uniform along the coil length. The performance from coils used to heat the inside or bore of a part also can be improved by placing the flux concentrator

or core inside the coil. Transverse flux coils can heat more effectively when a flux concentrator is placed on the face opposite the heating face.

The material chosen for a flux concentrator depends on the applied frequency, the kind of service, and the degree of exposure to radiated heat. Commonly used materials include stacks of silicon-steel laminations used at frequencies below 10 kHz or ferrites for higher frequencies, including those in the RF range. Figure 29 shows the effect of a flux concentrator on heating a shaft.

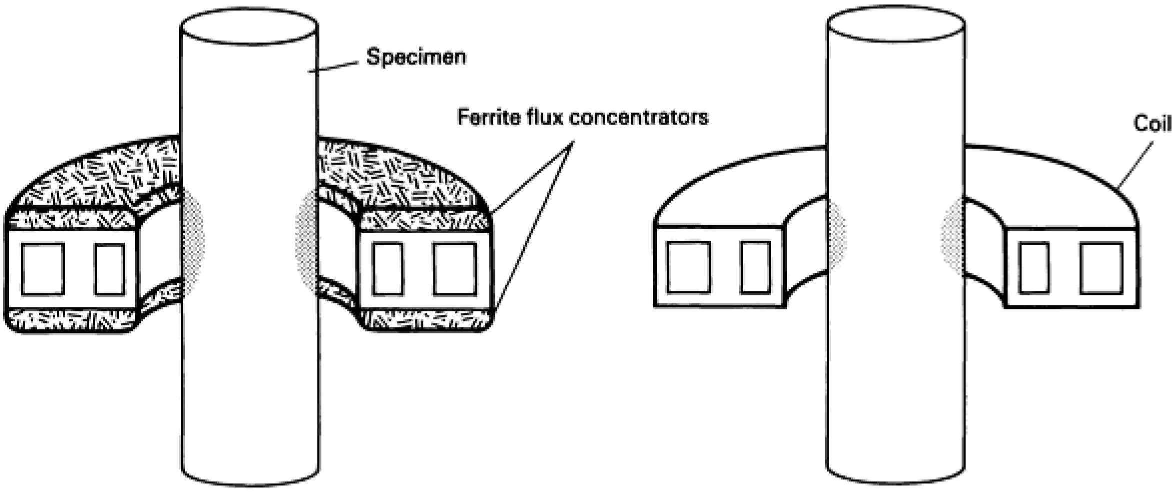

Fig. 29 The effect of using a flux concentrator on the heating of a shaft

Coil Construction and Cooling

Coil Construction. The most widely used material for coil construction is oxygen-free high-conductivity (OFHC) copper. Many high-frequency coils are made of standard round refrigeration tubing (which can be flattened) or special drawn tubing with square and rectangular cross sections. The coil conductor should be thicker as frequency is decreased, because the skin effect is less pronounced. To minimize coil losses, the current-carrying wall should not be much less than the depth of current penetration in copper. The various types of coil conductors used for lower frequencies include:

- Heavy-wall copper tubing
- Copper bar brazed to tubing
- Specially extruded tubing with a heavier wall at the hot face

Machined inductor coils are used primarily as single-turn inductors, and special heavy-wall shapes are primarily for 60 Hz coils. For brazed joints, both phosphorus copper and silver brazing alloys are used, the latter being preferred for electrical conducting joints and ones where ductility is needed.

Mechanical Design Considerations. When electrical currents travel in adjacent conductors, the two conductors are either attracted or repelled by a force that is proportional to the square of current flowing. Currents traveling in opposite directions cause a repelling force between two adjacent conductors, whereas two currents traveling in the same direction tend to attract the two conductors. These forces, which occur at coil turns and in the coil leads or bus, must be considered in coil design.

At high frequencies and at comparatively low currents (except for high power densities), the forces are minimal and free-standing tubing may be used. Coil turns may be supported with studs and brazed to each turn and then fastened to an insulating board to reduce the potential for cyclic movement or to maintain turns spacing.

Medium-frequency coils, which experience greater electromechanical forces, require more attention to the coil support system and to the integrity of brazed joints. Again, the forces, which are a function of current, may not be of real concern at low power levels. Because the repelling forces relax when a coil is deenergized, cyclical applications of power may

tend to work harden braze metal or even the basic copper and can cause fatigue failure in parts of the coil, particularly where stresses are concentrated.

Coils energized by line frequency or from triplers (180/150 Hz) require attention to details of how the turns are supported and how they will resist damage from low-frequency vibration. Brazed or welded studs and insulating board of heavy construction may be used for coils with spaced turns. Close wound coils can be constricted by using mica or melamine insulating rings between turns of rectangular copper tubing with the entire assembly clamped between end boards of hard insulating material with nonmagnetic metal tie rods and clamped with pressure maintained through bellville washers. Slotted nonmagnetic metal endplates can back up the insulating board. Another possibility is to cast the entire assembly in refractory or epoxy, but a great deal of attention should be paid to the materials used and the technique.

Electrical Characteristics. Power can be conveyed to induction heating coils by copper bus bars, tubing, flexible stranded cable or coaxial cable. Some inductance exists in all power leads and it produces an inductive reactance (X_L) expressed by the following equation:

$$X_L = 2\pi fL \qquad \textbf{(Eq 3)}$$

where f is frequency in Hz, and L is the inductance in henrys. Inductive reactance (X_L) can be offset by capacitive reactance (X_C), but the energy from capacitors increases the circulating current and the I^2R losses in the system, so it is desirable to minimize unnecessary inductance anywhere in the system, particularly in leads that carry high current at low voltages. This is especially true for high-frequency systems for low-voltage coils. Ideally, the voltage drop in the leads due to X_L will be a small fraction of the voltage across the heating coil or inductor.

The inductance of the leads is a function of the electrical gap between conductors, and in general it is best to minimize the space between them (Fig. 30) and support them to increase the area of opposing faces. This is one reason for using wide rectangular tubing, flat face-to-face copper bus, or coaxial cable. When insulated varnished cambric or other insulated cable is used for conductors at medium to high frequencies, extra flexible fine strand cable should be used and taped every foot to maintain a low inductance close configuration. This array can be supported in nonconductive or open-loop metal hangers or laid in an expanded metal aluminum trough. Ratings for open air operation for some of the standard cable sizes at 1, 3, and 10 kHz are given in Table 3.

(a) The power-carrying ability indicated is for motor-generator sets, typically from the generator to the control and/or the heat station. For most solid state converters the recommended power levels will be about 25% less because they operate with a slightly leading power factor and some additional reactive current must be carried. Manufacturers' recommendations should be followed.

(b) Cable sizes are designated by American Wire Gage (AWG) number where applicable or by actual size in thousands of circular mils (MCM). The size listed is the smallest cable that will carry the rated current. This cable is varnished cambric insulated, single braid, and standard strand. The maximum length listed was calculated for the following conditions: The voltage across the condensers is ≤ 1.1 times the generator terminal voltage, and the generator output power factor is 0.9 leading.

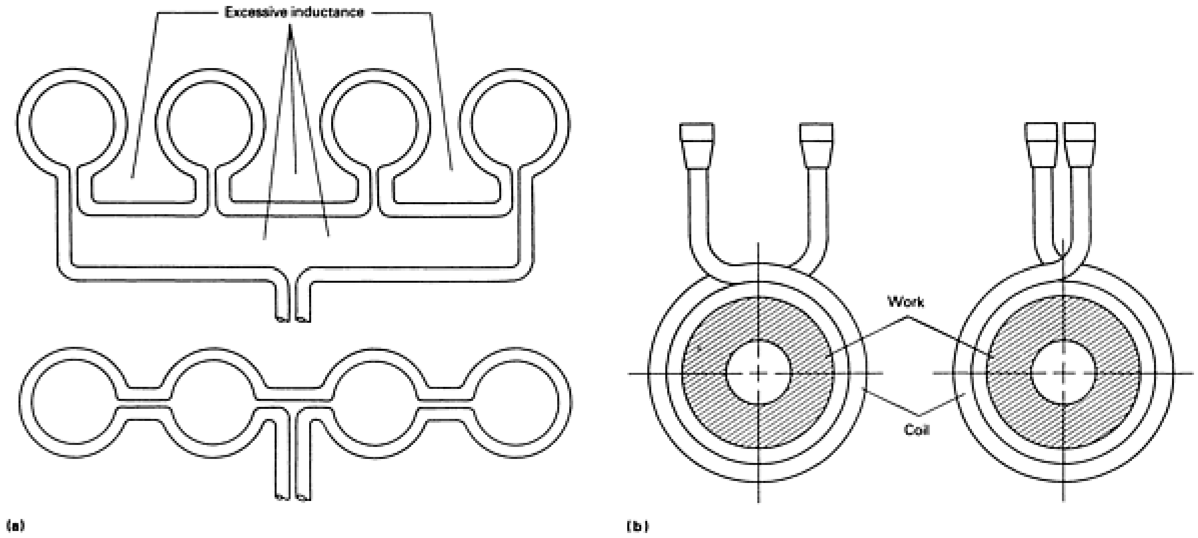

Fig. 30 Effect of coil-lead spacing on inductance of (a) multiplace inductors and (b) a single-turn coil. In both cases, closer spacing of conductors reduces lead inductance and thus power losses.

Water cooling, as described below, can be judiciously applied when needed, and the amount of air space or electrical insulating material between conductors must be appropriate for the voltages applied. In open air systems, the conductors should be smooth and clean and protected from dirt, water, and metal particles. Personnel should also be protected from exposure to any harmful voltages by covers and warning signs.

Coil Insulation. When heating coils are exposed to a high-temperature load for long periods of time (such as those used to austenitize tubulars in continuous quench-and-temper operations), the heating coils may provide better service and be more efficient with thermal insulation at the hot face. Electrically, this insulation is the same as air, and any added electrical gap will increase the coil current required to heat the metal, as well as reduce coupling efficiency. Hot-face thermal insulation is primarily used in coils up to about 10 kHz where the added electrical gap can be tolerated. Higher frequency coils may use a liner, but the thickness should be limited. The basic kinds of coil insulation are:

- Entire coil potted in a castable refractory
- Self-supporting coil with cast-in liner, a precast liner, or a precast liner with a split stainless steel or Inconel sleeve

Coil Cooling. Although most induction heating coils are water cooled, some low-temperature, low-kVA heating coils will function with convection or forced air cooling. Air cooling has been used on the following:

- Line-frequency core heaters, which have low I^2R losses because of their high power factor and low reactive current
- Solenoid coils used for low-temperature heating of steel and cast iron

The suitability of air or water cooling depends on whether the copper conductors are kept cool enough to maintain their strength. Coil cooling is also needed to minimize electrical resistance of the coil and to reduce the level of oxidation.

Cooling water passages should be as close as possible to the current-carrying face, which is usually adjacent to the work. Copper tubing can act both as conductor and cooling passage, or it may be brazed to solid copper body to simply act as the cooling passage. As a cooling passage, it should not alter the heat pattern. As a conductor, it should provide enough copper to carry current at the applied frequency.

Water pressure should be adequate to provide full flow without voids or steam pockets forming; typically gage pressures of 140 to 415 kPa (20 to 60 psig) are used. Much higher pressures up to 1035 kPa (150 psig) have been used to cool coils with very small water passages such as those used to heat small spaces such as small bores. It is advisable to use a minimum but adequate pressure.

If hard water is used for coil cooling and the temperature exceeds 55 °C (130 °F), some scale may build up in the cooling passages. If not cleaned out periodically, the water passages may become coated and/or restricted, in which case, cooling is impaired and overheating of the work coil or other water-cooled components may occur. Cleaning with an acid must be done carefully because overexposure to acid may produce leaks, particularly where the copper has been cold worked.

Impedance Matching

In maximizing the delivery of power from the power supply to the load (coil-work-piece) circuit, it is necessary to match or tune the load impedance with the output impedance of the power supply. This may require the use of a tank circuit either in parallel or in series with the inductor coil. The parallel circuit is most commonly used because it permits remote mounting of the tank circuit (heat station) with minimum losses in the transmission lines. The transmission voltage used is limited to the power supply voltage, unless a transformer is applied at the power source. Because the inductance of the transmission line becomes part of the tank inductance in a series circuit, the distance from the power supply to the work coil is limited for reasons of efficiency.

The apparatus to electrically match the output impedance of the power supply with the load circuit can be built into the power supply or be housed in a separate cabinet called a heat station. Some power supplies (such as solid-state converters and spark-gap converters) have the ability to follow load changes which occur during a heating cycle, even when iron and steel pass through a magnetic transformation at the Curie temperature.

In contrast, the power from fixed-frequency sources (such as a motor-generator or a tripler) may decrease significantly because of radical changes in coil/part impedance when magnetic materials are heated above the Curie temperature. In the interest of maintaining a high level of power to the load, it may be necessary to retune the system as the load becomes nonmagnetic.

Tuning of Fixed-Frequency Systems. Line-frequency power supplies, frequency multipliers, and motor-generators each produce output power at a single specific frequency. In order to obtain maximum power from the work coil, it is important to provide a tank circuit tuned to that specific frequency whose impedance matches that of the power supply. A series reactance or a series capacitor may be used to drop the supply voltage for voltage matching, but transformers are preferable because standard units are available in a wide variety of frequencies.

The schematic diagrams in Fig. 31 show the circuitry for both a high-impedance system using an autotransformer and a low-impedance tank circuit using an isolation transformer. Both systems have tapped transformer windings to match coil impedance to generator impedance and some means of connecting capacitance, as required, to tune the system to resonance at or near the operating frequency of the power supply. Because the capacitors are connected incrementally, it is not always possible to tune the circuit close to the output frequency of a motor generator, and thus, full output power is not always achieved.

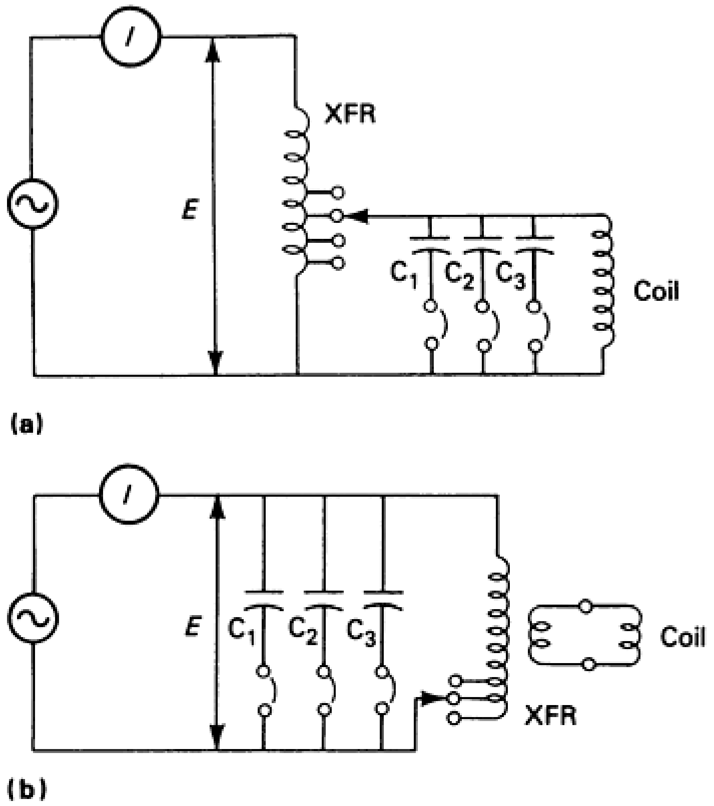

Fig. 31 Schematic circuit diagrams of low- to medium-frequency heat stations illustrating capacitor and transformer adjustments when using (a) an autotransformer for high-impedance induction coils and (b) an isolation transformer for low-impedance induction coils. Similar circuits are used in high-frequency systems (Fig. 9).

During the actual tuning operation, such as that for a motor-generator system, the field is slowly increased so that the meters begin to indicate. If the power factor is lagging, capacitance must be added in parallel to the tank circuit (assuming that a parallel tank circuit is used). If the power factor leads, capacitance might have to be removed. For set-up of a motor-generator and some solid-state converters, however, the tank circuit may be tuned to provide a slightly *leading* power factor. This helps to compensate for the internal inductive reactance and enables rated voltages to be established at the output terminals from the power supply. Operating with a slightly leading power factor also prevents exceeding the field-current rating when operating at rated voltage and power.

When the power factor has been corrected reasonably close to unity, power can be increased until either the voltage or the current reads the maximum permissible. Readings of all meters can then be taken. If the output voltage reaches a maximum before the current does, the coil voltage needs to be increased by reducing the primary-to-secondary ratio of the transformer. The ratio must be adjusted, or turns must be removed from the work coil based on the equation:

$$\text{Re}\,quired\ \text{turns} = \text{Present turns} \times \frac{\text{Amperes obtained at rated voltage}}{\text{Rated amperage}}$$

Should rated current be achieved before rated voltage, the primary-to-secondary ratio is too low. The ratio must be adjusted, or turns must be added to the work coil as follows:

$$\text{Re}\,quired\ \text{turns} = \text{Present turns} \times \frac{\text{Rated voltage}}{\text{Voltage obtained at rated amperage}}$$

When the work coil is modified, the circuit must be returned.

All fixed-frequency systems should be set up with the workpiece in the coil, because the impedance would differ dramatically if the part were not in place. Accordingly, balancing should be performed using short, low-power tests so that minimal heat is produced in the workpiece during setup and so that conditions for comparison therefore remain almost static. In tuning of a fixed-frequency system during progressive heating operations, readings and adjustments should be made with the part moving through the coil at its normal speed.

Tuning of Variable-Frequency Systems. Because the solid-state SCR-controlled power supplies generate frequencies determined by the tank circuit, these systems allow self-tuning. Nevertheless, it is first necessary to tune the system so the tank circuit is within the frequency band of the power supply. Once the tank is tuned to the frequency band of the supply, then the generator shifts frequency relative with changes in the tank circuit.

Transformers. As previously mentioned, transformers allow the change of output voltage from a power supply. Most transformers are water cooled. For frequencies up to about 10 to 25 kHz, the core is constructed of laminated silicon steel with lamination thickness ranging from 0.15 to 0.18 mm (0.006 to 0.007 in.) thick. For frequencies to 200 kHz, a ferrite core can be used. Above 200 kHz, no ferromagnetic core is used because significant losses can occur in ferrite at these higher frequencies.

Output transformers are only used when the output voltage of the supply differs from the voltage needed to energize the coil. At line frequencies (60 or 50 Hz) both air- and water-cooled transformers are used. At 180 or 150 Hz and above, water-cooled transformers are the norm. Tuning or resonating the load circuit can be achieved by maximizing the line or source current at a given voltage or by getting a close to unity indication on a reactive power (VAR) or power factor meter, if one is available. The object is to apply the desired power, which may be indicated by a kW meter at minimum voltage and minimum current.

An autotransformer (Fig. 31a) has a single winding, and it can be tapped to provide a variety of output voltages which are direct ratios of the turns and the primary voltage. This type of transformer is used where the primary/secondary turns ratio is no more than $2\frac{1}{2}$ to 1. It can be either water or air cooled depending upon frequency and power rating.

Isolated Winding Transformer. A typical two winding transformer can handle a wide range of ratios, well beyond the limited range of any autotransformer. The tapped variety (Fig. 31b) is a bit more expensive than the fixed ratio type, but it provides more load matching flexibility and is therefore more prevalent in commercial induction heating equipment. Taps can be either on the primary winding or the secondary winding, or both, but those in use with frequency converters almost invariably are tapped in the primary.

The typical medium- to high-frequency transformer uses a copper sheet wound as the secondary winding, mostly a single turn; some may be two or even three turns. Taps will be taken from the primary winding and brought to link-connected terminals. The windings are water cooled, and the core may have some water-cooled heat sinks stacked in the core. The high ratios are used to work into single-turn inductors or coils of only a very few turns, and ratios up to 32 to 1 are available in standard designs. Transformers in use up to 25 kHz have laminated silicon steel cores with the thickness of the individual laminations decreasing with increasing frequency.

Capacitors. Any induction heating load, by its very nature, reflects back to the power supply a great deal of inductive reactance, most of which should be corrected with capacitive reactance. Power factor correction capacitors then supply opposing reactive current to balance or resonate the circuit so the load appears to be almost entirely resistive. In this way energy transfer is maximized because the power supply does not have to furnish reactive current.

Because of their use in tuning, capacitors are usually rated in terms of reactive power (kVAR) for induction heating applications. The kVAR ability is an inverse square function of its applied voltage, and thus power factor correction (particularly at medium and high frequencies) is generally performed on the primary side of the load matching transformer, where the voltage is maximum. Because the transformer in this instance must carry full reactive current, and because its losses and current-carrying ability must be higher than with secondary correction, cooling becomes an important consideration. Should the coil voltage approach the rated operating voltages of standard capacitors, it may then be practical to consider capacitors on the secondary or coil side of the transformer. This condition occurs most often where autotransformers are used. The capacitor combination must have a high enough kVAR rating to match maximum output.

When a coil is changed or a new load introduced, the amount of capacitance to tune the circuit may need to be changed. As metal is heated, its resistivity increases, and this will have some limited effect on the load characteristics. However, it is the decreasing magnetic permeability (μ) and the loss of it above the Curie (magnetic transformation) temperature which requires some change to be made to the system, to maintain a reasonable level of power to the load. This may suggest the desirability for switching in additional capacitors, which is a practice often used in static deep-heating applications with motor-generator, line frequency, or tripler equipment.

Workhandling Equipment

Most manufacturers of induction heating equipment will offer mechanical handling apparatus to move the parts or material through the induction field. Vertical scanning units for hardening pins and shafts, and lift-rotate spindles designed to raise or lower parts into a coil and/or quench, may be available in standard packages. Most other workhandling systems will be specially engineered to meet the particular application requirements. Automated bar and tube-handling equipment is common for continuous annealing or the hardening and tempering of these product forms.

Special workhandling equipment can be almost anything from simple manually loaded holding fixtures to a completely automated materials-handling system. Automation is becoming more prevalent as induction heating is introduced. Hopperfeeders sort and orient a variety of parts such as fasteners of various types, cartridge cases, and small automobile engine parts. Because induction heating cycles are short, the process lends itself well to automated manufacturing. As such it eliminates carting parts to a separate heat-treating location, makes for a smooth flow of parts processed in an orderly fashion, and facilitates just-in-time delivery requirements.

Some of the basic requirements of a workhandling system for induction heating are:

- The material should be held without interfering with any part of the heat-treating process
- Parts or material processed must be positioned for each step of the process with the degree of accuracy required
- The part or material must be positioned properly and supported well enough to minimize distortion. In some cases, mechanical restraint may be used to accomplish this
- The part weight and/or the positioning devices should prevent it from moving when subjected to the electromechanical effects of the induction field (especially at lower frequencies)
- Electrical conducting materials used in construction of the fixture should be kept away from the heating field and stray induced currents avoided in drives, bearings, and moving parts

If the latter requirement is not entirely possible, fixture parts may be cut, slotted, electrically insulated from one another, or shielded by intercepting conductive material to reduce any induced heating effect. As a last resort they may be cooled by forced air, water, or even the quenchant. Nonfriction bearings should not be a part of any closed conducting loop through which induced current may flow.

Control Equipment

Induction heating power supplies should be equipped with meters to provide information needed for both initial tuning and for monitoring its performance during operation. Most of the electrical characteristics are measured from a current transformer (C/T) and a potential transformer (P/T) in the load circuit of the power supply.

Metering on fixed-frequency systems generally consists of a kilowatt meter, an ammeter, a voltmeter, and a kVAR or power-factor meter. These meters sometimes are read in percentages of their maximum ratings to simplify tuning. When the system is tuned properly, an increase in the output of the system will reflect increases in both current and voltage simultaneously. An increase in one and a decrease in the other are indicative of improper balance.

Solid state SCR converters use a system of logic to control firing of the SCR devices, and each manufacturer uses a logic system to provide the desired features of performance and control. Such a system may provide constant voltage, constant current, or constant power to the load, and it may allow the output frequency to float as it attempts to resonate with the changing characteristics of a metal being heated. Logic may also help a converter match a wide range of load conductance with very little frequency change.

Power Control. After the output circuit has been tuned to match the load, any needed power change is made by changing the voltage to the coil. The coil current (*I*) is essentially proportional to the impressed voltage (*E*), and so power ($E \cdot I$) delivered to the load is essentially a function of the voltage squared. The coil voltage, which can also be changed by transformer taps, thus determines the power level. If frequent tap changes are needed, no-load tap switches (manual or motorized types) can be used to make these voltage changes, either for set up or during an appropriate heating cycle.

On load, stepless voltage control is available through a number of different devices, the use of any one being appropriate only for certain kinds of equipment. Voltage control or stabilization on the line or primary side of a heater is available through:

- On-load motorized tap switch
- Motorized induction regulator
- Superior electric-type regulator
- Solid state (SCR) voltage controller (caution required for direct use on capacitance corrected loads)
- Saturable reactor
- Saturated transformer (voltage-regulating only)

Triplers and line-frequency induction heaters might use one of the line-side voltage controlling devices listed above. For a very limited range of output voltage control, a spark-gap converter may also use these devices. Most types of frequency converters can have a built-in system for stepless control or regulation of the output voltage:

- *Motor generator.* Output voltage is a function of the generator field current, so control of the generator voltage in the low-energy field controls the high-energy output of the generator
- *Solid state.* Output voltage can be controlled with solid state devices in the direct current (dc) supply, and/or by controlling the firing of dc to the output circuit
- *Vacuum tube oscillator.* Use of three-element rectifier tubes (thyrations) or solid state devices in the dc supply control voltage

By far most induction heat-treating operations are based upon a predetermined level of power applied for a given length of time. Repeatability of the treatment depends upon maintaining that cycle of power, which is a function of the applied coil voltage, and accurately timing the period it is applied. Timing a repeated *controlled* energy cycle is by far the most widely used process control technique.

Transformation Hardening of Steel

The difference between heat-treatment temperatures for induction heating and furnace heating is related to the inherent short heating times of the induction method and its effect on transformation temperatures. In this section, a number of key parameters that influence the hardening response of steels that have undergone induction heat treating are described. These include:

- Time-temperature relations for induction hardening and tempering
- Electrical and magnetic properties of steels
- Selection of induction frequency and power
- The effect of prior microstructure

Time-Temperature Relations

Induction Hardening. As with parts hardened by conventional heat-treating methods, the hardness and hardness profile of induction austenitized parts depend solely on the chemical composition of the steel and the quenching medium. Therefore, the primary metallurgical question that arises in induction hardening relates to austenitizing.

As with austenitizing by conventional furnace techniques, time and temperature are the two critical parameters that must be controlled. To completely austenitize a steel, a certain amount of time at or above the A_3 temperature is required. The

time to form a totally austenitic microstructure depends on the austenitizing temperature selected and the starting microstructure. In all cases, the speed with which austenite is formed is controlled by the diffusion of carbon, a process which can be accelerated a great deal by increasing temperature. For example, the time for complete austenitization in a plain carbon steel of eutectoid composition with an initial microstructure of pearlite is decreased from approximately 400 s at an austenitizing temperature of 730 °C (1345 °F) to about 30 s at an austenitizing temperature of 750 °C (1380 °F), as shown in Fig. 32. Each of these times is considerably increased if the starting microstructure is spheroidized with large carbide particles. This occurs because the diffusion distance for carbon, which must be transported from the carbon-rich carbide phase, is considerably larger than in pearlite, which has thin lamellae of ferrite and carbide. Conversely, the finer bainitic and martensitic microstructures tend to be reaustenitized more readily than pearlite.

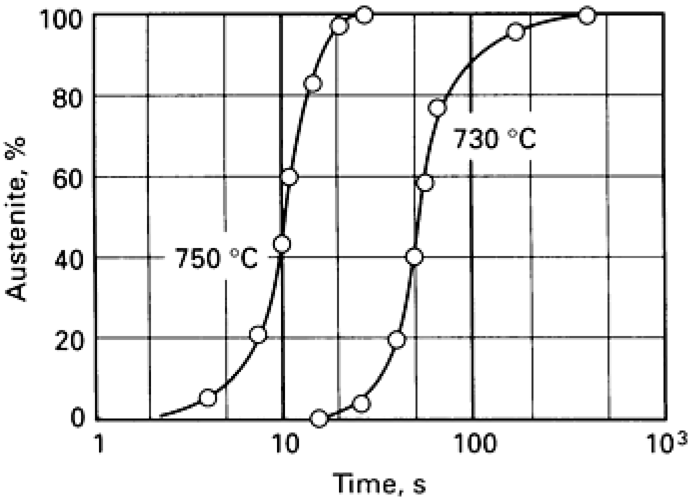

Fig. 32 Effect of austenitizing temperature on the rate of austenite formation from pearlite in a eutectoid steel

Data such as those in Fig. 32 suggest that at high enough temperatures, austenite forms in a fraction of a second. This fact is relied upon in induction surface hardening (very rapid heating rates) or induction through hardening (moderate heating rates) in which the workpiece surface or cross section is raised to a higher temperature than is normally used in much slower, furnace-based processes.

A tremendous amount of metallurgical research has been directed at the determination of the upper critical temperature (Ac_3) that signifies complete austenitization during continuous heating cycles such as those used in induction heating. Because the only "soaking" time available for phase transformation in these cases is that time after which the equilibrium critical temperatures (Ae_3 or Ae_{cm}) is exceeded, the continuous-heating critical temperatures are always above the equilibrium ones. This difference increases with heating rate, as might be expected, an effect shown in Fig. 33 for the Ac_3 temperature for 1042 carbon steel. Here the Ac_3 temperature is the one at which it has been estimated that the austenite reaction is complete. These data also show that the increase in critical temperature depends on the initial microstructure. The fine quenched-and-tempered, or martensite, microstructure revealed the least change in Ac_3 temperature as compared to the equilibrium Ae_3 temperature; whereas the same steel with annealed microstructure exhibits the largest difference in Ac_3 as compared to the Ae_3 obtained from very slow heating rates. Such a trend is readily explained by the fact that the diffusion distance to redistribute carbon is shorter in the former instance and longer in the latter microstructure in which carbides are much larger.

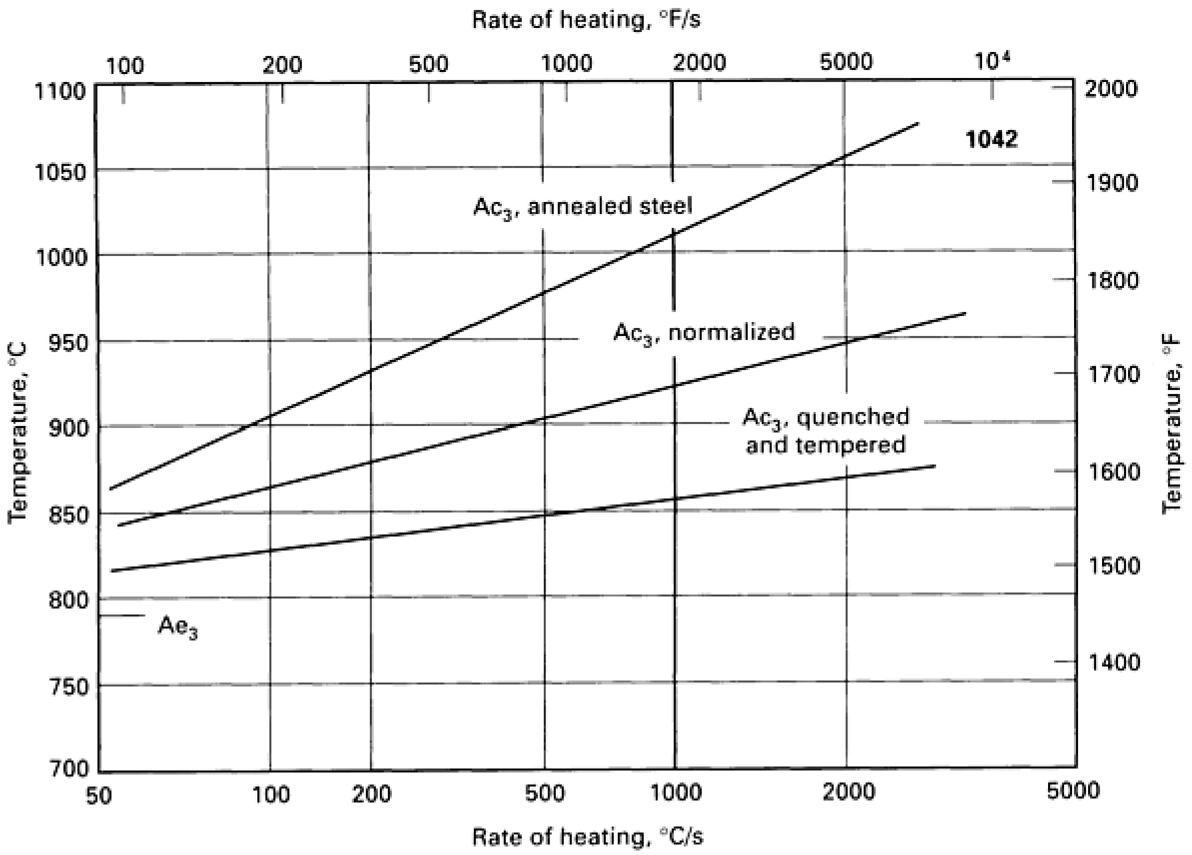

Fig. 33 Effect of prior structure and rate of heating on Ac_3 transformation temperature of 1042 steel

Data similar to those for 1042 steel are given in Fig. 34. For eutectoid 1080 carbon steel, the Ac_1 and Ac_3 temperatures nearly coincide during "slow" heat treatments. By contrast, they differ for rapid heating (Fig. 34). The lower critical temperature can be taken as one at which the reaction started, and the upper one as that at which transformation to austenite was completed. At the higher heating rates, the Ac_1 and Ac_3 are higher than at lower rates, an effect which offsets the shorter times at temperature.

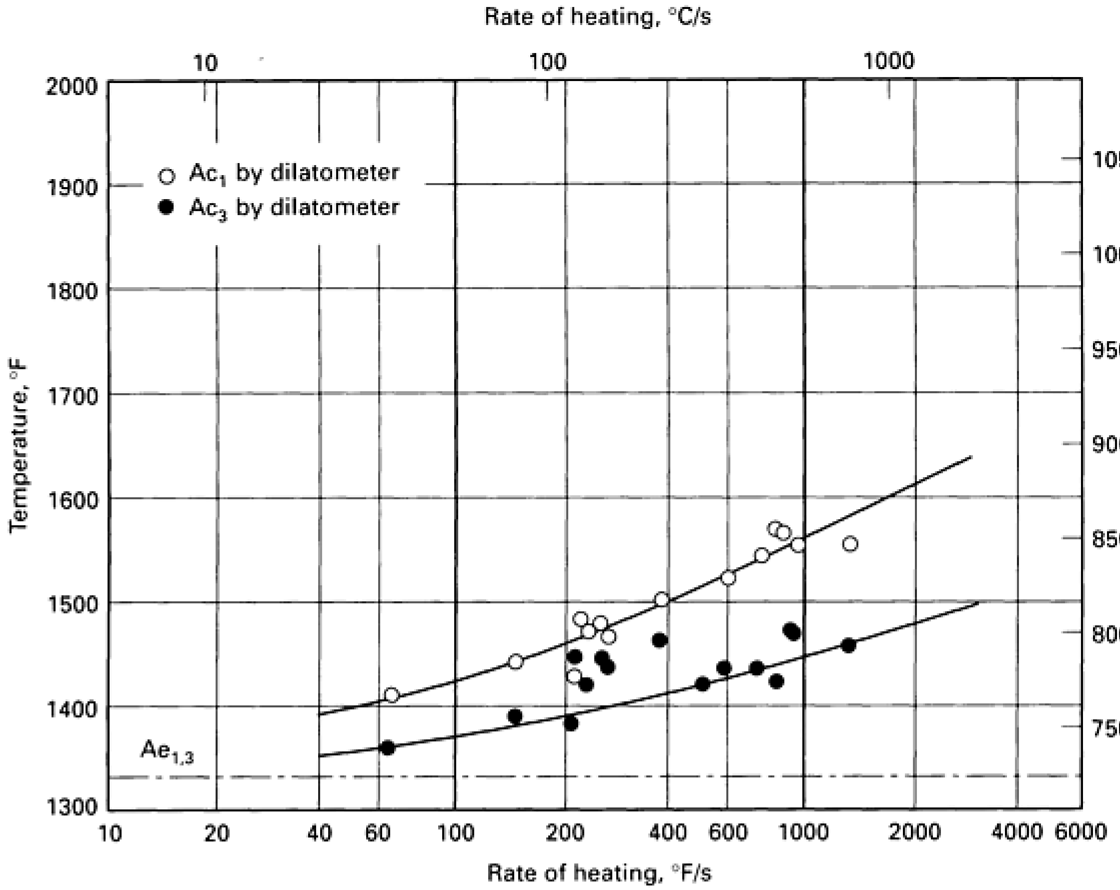

Fig. 34 Effect of heating rate on Ac_1 and Ac_3 temperatures for annealed 1080 steel

The above measurements are most useful when only the surface layers of a steel part are to be austenitized and hardened. In these cases, continuous rapid heating to the Ac_3 temperature is all that is needed. In other situations, in which deeper hardening or through-hardening is necessary, a certain amount of actual soaking time at temperature may be required.

Based on data such as those in Fig. 33 and 34, guidelines have been derived for the required austenitizing temperature for induction hardening of a wide range of steels (Table 4). Generally, the recommended temperatures increase with increasing A_3 temperature; they are approximately 100 °C (180 °F) above the equilibrium upper critical temperature primarily to reduce or eliminate totally the austenitizing time during continuous induction heating cycles. However, they are still below that at which undesirable austenite grain growth occurs in the short times characteristic of induction-based heating processes. The recommended austenitizing temperatures are at least another 100 °C (180 °F) higher in alloys with strong carbide-forming elements (for example, titanium, chromium, molybdenum, vanadium, niobium, or tungsten) than they are in carbon steels. These increases are a result of large increments in the critical temperatures of alloy steels.

Table 4 Approximate induction austenitizing temperatures for carbon and alloy steels

Carbon content, %	Temperature for furnace heating		Temperature for induction heating	
	°C	°F	°C	°F
0.30	845-870	1550-1600	900-925	1650-1700

0.35	830-855	1525-1575	900	1650
0.40	830-855	1525-1575	870-900	1600-1650
0.45	800-845	1475-1550	870-900	1600-1650
0.50	800-845	1475-1500	870	1600
0.60	800-845	1475-1550	845-870	1550-1600
>0.60	790-820	1450-1510	815-845	1500-1550

Note: Recommended austenitizing temperatures for a specific application will depend on heating rates and prior microstructure Free-machining and alloy grades are readily induction hardened. Alloy steels containing carbide-forming elements (for example, niobium. titanium. vanadium. chromium, molybdenum. and tungsten) should be austenitized at temperatures at least 55 to 100 °C (100 to 180 °F) higher than those indicated.

In addition to the increase in recommended austenitizing temperatures in alloy steels, induction austenitizing times may also need to be slightly increased. This is because of the kinetics of alloy carbide dissolution in austenite, which can be substantially slower than those of cementite dissolution, particularly when NbC, TiC, and VC are involved. Such increases in induction hardening temperature and time generally are not deleterious from the viewpoint of austenite grain growth, however, because of the effects of alloying.

The above recommendations for induction hardening temperatures should be used only as a guide. This is especially true for modern plain carbon steels, which are typically melted using a large percentage of scrap that may contain microalloyed high-strength low-alloy steels. Thus, the steel may still be considered to be nominally of the plain carbon type but may contain trace amounts of niobium, vanadium, and/or titanium, whose presence may greatly affect heat-treating response. For this reason, it is wise to obtain a complete chemistry on each lot of steel employed in induction hardening processes or to determine proper austenitizing temperatures experimentally.

Another important feature of induction hardening is its ability to impart as-quenched hardnesses somewhat higher than those of conventionally furnace-hardened steels. This trait is illustrated in Fig. 35 for plain carbon steels of various carbon contents. Data are presented for surface induction hardened (curve A), furnace through-hardened (curve B), and furnace-hardened (curve C) specimens given a low-temperature heat treatment consisting of cooling to liquid nitrogen temperatures and subsequently tempering at 100 °C (210 °F). The higher hardnesses of the induction hardened specimens may be attributable to three sources: residual stresses, smaller amounts of retained austenite, and carbon segregation. As to the first effect, compressive residual stresses are developed in surface-hardened steels because of the smaller density of martensite as compared with bainite or pearlite. During cooling following austenitizing, the higher-density inner layers shrink more than the surface layers, leading to such residual stresses (and thus increments in hardness). The second factor, smaller amounts of retained austenite in induction hardened steels, is a result of the finer martensite generally resulting from such steel heat treatments; the martensite may also be harder because it was formed from finer-grain, less-homogeneous austenite having a larger number of imperfections. The last factor, the increment in hardness due to carbon segregation, derives from the fact that induction austenitizing normally involves rapid heating and requires short holding times, which may lead to variation in carbon content within the austenite grains. Thus, a mixture of high-carbon and low-carbon martensite is formed during quenching. It is the high-carbon martensite which gives rise to higher hardnesses. This effect decreases in steels whose carbon contents exceed approximately 0.6 to 0.8 wt%, above which the hardness of martensite does not change.

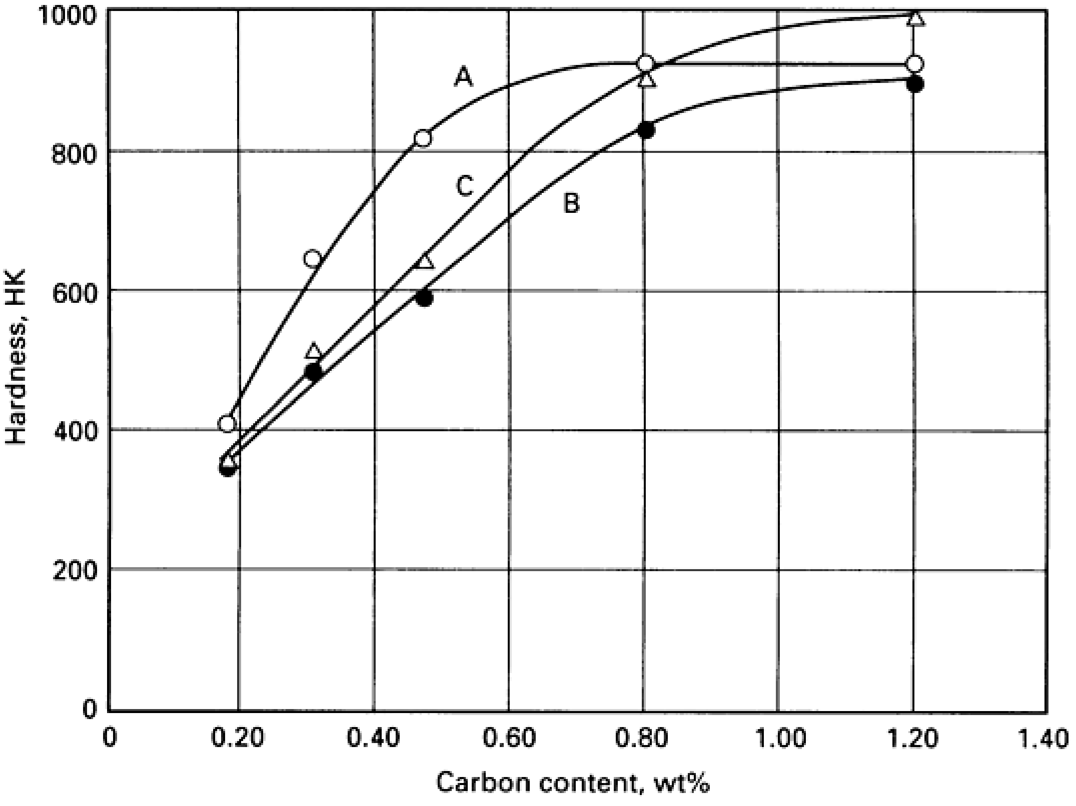

Fig. 35 Effect of carbon content on hardness in plain carbon steels. Curve A: induction hardened. Curve B: furnace hardened and water quenched. Curve C: furnace hardened, water quenched, and tempered. The quenched-and-tempered steels were treated in liquid nitrogen following water quenching prior to tempering at 100 °C (210 °F) for 2 h.

Induction Tempering. The major differences between induction and furnace tempering cycles lie in the times and temperatures involved. Tempering of hardened steel structures, such as martensite, involves diffusion of carbon atoms to form iron carbide (Fe_3C, or cementite). The extent of diffusion increases with both increasing temperatures and time. Thus, a short time/high-temperature treatment and a longer time/lower-temperature treatment will provide similar tempering responses. The former process would be typical of induction treatment and the latter of furnace treatment. The data in Fig. 36 illustrate this point. The results show the tempering response for a quench hardened 1050 steel that was tempered at a variety of temperatures between 150 and 650 °C (300 and 1200 °F). Consider, for example, the processing conditions to obtain a hardness of 40 HRC. Induction heat treatment at 540 °C (1000 °F) for 5 s gives this hardness, as does a much longer (1 h) furnace treatment at 425 °C (800 °F). Because other mechanical properties of quenched-and-tempered steels, such as yield and tensile strength, elongation, reduction in area, and fracture toughness, often correlate with hardness, these two different tempering treatments apparently yield a very similar product.

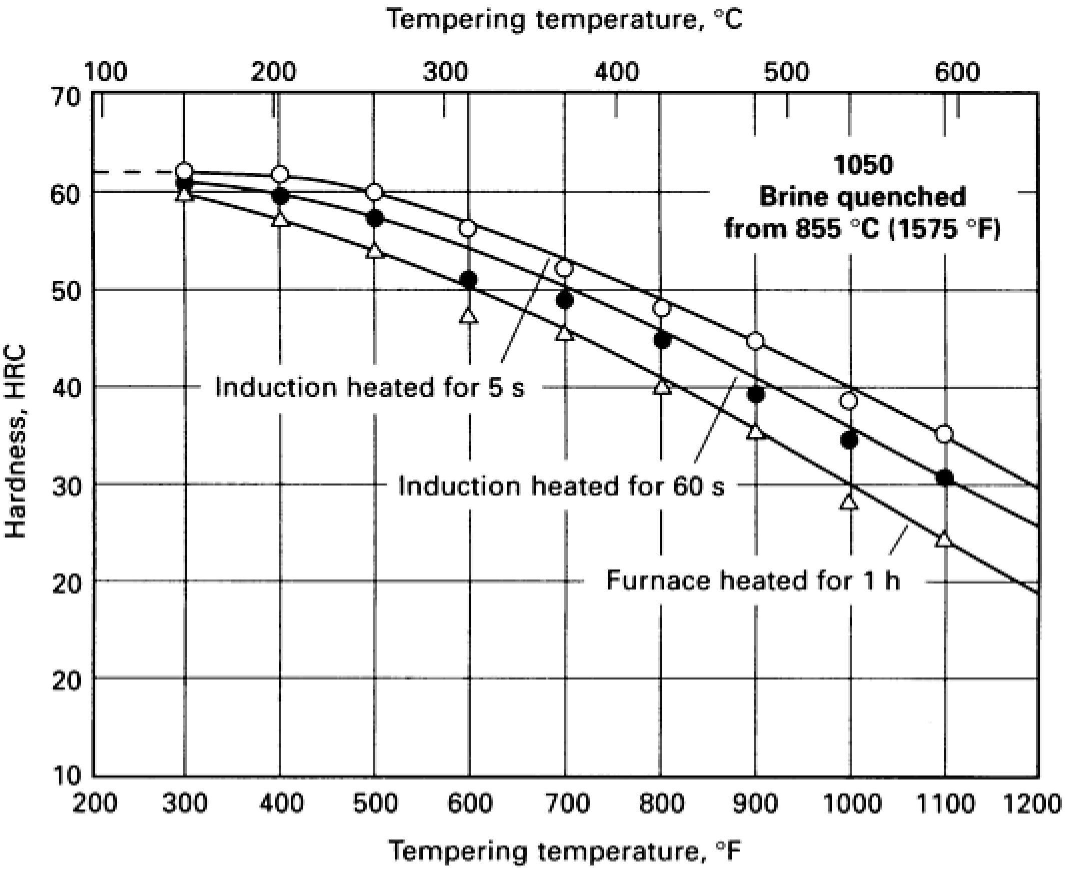

Fig. 36 Hardness as a function of tempering temperature and time for furnace and induction treated 1050 steel austenitized at 855 °C (1575 °F) and quenched in brine

Equivalent time/temperature cycles for tempering can be determined in several ways. For example, tempering experiments can be conducted at a variety of temperatures for a range of times; the hardness for each treatment is determined and then plotted, as in Fig. 36, to establish time-temperature relationships. This method, however, involves considerable time and effort.

A simpler technique uses a mathematical function known as the tempering parameter (T.P.). A number of researchers have found that the hardness of tempered martensite (as well as tempered bainite and pearlite) can be correlated to a certain function of the tempering time and tempering temperature. The formulation of the tempering parameter most widely used is that developed by Grange and Baughman:

$$\text{T.P.} = T(\text{C} + \log t)$$

where T is the absolute tempering temperature in degrees Rankine, C is a constant equal to 14.44, and t is tempering time in seconds.

To illustrate the application of the tempering parameter, consider the 40 HRC data discussed in Fig. 36. The tempering parameters for the two treatments are:

$$\text{T.P. furnace} = (800 + 460) \cdot (14.44 + \log 3600) = 22{,}675$$

$$\text{T.P. induction} = (1000 + 460) \cdot (14.44 + \log 5) = 22{,}105$$

Since the tempering parameters are almost identical, the hardness and other mechanical properties yielded by the two treatments should be nearly the same.

Electrical and Magnetic Properties of Steel

As described earlier in this article in the section "Principles of Induction Heating," the important material properties that determine the success of induction heating are the resistivity of the material, ρ, and relative magnetic permeability, μ. Both of these factors enter the equation for reference depth, *d* (see Eq 2). Since the values of ρ and μ are fixed once the material is selected, the only adjustable parameter is the frequency, *f*. Typically, higher frequencies are chosen for surface hardening and lower frequencies for through-hardening.

The resistivities of metals vary with temperature. Figure 37 shows this behavior for two ferrous alloys--electrolytic iron, an alloy with a negligible amount of carbon, and a 1% C steel. Both alloys have a similar dependence of resistivity on temperature. This can be attributed to the fact that both consist largely of ferrite at low temperatures and austenite at high temperatures. In fact, a change in slope of the curves occurs at temperatures between 700 and 800 °C (1290 and 1470 °F)--a region in which phase transformations occur.

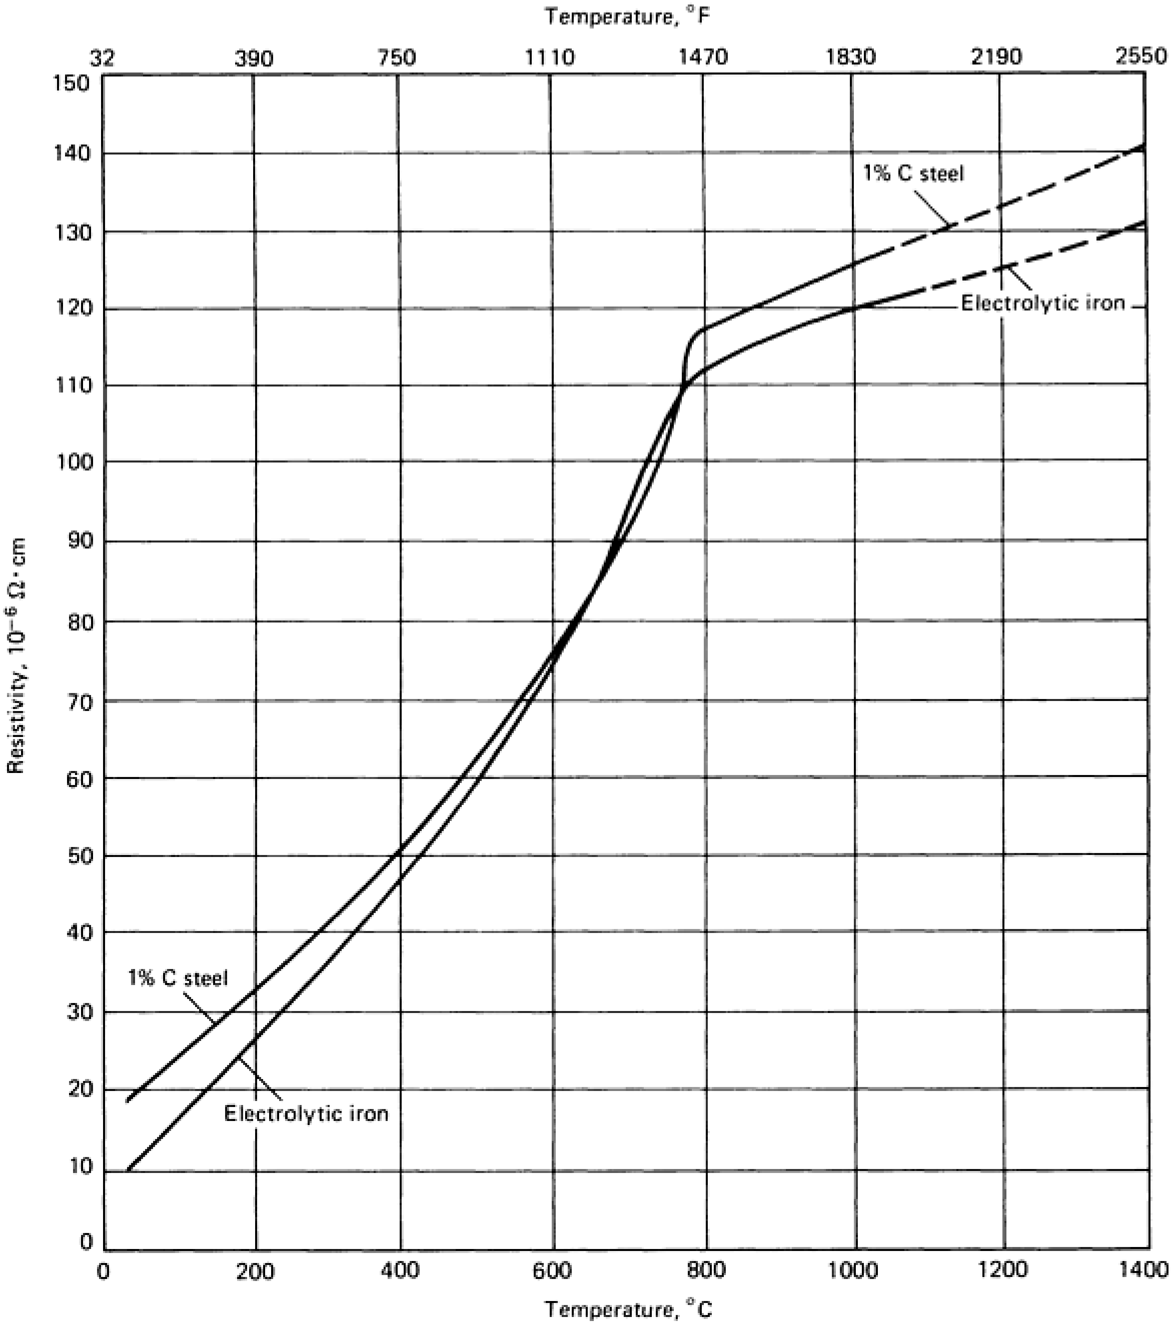

Fig. 37 Electrical resistivity versus temperature for electrolytic iron and a 1% C steel

The temperature at which the slope of the resistivity versus temperature plot for steel changes also coincides with that at which magnetic properties show a related effect. As the temperature is increased, the relative magnetic permeability of steels decreases until the Curie temperature is reached. Below this temperature, relative permeability varies with the intensity of the magnetic field and hence the current in carbon steels. For steels with less than 0.45% C, this temperature is 770 °C (1420 °F). In higher-carbon steels, the Curie temperature follows the A_3 line on the iron-carbon phase diagram to the eutectoid composition; thereafter, it coincides with the A_1 line. Alloying elements in steels change the Curie point by small amounts. Molybdenum and silicon increase it, and manganese and nickel decrease it.

In physical terms, the decrease in magnetic permeability with temperature in carbon steel signifies the loss of ferromagnetic properties and some of the ease with which these steels may be heated by induction. Below the Curie point, heating occurs as a result of both eddy-current losses and hysteresis losses. The latter are no longer present once the ferromagnetic property of steels is eliminated. Such a consideration is very important with regard to the austenitizing of steels in the hardening operation since this is done above the Curie temperature. Figure 38 illustrates this effect. Here it will be noticed that, below the Curie point, the amount of energy needed to heat a given mass of steel by induction is proportional to the temperature increase. Once the Curie temperature is reached, the required amount of energy per degree of temperature is substantially larger. Once the steel is above this point, however, the necessary electrical energy, although reduced, is still greater than that needed for low-temperature heating. When austenitizing temperatures only slightly above the Curie temperature are to be used, no adjustments in induction equipment are usually necessary. When the temperatures must be relatively high, on the other hand, devices such as load-matching circuits may be employed. These vary the impedance of the power source to compensate for the change in the magnetic properties of the steel.

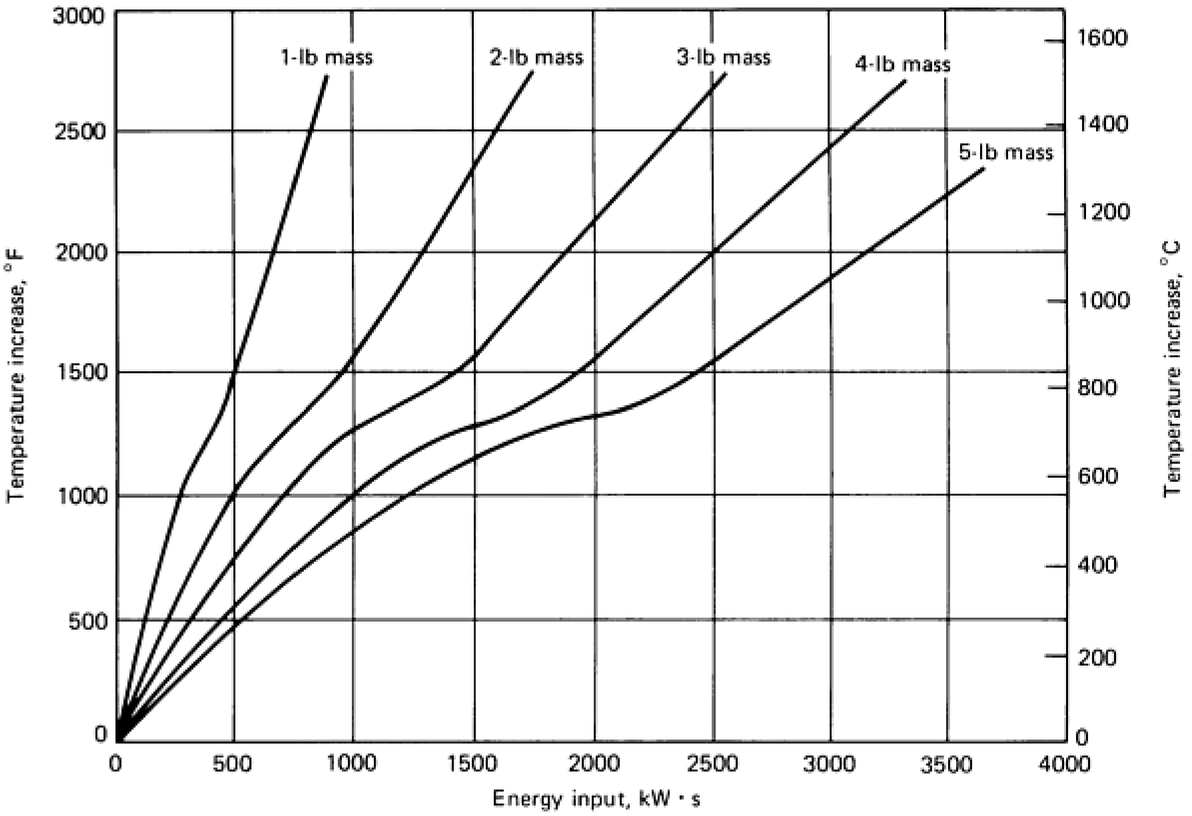

Fig. 38 Temperature increase as a function of energy input for induction heated carbon steel. Note the decrease in heating rate as the Curie temperature (770 °C, or 1420 °F) is approached and exceeded.

Heating Parameters

The temperature pattern generated by induction heating is influenced by such variables as:

- Workpiece characteristics (part geometry and electrical-magnetic properties)
- Coupling distance and coil design
- Frequency selection
- Power density (kilowatts per unit area exposed to the inductor)
- Heating time

The choice of suitable heating parameters is, to a large extent, determined by the temperature required and the depth of heating. Workpiece characteristics are also important. The distribution of induced current is influenced also by the magnetic and electrical characteristics of the part being heated, and because these properties change with temperature (see discussion above), the current distribution will change as the work is heated.

Optimum heating for a given workpiece and heat treatment requires detailed knowledge of the application and equipment. Initial guidance can come from charts or calculations for a specific set of conditions. Many induction heating equipment manufacturers have extensive computer programs based upon laboratory tests and production/operating data, which they use to recommend the proper apparatus and suggest application parameters. An estimate of what may be required for a new application can often be derived from results obtained on similar parts or by careful observation of the part itself as it is being heat treated. Final operating parameters are usually determined by experimentation.

Basic process control for most induction heating applications consists of applying power through a voltage-regulated power supply, for a measured period of time, and this has proved to be satisfactory for a wide variety of operations. Solid state inverters through their logic circuits can provide constant voltage, constant current, or constant power output and each in a particular way can help to ensure a repeatable heating effect with time under a wide variety of changing conditions. For a stationary hardening operation either an electronic or a synchronous timer can be used to control the heating time, any needed load-matching adjustments, and application of the quench. If energy input to the product is considered an appropriate measure of control, a kilowatt-second or kilowatt-hour energy monitor can be used to terminate a heating cycle. Typical heating and energy requirements for various induction processes are listed in Tables 5 and 6.

Frequency Selection

Frequency is the first parameter considered for induction heating. Primary considerations in the selection of frequency are depth of heating, efficiency, type of heat treatment (such as surface hardening versus subcritical annealing), and the size and geometry of the part.

The frequencies and power supplies commonly used in the induction hardening of steel are compared in Table 7. As shown in this tabulation, the lower frequencies are more suitable as the size of the part and the case depth increase. However, because power density and heating time also have an important influence on the depth to which the part is heated, wide deviations from Table 7 may be made with successful results. This interrelationship is shown in Fig. 39 in terms of case depth for surface hardened steel. In some instances, the determining factor in selecting the frequency is the power required to provide power density sufficient for successful hardening, as lower-frequency induction equipment is available with higher power ratings.

Table 7 Selection of power source and frequency for various applications of induction hardening and tempering of steel

Heat-treatment criterion	**Section size**	**Power lines,**	**Frequency converter,**	**Solid state or motor**	**Vacuum tube,**

(a) **Surface hardening ratings:** *Good* indicates frequency that will most efficiently heat the material to austenitizing temperature for the specified depth. *Fair* indicates a frequency that is lower than optimum but high enough to heat the material to austenitizing temperature for the specified depth. With this frequency, the current penetration relative to the section size causes current cancellation and lowered efficiency. *Poor* indicates a frequency that will overheat the surface unless low-energy input is used. Efficiency and production are low, and capital cost of converters per kilowatt-hour is high.

(b) **Through hardening ratings:** *Good* based on heating rates in Fig. 40(b). *Fair* is based on a smaller heating rate, but fair may also indicate a frequency higher than optimum that can overheat the surface at high-energy inputs. Converters cost more per kilowatt-hour than the converters

of optimum frequency. With some equipment, the efficiency may be lower. *Poor* indicates a frequency that will overheat the surface unless low-energy input is used. Efficiency and production are low and capital cost of converters per kilowatt-hour is high.

(c) **Tempering ratings** are based on efficiency, capital cost, and uniformity of heating. *Good* indicates optimum frequency. *Fair* indicates a frequency higher than optimum that increases capital cost and reduces uniformity of heating, thus requiring lower heat inputs. *Poor* indicates a frequency substantially higher than optimum that substantially increases capital cost and reduces uniformity of heating, thus requiring substantially lower heat inputs.

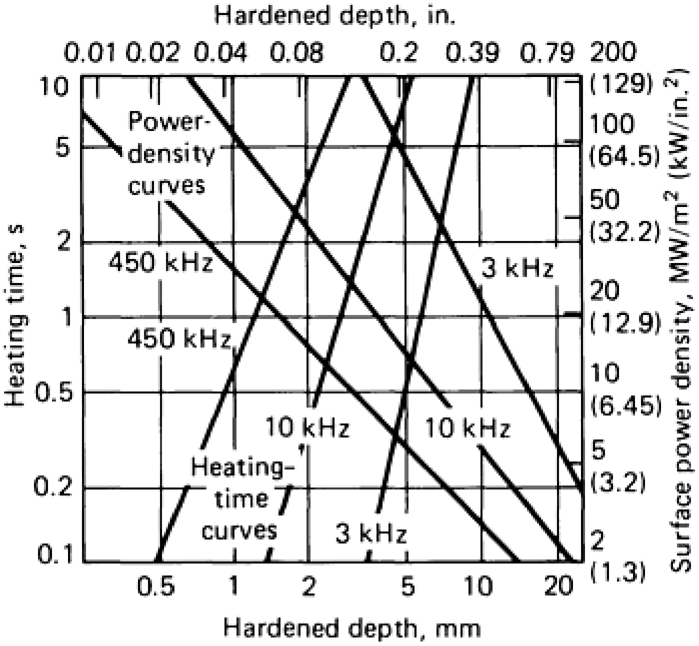

Fig. 39 Interrelationship among heating time, surface power density, and hardened depth for various induction generator frequencies

The equation given earlier in this article for reference depth, *d*, can be used to estimate the optimal generator frequency for induction hardening of steel . For surface hardening, the desired case depth is typically taken to be equal to about one-half the reference depth when selecting frequency. By contrast, when through-hardening is desired, the frequency is usually chosen such that the reference depth is a fraction of the bar radius (or an equivalent dimension for parts which are not round). This is necessary in order to maintain adequate "skin effect" and to enable induction to take place at all. If the reference depth is chosen to be comparable to or larger than the bar radius, there will be two sets of eddy currents near the center of the bar induced from diametrically opposed surfaces of the bar. These will tend to go in two different directions and thus cancel each other. To avoid this, frequencies for through-hardening are often chosen so that the reference depth does not exceed approximately one-fourth of the diameter for round parts or one-half the thickness for plates and slabs when using solenoid coils. When the bar diameter is less than four reference depths, or slab thickness less than two reference depths, the electrical efficiency drops sharply. By contrast, little increase in efficiency is obtained when the bar diameter or slab thickness is many times more than the reference depth.

Typical frequency selections for induction hardening of steel parts are listed in Table 7 and Fig. 40. Those for surface hardening will be examined first. For very thin cases such as 0.40 to 1.25 mm (0.015 to 0.050 in.) on small-diameter bars, which are easily quenched to martensite, relatively high frequencies are optimal. If the reference depth is equated to the case depth, the best frequency for a 0.75 mm (0.030 in.) deep case on a 13 mm (0.5 in.) diameter bar is found to be around 550 kHz. When the surface of a larger-diameter bar is hardened, particularly when the case is to be deep, the frequency is often chosen so that the reference depth is several times the desired case depth. This is because the large amount of metal below the surface layer to be hardened represents a large thermal mass which draws heat from the surface. Unless very high power densities are employed, it is difficult to heat only the required depth totally to the austenitizing temperature. As an example, consider the recommended frequency for imparting a 3.8 mm (0.15 in.) hardened case to a bar 75 mm (3 in.) in diameter. If the reference depth were equated to the case depth, a frequency of about 20 kHz would be selected, which would provide only "fair" results. If a frequency of 3 kHz were chosen, however, the reference depth would be

about 10 mm (0.41 in.), or about $2\frac{1}{2}$ times the required case depth. However, it is unlikely that the entire reference depth would ever reach austenitizing temperatures for the reason mentioned above.

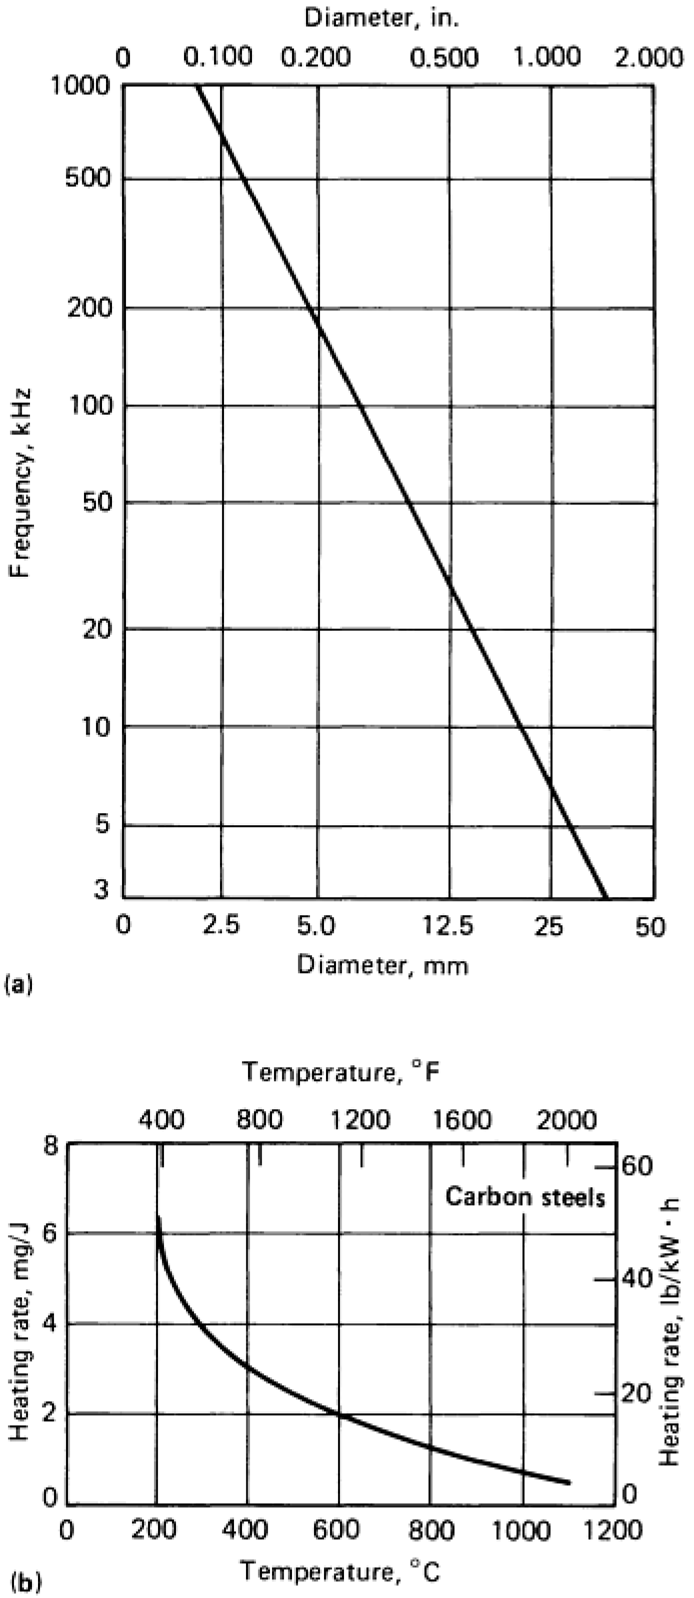

Fig. 40 Typical frequency selections and heating rates for induction hardening of steel parts. (a) Relationship between diameter of round steel bars and minimum generator frequency for efficient austenitizing using induction heating. (b) Heating rate for through heating of carbon steels by induction. For converted frequencies, the total power transmitted by the inductor to the work is less than the power input to the machine because of

converter losses. See also Table 7.

For through-hardening of a steel bar or section, the optimal frequency is often based on producing a reference depth about one-fourth of the bar diameter or section size. For instance, through-heating and through-hardening of a 64 mm (2.5 in.) diameter bar would entail using a generator with a frequency of about 1 kHz. If much lower frequencies were employed, inadequate skin effect (current cancellation) and lower efficiency would result. On the other hand, higher frequencies might be used. In these cases, however, the generator power output would have to be low enough to allow conduction of heat from outer regions of the steel part to the inner ones. Otherwise, the surface may be overheated, leading to possible austenite grain growth or even melting.

Power Density and Heating Time

Once the frequency has been selected, a wide range of temperature profiles can be produced by varying the power density and heating time. Selection of these two heating parameters depends on the inherent heat losses of the workpiece (from either radiation or convection losses) and the desired heat conduction patterns of a particular application.

In through-heating applications, the power needed is generally based on the amount of material that is processed per unit time, the peak temperature, and the material`s heat capacity at this temperature. Power specification for other operations, such as surface hardening of steel, is not as simple because of the effects of starting material condition and the desired case depth.

Surface heating is used primarily in the surface hardening of steel parts such as shafts and gears. In this type of application, high power densities and short heating times are used when thin case depths are desired.

Typical power ratings for surface hardening of steel are given in Table 8. These are based on the need to heat to austenitizing temperature (Table 4) very rapidly and have proven to be appropriate through the years of experience. When using these or other fixed ratings, however, the effect of heating time on case depth (Fig. 39) must be considered.

Table 8 Power densities required for surface hardening of steel

Frequency, kHz	Depth of hardening[a]		Input[b][c]					
			Low[d]		Optimum[e]		High[f]	
	mm	in.	kW/cm^2	$kW/in.^2$	kW/cm^2	$kW/in.^2$	kW/cm^2	$kW/in.^2$
500	0.381-1.143	0.015-0.045	1.08	7	1.55	10	1.86	12
	1.143-2.286	0.045-0.090	0.46	3	0.78	5	1.24	8
10	1.524-2.286	0.060-0.090	1.24	8	1.55	10	2.48	16
	2.286-3.048	0.090-0.120	0.78	5	1.55	10	2.33	15
	3.048-4.064	0.120-0.160	0.78	5	1.55	10	2.17	14
3	2.286-3.048	0.090-0.120	1.55	10	2.33	15	2.64	17
	3.048-4.064	0.120-0.160	0.78	5	2.17	14	2.48	16

	4.064-5.080	0.160-0.200	0.78	5	1.55	10	2.17	14
1	5.080-7.112	0.200-0.280	0.78	5	1.55	10	1.86	12
	7.112-8.890	0.280-0.350	0.78	5	1.55	10	1.86	12

(a) For greater depths of hardening, lower kilowatt inputs are used.

(b) These values arc based on use of proper frequency and normal overall operating efficiency of equipment. These values may be used for both static and progressive methods of heating; however, for some applications, higher inputs can be used for progressive hardening.

(c) Kilowattage is read as maximum during heat cycle.

(d) Low kilowatt input may be used when generator capacity is limited. These kilowatt values may be used to calculate largest part hardened (single-shot method) with a given generator.

(e) For best metallurgical results.

(f) For higher production when generator capacity is available

Through Heating. Power ratings for through hardening of steel are much lower than those for surface hardening to allow time for the heat to be conducted to the center of the workpiece. After awhile, the rates of increase of the surface and center temperatures become comparable due to conduction, and a fixed temperature differential persists during further heating. Using methods described by Tudbury (see the Selected References at the end of this article), the allowable temperature differential permits the generator power ratings to be selected. The basic steps in selecting the power rating are as follows:

- Select the frequency and calculate the ratio of bar diameter (or section size) to reference depth, a/d. For most through-heating applications, this ratio will vary from around four to six
- Using the values of the thermal conductivity (in W/in. · °F) and a/d, estimate the induction thermal factor, K_T (Fig. 41)
- The power per unit length is calculated as the product of K_T and the allowable temperature differential (in °F) between the surface and center, T_s - T_c. Multiplying this by the length of the bar yields the net power required in kilowatts

In addition to these estimates, radiation heat loss must also be considered when determining power ratings. The upper limit of radiation losses, which is defined by the emission characteristics of a blackbody, is shown in Fig. 42 as a function of temperature. Actual workpiece materials will exhibit less radiation loss than in Fig. 36 because they do not have the broad spectral range of blackbodies.

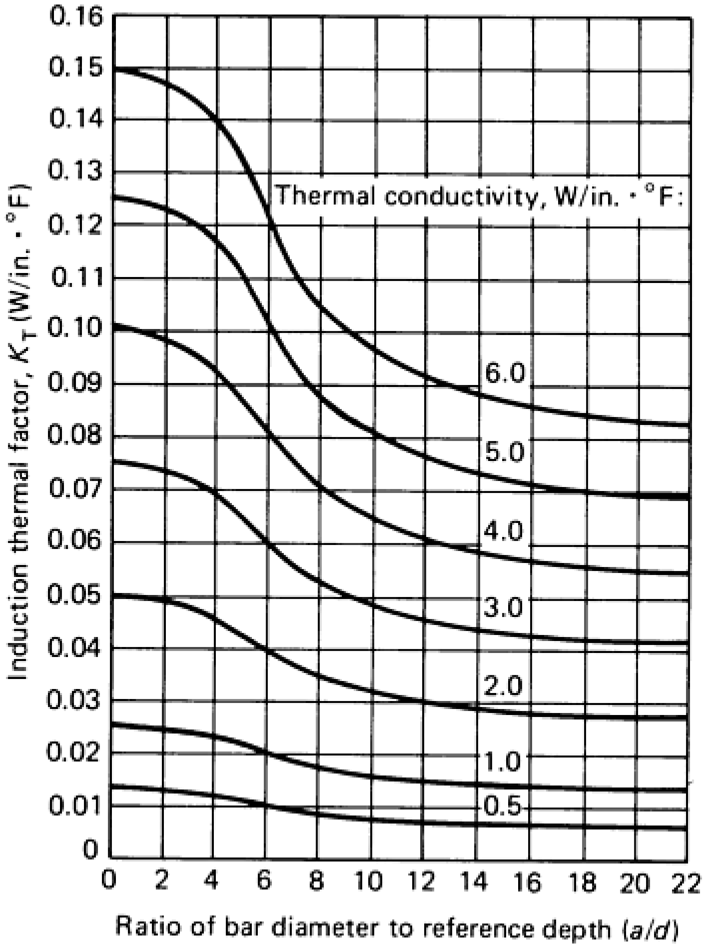

Fig. 41 Induction thermal factor for round bars as a function of the ratio of bar diameter to reference depth (*a*/*d*) and the thermal conductivity

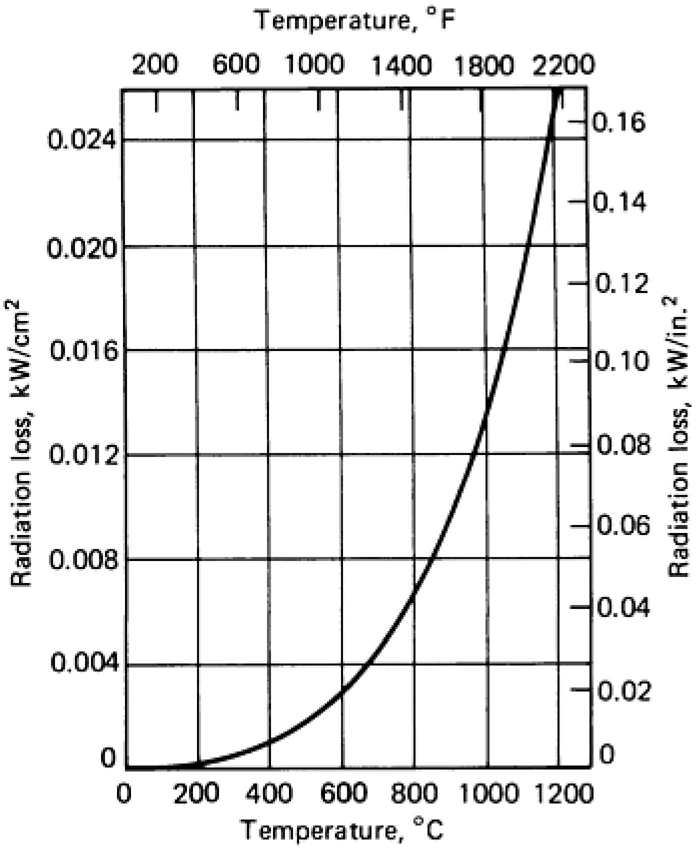

Fig. 42 Radiation heat loss as a function of surface temperature. Losses are based on blackbody radiation into surroundings at 20 °C (70 °F).

In order to avoid calculations of power requirements, tables of power densities ordinarily used for through heating of steel (for hardening as well as other uses, such as forging) are available. One such listing is shown in Table 9. These values of power densities are based on typical electrical efficiencies and proper selection of frequency (which lead to *a*/*d* ratios in the range of four to six). It may be noted that the larger-diameter bars, which can be heated efficiently with lower-cost, lower-frequency power supplies, typically employ smaller power densities than small-diameter bars (see Table 10). This is because of the greater times required for heat to be conducted to the center of the larger pieces. Also, it can be seen that lower frequencies such as 60 and 180 Hz are not ordinarily recommended for through heating of steel when temperatures above approximately 760 °C (1400 °F) are desired. This is due to the increased reference depth (and decreased skin effect) above the Curie temperature where the relative magnetic permeability drops to unity. An exception to this practice is the use of 60 Hz sources for induction heating of very large parts such as steel slabs in steel mills. Tempering treatments may also use 60 Hz sources (Table 11).

Table 9 Approximate power densities required for through-heating of steel for hardening, tempering, or forming operations

Frequency[(a)], Hz	Input[(b)]									
	150-425 °C (300-800 °F)		425-760 °C (800-1400 °F)		760-980 °C (1400-1800 °F)		980-1095 °C (1800-2000 °F)		1095-1205 °C (2000-2200 °F)	
	kW/cm²	kW/in.²	kW/cm²	kW/in.²	kW/cm²	kW/in.²	kW/cm²	kW/in.²	kW/cm²	kW/in.²

(a) Power transmitted by the inductor at the operating frequency indicated. For converted frequencies, this power is approximately 25% less than the power input to the machine, because of losses within the machine.

(b) At the operating frequency of the inductor

One mitigating effect which must be considered when establishing power requirements for austenitizing is the delay between the time at which the power is turned off and the time at which the quench is applied. Following heating, the temperature at the surface drops more rapidly than that at the center of the workpiece. Eventually, the center temperature becomes greater. Because of this, the heating and cooling cycles can often be adjusted to compensate for the nonuniform heating which characterizes induction processes. Thus, greater input power and higher heating rates can sometimes be realized than when quenching follows immediately after heating.

Induction Heat Treatments

Electromagnetic induction affords one way to develop the necessary heat for a number of different heat-treatment operations such as:

- Surface and through hardening
- Tempering and stress-relieving
- Normalizing and annealing
- Precipitation hardening or aging
- Grain refinement

Surface Hardening by Induction. Surface hardening of a steel part consists of raising a surface layer above the transformation temperature (denoted by Ac_3 on the Fe-C phase diagram) at which it will be transformed to austenite and rapidly cooling the part to produce a hard martensitic structure in this region. Design of surface-hardening treatments demands consideration of the work-piece material and its starting condition, the effect of rapid heating on Ac_3 or Ac_{cm} temperature, property requirements, and equipment selection.

Induction surface hardening is applied mostly to hardenable grades of steel, although some carburized and slow-cooled parts are often reheated in selected areas by induction heating. Some typical induction surface hardened steels are:

- Medium-carbon steels, such as 1030 and 1045, used for automotive drive shafts, gears, and so forth
- High-carbon steels, such as 1070, used for drill and rock bits, hand tools, and so forth
- Alloy steels used for bearings, automotive valves, and machine-tool components

As described earlier in this article, frequency and power selection influence the case depth. A shallow fully-hardened case ranging in depth from 0.25 mm to 1.5 mm (0.010 to 0.060 in.) provides a part with good wear resistance for applications involving light to moderate loading. For this kind of shallow hardening, the depth of austenitizing may be controlled by using frequencies on the order of 10 kHz to 2 MHz, power densities to the coil of 800 to 8000 W/cm^2 (5 to 50 kW/in.^{2}), and heating time of not more than a very few seconds. Pump shafts, rocker arm shafts, and sucker rods are typical parts which benefit from a shallow hardened case for wear resistance.

Where high loading stresses penetrate well below the surface, whether it be bending, torsion, or brinneling, the metal needs to be strengthened so at any depth its yield strength exceeds the maximum applied stress at that depth. Because loading stresses drop off exponentially from the surface to the center of a shaft, it is obvious a deep case with high hardness can be effective in strengthening below the surface. Consequently, parts subjected to heavy loads, particularly cyclic bending, torsion, or brinneling, may require a thicker case depth (that is, deeper hardness). The hardened depth might then be increased to 1.5 to 6.4 mm (0.60 to 0.250 in.), which would require:

- Frequencies ranging from 10 kHz down to 1 kHz
- Power densities on the order of 80 to 1550 W/cm^2 ($\frac{1}{2}$ to 10 kW/in.^{2})
- Heating times of several seconds

Heavy duty gears, drive axles, wheel spindles, and heavily loaded bearings are typical parts to which this kind of strengthening surface heat treatment is most applicable.

Required hardness patterns can be determined from stress calculations, because hardness values can be translated to yield strength. The required case depth also depends on the distribution of the residual compressive stresses (induced by the transformation hardening of the surface region) and the loading stresses within the body of the part. Where a transformation hardened case ends, either in depth or at the termination of a hardened surface pattern, a stress reversal will most likely occur. This condition should be avoided in any region of the part that carries any significant portion of the load.

For example, the hardness pattern on a load-carrying gear should not terminate in the root when bending stresses tend to concentrate. On the other hand, fly wheel ring gears and some sprockets are just hardened on the tooth flanks only to resist wear. The discontinuous pattern reduces distortion because there is no hoop stress from hardening a continuous ring. If a spline or a keyway is in the torsional load transmitting part of a shaft, it should be hardened below the root or notch.

Selective Hardening. The ability to limit the heated surface area as well as the depth makes induction heating particularly attractive for parts in which the loading stresses or the need for wear resistance is concentrated in some portion of the part. Localized hardening not only increases the metal's outer layer strength (where most of the operating load is carried), but it may also bestow favorable residual compressive stresses in those same surface layers. Selective treatment also saves time and energy, and will minimize thermally-induced distortion. One precaution to be observed concerning the hardening of selective regions is that the area of transition from compressive residual stresses to tensile residual stresses is located away from stress concentrations.

Volume Surface Hardening. Another category of surface induction hardening is achieved by austenitizing and quenching ferrous metals to an even greater depth; often below the hardenability of the metal, but nevertheless to a depth controlled by the induction process. This technique is sometimes referred to as volume surface hardening. Depths of hardness up to 25 mm (1 in.) over 600 HB have been achieved with a 1% C, 1.3 to 1.6% Cr steel that has been water quenched. Frequencies from 60 Hz to 1 kHz are used, with power densities expressed as a fraction of a kW/in.^{2} and heating times from about 20 to 140 s. Typical of parts hardened in this manner are mill rolls 180 to 915 mm (7 to 36 in.) in diameter, track rollers, and railway axle boxes.

Through hardening with induction heating is often accomplished with medium frequencies (180 Hz to 10 kHz), and at times with line-frequency equipment. In some applications it may be advantageous to use two frequencies: a lower frequency to preheat the steel to some subcritical temperature, followed by a higher frequency to achieve full austenitizing temperature. The choice of using a lower frequency to preheat might be dictated by economics (that is, less expensive equipment with a bit higher conversion efficiency); however, it may also provide application benefits such as reduced thermal shock and/or shorter heating time.

To date, the high-tonnage operations using through hardening with induction heating involve the processing of pipe and tube. These operations can also include tempering, normalizing, or stress relieving. High-strength, round and rectangular bar stock, truck frame channels, and other long members are also heated and quenched horizontally one after the other. The tempering portion of a quench-and-temper treatment may follow in line directly after quenching, often using the same frequency as preheating because both preheating and tempering only heat to a subcritical temperature. Few piece parts are through hardened with induction methods, unless a localized heat treatment or a special pattern of hardness is specified.

Tempering for the purpose of decreasing hardness and increasing toughness is a subcritical heat treatment which can be accomplished at high efficiency with induction heating. As suggested above, tempering is often applied in line in a continuous heat-treating system, directly after through hardening. Other applications of induction tempering include:

- Localized tempering of carburized or furnace hardened parts in areas which require further machining such as threading or broaching. A typical example is the splined bore of carburized gear tempered to facilitate final sizing with a broach
- Induction tempering to increase the ductility of work hardened parts. Typical examples include the tempering of deep drawn steel cylinders between drawing operations and the tempering of cold headed bolts and cold rolled splines or threads

Tempering may be preferable to normalizing or full annealing for some ductility and machinability needs because as a subcritical treatment there is no danger of forming any hard products of transformation.

However, induction tempering of hardened steel can be limited by the type of temperature gradients developed during induction heating. Tempering is a very temperature-sensitive application because the mechanical properties of a hardened and tempered iron or steel are primarily a function of the ultimate tempering temperature achieved. Therefore some degree of temperature uniformity is undertaken in this operation. This consideration limits induction tempering of property-sensitive parts and materials to fairly uniform sections, primarily those approaching a round shape. If the treated

part is anything but a smooth round, surface temperature differentials can occur at corners or in light sections during high-temperature tempering. Some metal may also reach austenitizing temperature. If so, a real danger of rehardening from mass quenching exists, particularly if the steel is an alloy grade. Slow deep heating, or a heat-soak, and reheat (two or three times) cycle has been found helpful in achieving a hardness which is machinable. A frequency as low as practical for the product size and configuration should be used to minimize overheating of thin sections and corners.

Stress relieving is not intended to significantly modify mechanical properties. Instead, the purpose is to relieve residual stresses from hardening or cold working. If the as-quenched hardness is high and/or the part geometry is such that high localized residual stresses can occur, stress relieving should take place immediately after hardening. However, if the residual stresses can improve the load-carrying ability and the fatigue life of the part, then stress-relieving temperatures should be below 260 °C (500 °F) to retain the highest practical value of the compressive residual stress.

Parts heated and quenched in one position may be stress relieved after quenching by applying low power to the hardening inductor. The resultant temperature pattern will not be uniform over the entire pattern of hardened metal so this should only be considered where the stress-relieving operation is not critical and temperature variation can be tolerated. Therefore, some prefer to perform stress relieving in an oven or furnace for reasons of time and uniformity.

Nonetheless, parts such as drive axles, power take-off shafts, and wheel spindles have been stress relieved by induction after quenching. Surface hardened parts either scanned or locally treated on indexing fixtures may be stress relieved at a second heating station using some lower level of power. The energy can be supplied at reduced level either from the hardening power supply, or from a second smaller unit, perhaps even at a lower frequency. A coil which is designed to heat the entire area uniformly can be used at the stress-relieving station.

A low-temperature stress-relieving effect may occur after induction hardening by terminating the quench at a time when the surface is at quench temperature but some residual heat remains in the layers below. This residual heat can provide a measure of stress relief by conducting back into the quench-hardened metal. When scanning or progressive hardening is vertical, stress relieving with residual heat is not practical because the surface contact time of the quenchant cannot be controlled and will vary along the part length. This technique can only be considered practical when scan hardening is horizontal. A low-power heat application on a return stroke is also a possibility for stress relieving in any scanning operation, but any of these methods need to be studied carefully.

Annealing heat treatments with induction heating include a variety of different methods and heat treatments. The methods of induction annealing can range from localized annealing to the continuous annealing of sheet and strip, and different types of anneal treatments are performed on both ferrous and nonferrous alloys. For the purposes of this discussion, the variety of induction anneals are briefly reviewed in terms of the following three categories:

- Localized annealing of welded tubular products or cold formed fasteners
- Continuous annealing of sheet or strip
- Annealing treatments for ferritic (magnetic) steels

Localized Induction Annealing. A wide variety of parts are locally annealed specifically to improve their cold-working properties or machinability, or simply to develop a microstructure with certain needed mechanical properties. Cold rolled threads and cold formed heads on studs, or the mouth and neck of steel and brass cartridge cases are examples of locally annealed parts.

Both weld metal and metal adjacent to an arc weld, a pressure butt weld, or a friction weld may be locally induction annealed to improve the weld zone ductility and remove any hard products of transformation. Continuous seam welded pipe and friction welded oil field tool joints are typical examples of manufactured products. Post annealing of arc welded alloy steel pipe in such places as refineries and electric power plants may be accomplished with induction heaters using 60 Hz or 400 Hz from either a portable transformer or motor-generator. Energy is applied through thermally insulated cable wrapped around the pipe and spaced with insulating board. Some equipment is designed specifically for this kind of application and also to preheat pipe prior to welding, although welding power supplies are sometimes used.

Continuous Induction Annealing. Transverse flux (Fig. 28) induction heating is being used to continuously anneal both ferrous and nonferrous strip. Here frequency considerations are based less upon the thickness of the strip, and more upon the separation of currents on the face and how they will affect uniformity of heating. New application techniques improve

the process flexibility so a single inductor can handle a wider range of strip widths, and computer modelling has shown how to heat more uniformly.

Induction Annealing of Magnetic Steels. Ferritic (magnetic) steels, which can be annealed either above or below the critical temperature for ferrite-austenite transformation, require careful attention to heating and cooling characteristics when induction methods are used for heating. In subcritical annealing, for example, the objective is to reduce hardness and improve ductility by heating only in the range of tempering temperatures (below 760 °C, or 1400 °F). In this subcritical process, however, undesirable transformation can occur because induction heating has the potential for producing high-temperature gradients (see the discussion in the previous section on Tempering).

Critical annealing (or normalizing), which involves heating above the transformation temperature to effect recrystallization, also requires careful attention to temperature gradients and cooling procedures. Products which lend themselves to continuous horizontal annealing (or normalizing) are steel wire, bar, tubulars, and simple shapes. The appropriate frequency will be determined by the metal cross section or thickness. In some cases, two frequencies are used during critical annealing, one for the initial subcritical (magnetic) stage followed by a higher frequency for supercritical (nonmagnetic) heating.

Annealing, in the strict sense, is not often performed by just induction heating alone, but induction heated parts are sometimes control cooled in a chamber. For example, stacked flywheel ring gears are heated in an induction coil, then transferred to a insulated thermally-controlled cooling tunnel. However, if localized heating is used, then induction annealing is generally followed by air cooling because the adjacent cold metal accelerates the cooling process. Some grades of steel may have a tendency to produce hard products of transformation with this type of treatment, similar to the undesirable transformations that can occur during induction tempering.

Localized Induction Heating for Grain Refinement. With the rapid local heating capabilities of the induction process, grain refinement can be achieved in the critical outer layers of steel bar or billet by allowing the colder core metal to recrystallize the transformed outer layer metal in a staged heating process. Induction heating is also used to effect recrystallization for the purpose of refining a coarse grain from the high temperatures of welding on continuous electrically welded pipe. For arctic service, where low-temperature impact properties are an important consideration, two to four successive recrystallization heaters have been placed in line after the welding station. As a thermal process, the grain refinement is accomplished by heating the steel above the transformation temperature to effect recrystallization, followed by rapid cooling to restore the original ferrite structure.

Precipitation Hardening or Aging. Heat produced from induced currents, if fairly uniform, can be effectively used to accelerate aging and produce precipitation hardening in metal with a supersaturated constituent. Certain cold worked steels (typically continuously scanned bars) are strengthened by a subcritical induction heat treatment, called strain aging. Because aging is time and temperature dependent, induction aging parameters can differ from furnace aging.

Quench Systems

Quenching techniques are as important a design feature of induction hardening lines as the equipment and coil used for austenitizing. The important questions to be answered when determining quenching systems include the following:

- Part size and geometry
- Type of austenitizing operations (surface or through hardening)
- Type of heating method (single-shot or scanning)
- Hardenability of steel and quenchant needed

The two most common types of systems consist of spray quench rings and immersion techniques. When quench rings are used for round bars, their shape, like the coil, is generally round (Fig. 43). The ring may be located concentric with the coil or directly underneath or alongside it (Fig. 24a) as in single-shot induction hardening setups. In those using induction scanning, parts move through the quench ring and coil, with quenching occurring immediately after heating (Fig. 24b). For nonsymmetric parts, the quenching apparatus, like the coil, is generally of the same shape as the part.

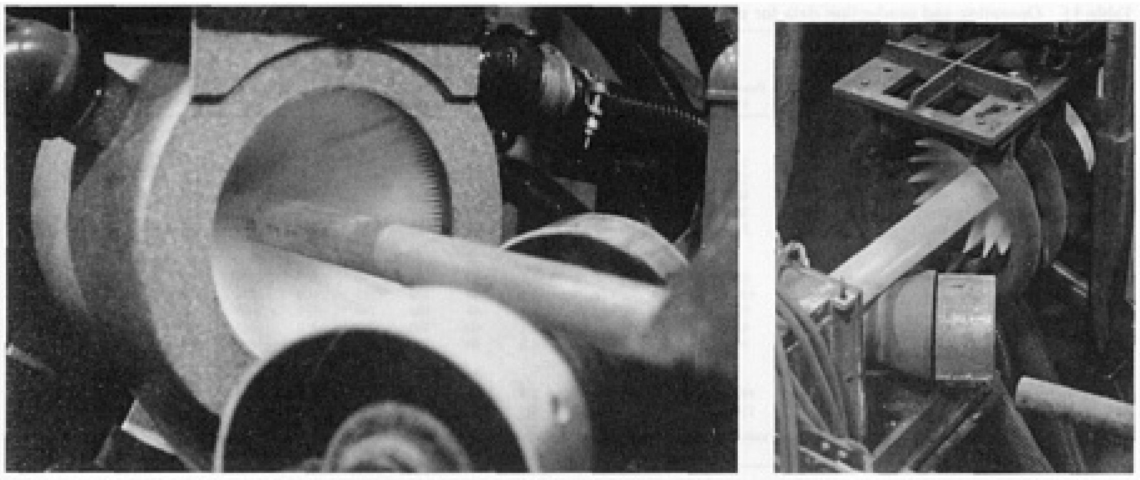

Fig. 43 Examples of quench rings for continuous hardening and quenching of tubular members. Courtesy of Ajax Magnethermic Corporation

In addition to the coil-and-quench-ring arrangements mentioned above, eleven basic arrangements for quenching induction hardened parts are shown schematically in Fig. 44. In correlation with the lettering here, these arrangements are briefly described as follows:

- (a) Heat in coil; manually lift part out of coil; submerge part in tank of agitated quench medium. Used where limited production does not warrant the cost of an automated quench
- (b) Heat and quench in one position; quench by means of integral quench chamber in inductor. Called single-shot method
- (c) Heat in coil with part stationary; quench ring moves in place. Single-shot adaptation of scanning method
- (d) Part is hydraulically lowered into quench tank after single-shot heating. Quench medium is agitated by submerged spray ring or propeller
- (e) Vertical or horizontal scanning with integral spray quench. Single-turn inductor. Used for shallow hardening
- (f) Vertical or horizontal scanning with multiturn coil and separate multirow quench ring. Used for deep-case or through hardening
- (g) Coil scans and heats workpiece; self-quench or compressed air quench. Used in special applications with high-hardenability steels
- (h) Horizontal cam-fed parts are pushed through coil, then dropped onto submerged quench conveyor
- (i) Vertical scanning with single-turn inductor in combination with integral dual quench: one quench ring for scan hardening, the second for stationary quenching when the scanning travel stops. Used for parts having a diameter or a flange section too large to travel through the inductor, wherein it is desired to harden up to the shoulder or flange
- (j) Vertical scanning with single-turn inductor with integral spray quench and submerged quench in tank
- (k) Split inductor and integral split quench ring. Used for hardening crankshaft bearing surfaces

Sufficient quenchant flow must be maintained to cool the part or section being quenched. Because induction heating systems are themselves compact, quenching systems are frequently designed smaller than they should be. To avoid this, the capacity of the pumping system should be at least three or four times the flow rate needed for proper quenching, and the quenching flow rate should be adjusted so that quenchant does not boil off once the part leaves the quench-ring location. Furthermore, if part rotation is used during heating and quenching, its rate must be kept low enough to avoid excessive quenchant from being thrown off.

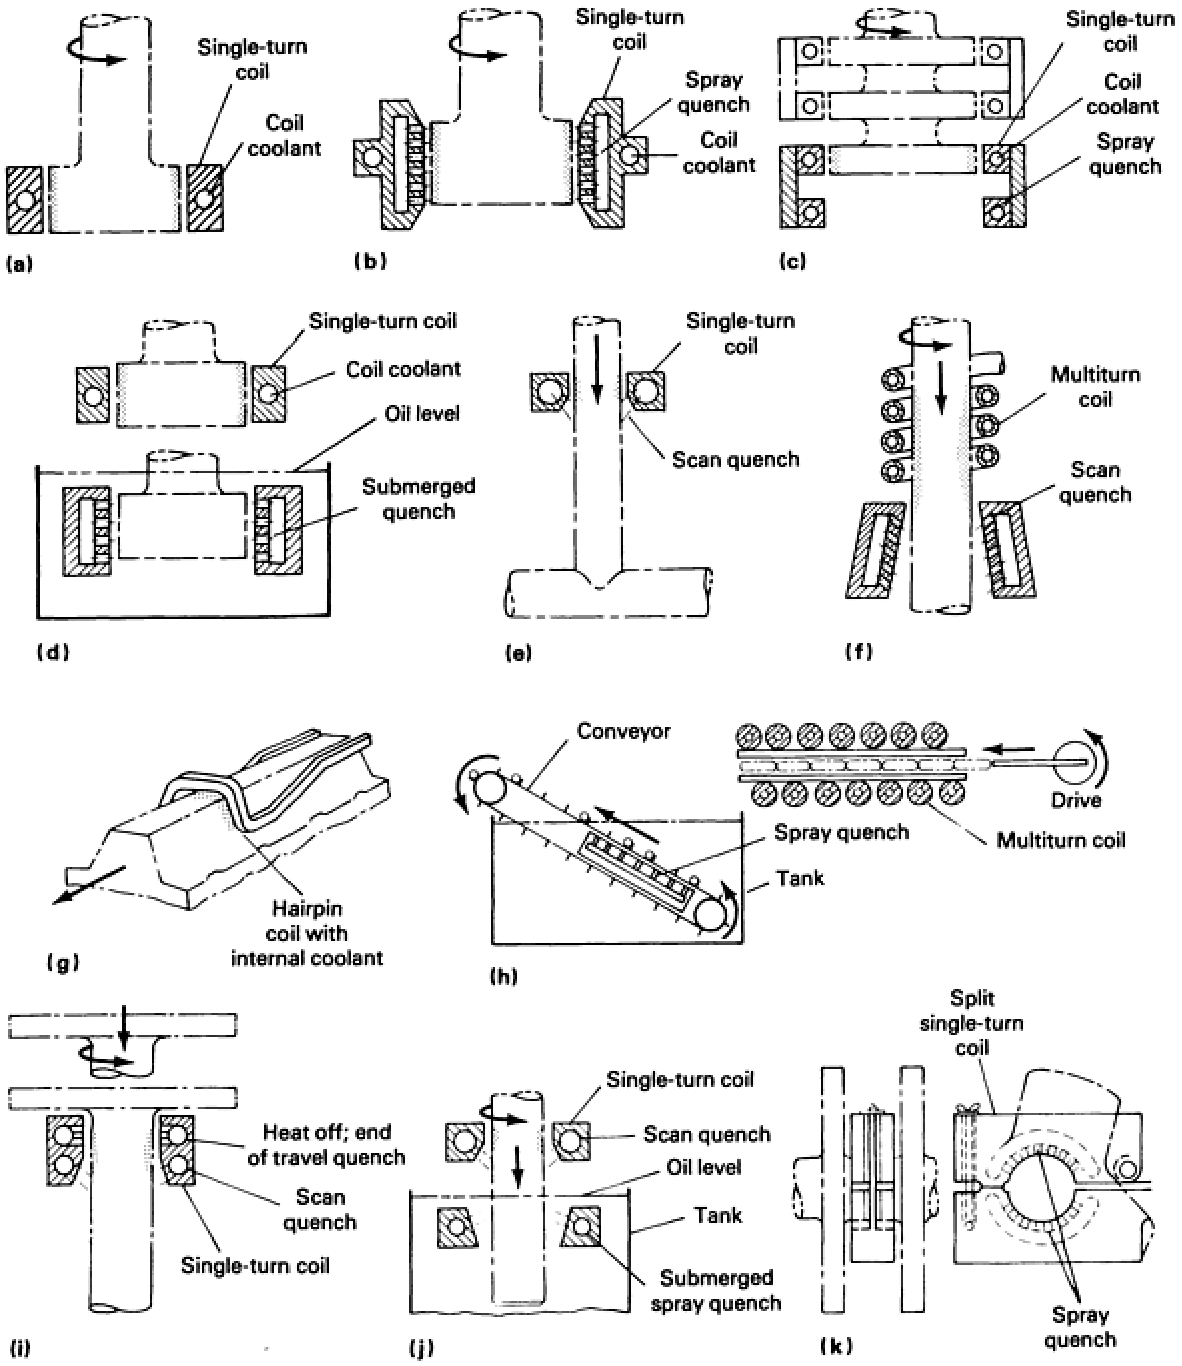

Fig. 44 Eleven basic arrangements for quenching induction hardened parts. See text for details.

As with furnace heat treatments, water and oil are frequently used as quench media in induction heat-treatment practice. Water is the more common. Oil is typically used only when heat treatment is to be performed on steels of high hardenability, or on parts in which cracking or distortion are likely to occur.

When water is used, it is best to select a supply which is reasonably clean and not extremely hard. Dirt may tend to clog the orifices of the quench tooling; similarly, hard-water deposits, which may build up slowly in quench rings, cut down on their efficiency and may necessitate replacement or extensive cleaning. Besides cleanliness requirements, the water temperature should also be controlled, preferably in the range of 15 to 40 °C (60 to 105 °F). This is most easily done when the water supply is large and when specialized recirculating systems are used.

Oils for quenching come in three generalized categories: general-purpose quenching oils (paraffin-type oils), "fast-quenching" oils, and soluble oil-water mixtures. Care must be exercised with all of these oils to provide adequate

ventilation for removal of oil vapors from the air and, thus, to prevent flash fires. This is especially important with some of the low-flash point, fast-quenching oils. The best way to control and minimize the presence of oil vapors is to supply a large amount of oil which completely covers the heated portion immediately below the inductor until the temperature of the quenched area is below the vaporization temperature of the oil.

Equally common and successful quenchants for induction hardening applications include polyvinyl alcohol solutions and compressed air. The former have become very popular in recent years and are used in hardening parts with borderline hardenability for which oil does not cool fast enough and water quenching leads to distortion or cracking. Unlike oil, polyvinyl alcohol, one of the so-called polymer quenchants, is not flammable and does not produce objectionable fumes or irritate the skin. Compressed-air quenching is typically used for high-hardenability, surface-hardened steels from which relatively little heat needs to be removed. Typical applications include gear teeth.

Quench Control. Adequate controls are necessary to ensure consistent results in induction heat treatment. Such controls for spray quenches include those for quenchant flow, temperature, timing, and so forth. The overall flow rate, *per se*, is controlled by adjustments of the pumping system itself. However, other considerations such as quench-device coupling and hole spacing in the quench device are also important. Often in single-shot operations, coupling--or the distance between the quench ring and part to be hardened--is very close, sometimes as little as 1.3 mm (0.051 in.). When several different sizes are to be treated, however, this distance may vary. Large distances are not desirable, however, because the velocity of the quenchant stream drops as the stream lengthens. This explains why the quench ring is often contoured to the part, that is, to maintain uniform coupling between the two.

The size and spacing of the orifices in the spray-quench device are a second important consideration in quench control. These can be adjusted to produce uniform quenching and avoid cracking or soft spots. Usually, this involves designs with many small holes rather than a few large ones. The lower limit on size is the minimum size that can be drilled on a production basis, as well as that which can be kept free of dirt. Also, smaller pieces heat treated by single-shot methods generally require smaller holes than large ones.

Spacing of the holes in the quench device must be such that each one has approximately the same amount of area to quench. Sometimes, staggering or overlapping of these areas is useful to be sure that the entire part is quenched. In practice, however, spacing may vary although the ratio of quench-device surface area to orifice area is typically about 10 to 1 or 20 to 1 for setups with narrow or wide coils, respectively. In either case, however, additional holes are placed at the end in order to provide quenchant flow to the ends of parts in single-shot applications.

The number of rows of holes in the quench device depends on the cooling rate necessary to harden the steel, the depth of heating (surface or through), the properties of the quench medium, the rate of travel (in scanning operations), and the configuration of the part. The desired surface finish may even affect the quench design and quench action. One of the major differences between quench rings for single-shot and scanning arrangements lies in the angular orientation of the holes. Single-shot spray-quench devices have orifices which are perpendicular (that is, radial) to the axis of the part. By contrast, the optimal angle between the axis of the holes and part axis in induction scanning setups is 30 °. This angle is selected to allow sufficient quenching action while at the same time preventing the quenchant from interfering with the heating part of the operation.

Control of the temperature of the quenching medium and its timing are also important. To this end, heat exchangers or cooling towers are often integral parts of an induction heating installation. In addition, electronic controls are often used to maintain timing of the quench cycle. This is particularly important when a tempering operation directly follows the hardening one or a so-called "autotempering" process is employed. In the former instance, the quench duration is typically adjusted so that the part temperature does not drop completely to room temperature. Leaving a small amount of residual heat in the component makes subsequent induction heating easier but does not affect the quality of the temper. In the latter case, the quench time may be controlled to bring the part temperature down precisely to tempering temperature, for instance, when a tempered pearlite or a tempered bainite microstructure is needed. Such an operation frequently involves precise temperature monitoring equipment and electronic feedback circuitry. One of the most interesting applications of this technique is the hardening and tempering of railroad rails (see the following section "Applications of Induction Heat Treatment"). Following austenitizing, the surface of the rail is air quenched to 425 °C (800 °F). Subsequently, the surface temperature climbs back to 595 °C (1100 °F) because of residual heat from the interior of the rail, leading to autotempering. Finally, a sustained cold-water quench is applied to bring the entire rail down to room temperature.

When quenching is done improperly, several problems may arise, including soft spots, quench cracks, and part distortion. Soft spots sometimes occur when water is used as the quenchant; they result from the formation of steam pockets on the part surface which prevent rapid enough cooling for the formation of martensite. As might be expected, this problem is

most severe in low-hardenability steels and can be alleviated by improved quench ring design or changes in the quenching device/part configuration. Quench cracks are typically due to one or more of four separate factors:

- Excessive quench severity (which is particularly troublesome in higher-carbon steels)
- Nonuniformity of quenching
- Changes in part contours with insufficient transitional areas
- Surface roughness (for example, tool marks)

Part distortion is commonly caused by relief of residual stresses, uneven heating, nonuniform quenching, or part geometry. In many cases, these can be controlled by modifications to the heating and quenching operations.

Applications of Induction Heat Treatment

Since its introduction in the 1930s, induction heat treatment has been applied to a large variety of mass-produced, commercial products. The initial applications involved hardening of the surfaces of axisymmetric steel parts such as shafts. Subsequently, surface-hardening techniques were developed for other parts whose geometries were not so simple. Most recently, induction hardening and tempering techniques have been developed for purposes of heat treating to large case depths and heat treating of entire cross sections. Types of parts to which induction is commonly applied include the following:

Surface-Hardening Applications

- *Transportation field:* crankshafts, camshafts, axle shafts, transmission shafts, splined shafts, universal joints, gears, valve seats, wheel spindles, and ball studs
- *Machine-tool field:* lathe beds, transmission gears, and shafts
- *Metalworking and hand-tool fields:* rolling-mill rolls, pliers, hammers, and so forth

Through-Hardening Applications

- Oil-country tubular products
- Structural members
- Spring steel
- Chain links

In this section, applications and advantages of induction methods of heat treatment for some of the parts listed above will be discussed.

Surface-Hardening Applications

Crankshafts for internal-combustion engines were probably the first parts to which induction hardening techniques were applied. Because the explosive forces of the engine must pass through the crankshaft, severe demands in terms of strength and wear resistance are placed on the steel used in manufacturing the crankshaft. These demands are ever-increasing with the rising horsepower ratings of engines used in automobiles, tractors, and other vehicles.

The most stringent demands are placed on the journal and bearing surfaces. Journals are the parts of the rotating shaft which turn within the bearings. Prior to the advent of induction heating, methods such as furnace hardening, flame hardening, and liquid nitriding were used. However, each of these processes presented problems such as inadequate or nonuniform hardening and distortion. Induction hardening overcomes many of these problems through rotation of the part during heat treating and selection of frequency and power to obtain adequate case depth and uniform hardness. In one of the most common steels used for crankshafts, 1045, case hardnesses of about 55 HRC are readily obtained. Other advantages of the induction process for crankshafts include:

- Only the portions which need to be hardened are heated, leaving the remainder of the crankshaft relatively soft for easy machining and balancing
- Induction hardening results in minimum distortion and scaling of the steel. The rapid heating associated with induction heat treating is advantageous in avoiding scaling in other applications as well
- Because induction heat-treating processes are automated, an induction tempering operation immediately following the hardening treatment is readily feasible
- The properties of induction hardened crankshafts have been found to be superior to those of crankshafts produced by other techniques. These properties include strength and torsional and bending fatigue resistance. These improvements have enabled crankshafts to be reduced in size and weight

Presently, crankshafts are being made from steel forgings as well as from cast iron. In the latter case, surface hardness levels of 50 HRC are easily obtainable after induction heating and air quenching. The resultant microstructure is a mixture of bainite and martensite, the pure martensite phase being avoided altogether. Such a dual microstructure minimizes the danger of crack formation at holes and eliminates the need for chamfering and polishing in these regions. The air quench allows residual heat left in the workpiece to minimize quench stresses and to autotemper the bainite which forms during cooling. After a prescribed period of time, the air quench is followed by a water quench during which the martensite phase is produced from the remaining austenite.

Axle shafts used in cars, trucks, and farm vehicles are, with few exceptions, surface hardened by induction. Although in some axles a portion of the hardened surface is used as a bearing, the primary purpose of induction hardening is to put the surface under a state of compressive residual stress. By this means, the bending and torsional fatigue life of an axle may be increased by as much as 200% over that for parts conventionally heat treated (Fig. 45). Induction hardened axles consist of a hard, high-strength outer case with good torsional strength and a tough, ductile core. Many axles also have a region in which the case depth is kept very shallow so that the part can be readily straightened following heat treatment. In addition to substantially improving strength, induction hardening is very cost-effective. This is because most shafts are made of inexpensive, unalloyed medium-carbon steels which are surface hardened to case depths of 2.5 to 8 mm (0.1 to 0.3 in.) depending on the cross-sectional size. As with crankshafts, typical hardness (after tempering) is around 50 HRC Such hard, deep cases improve yield strength considerably as well.

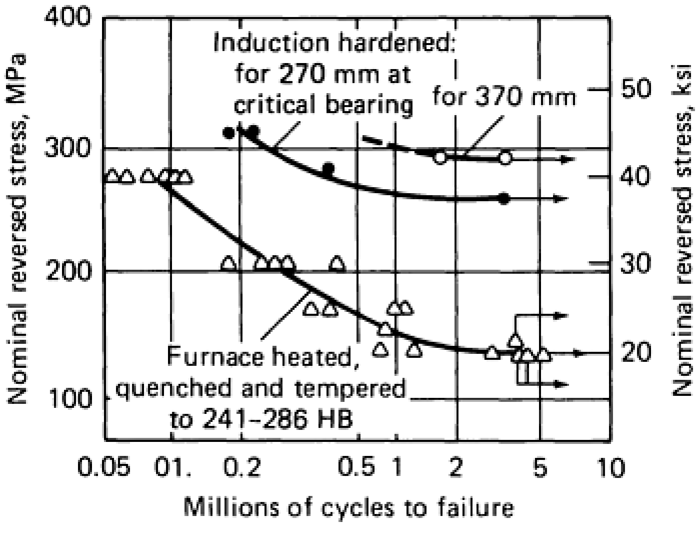

Fig. 45 Bending fatigue response of furnace hardened and induction hardened medium-carbon steel tractor axles. Shaft diameter: 70 mm (2.75 in.). Fillet radius: 1.6 mm (0.063 in.)

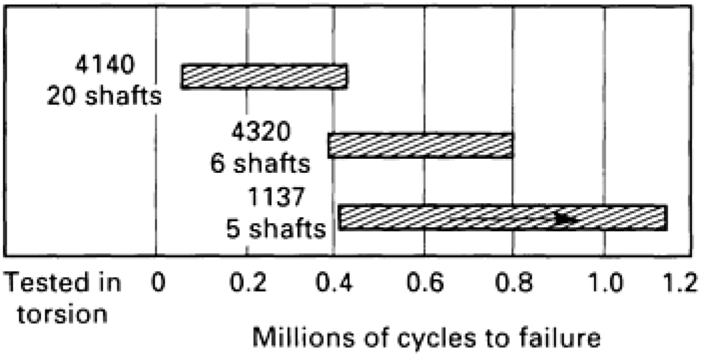
Modern transmission shafts --particularly those for cars with automatic transmissions--are required to have excellent bending and torsional strength besides surface hardness for wear resistance. Under well-controlled conditions, induction hardening processes are most able to satisfy these needs, as shown by the data in Fig. 46, which compares the fatigue resistance of through-hardened, case carburized, and surface induction hardened axles. The induction hardening methods employed are quite varied and include both single-shot and scanning techniques.



Steel	Surface hardness, HRC	Method of hardening
4140	36-42	Through-hardened
4320	40-46	Carburized to 1.0-1.3 mm (0.040-0.050 in.)
1137	42-48	Induction hardened 3.0 mm (0.120 in.) min effective depth and 40 HRC

Fig. 46 Comparison of fatigue life of induction surface hardened transmission shafts with that of through-hardened and carburized shafts. Arrow in lower bar (induction hardened shafts) indicates that one shaft had not failed after testing for the maximum number of cycles shown.

Induction hardening of crankshafts, axles, and transmission shafts is becoming an increasingly automated process. Often, parts are induction hardened and tempered in-line. One such line for heat treating of automotive parts is depicted schematically in Fig. 47. It includes an automatic handling system, programmable controls, and fiber-optic sensors. Mechanically, parts are handled by a quadruple-head, skewed-drive roller system (QHD) after being delivered to the heat-treatment area by a conveyor system. The roller drives, in conjunction with the chuck guides, impart rotational and linear motion to the incoming workpiece. Once a part enters the system, the fiber-optic sensor senses its position and initiates the heating cycle for austenitization. This sensor is also capable of determining if the operation is proceeding abnormally (for example, if the part is being fed improperly) and can automatically shut down the system.

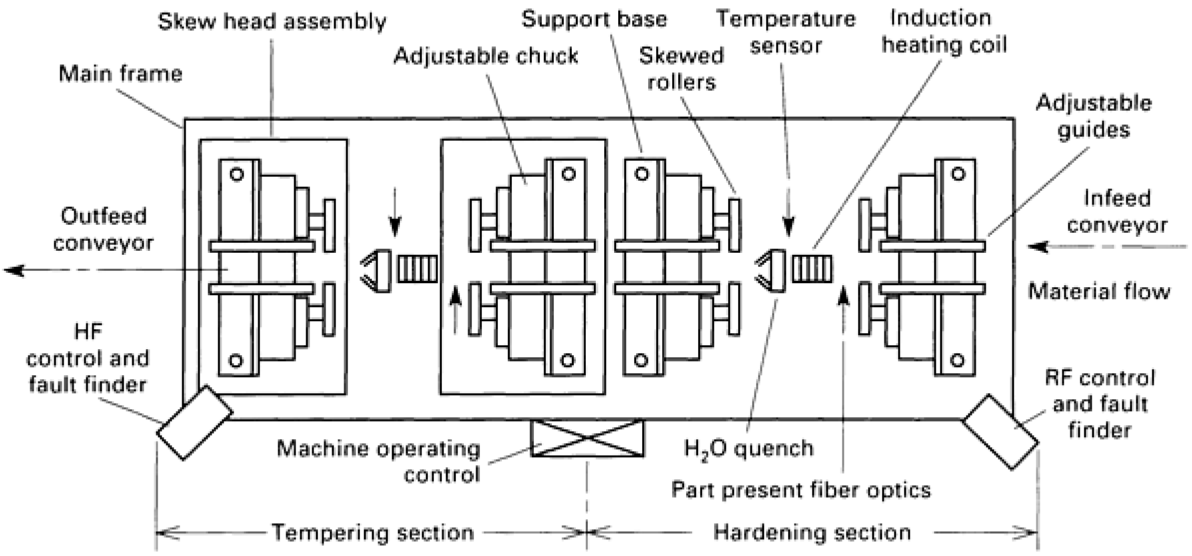


Fig. 47 Automated, quadruple-head, skewed drive roller system used for in-line induction hardening and tempering of automotive parts

In the hardening cycle of the QHD system, the induction generator frequency is generally either in the radio-frequency range (approximately 500 kHz) for shallow cases or in the range from 3 to 10 kHz for deeper cases. In either instance, a temperature controller automatically senses if the part has been heated to a temperature too high or too low, in order to prevent an improperly austenitized piece from passing through the system. Assuming that the part has been heated properly, it then passes through a quench ring, which cools it to a temperature of 95 °C (200 °F) to form a martensitic case, prior to moving into the tempering part of the heat-treatment line. Again, a fiber-optic system senses the presence of the part and begins the heating cycle, using low-frequency current generally around 3 kHz, since the desired tempering temperature is approximately 400 °C (750 °F)--a temperature at which the steel still has a large magnettic permeability. Once again, the part is automatically heated, quenched, and moved from the heat-treatment station, this time onto a conveyor which takes it to the machining area for grinding.

The control system of this line is designed to allow decision making by programmable controls. Thus, all aspects of the heat-treating process and mechanical operations are preprogrammed and may be changed easily to accommodate different part sizes and heat-treating parameters. With such a process users have been able to increase production rates more than threefold over those obtainable with conventional heat-treating lines.

Gears. Reliability and high dimensional accuracy (to ensure good fit) are among the requirements for gears such as those used in transmissions for farm equipment and related applications. Keeping distortion as low as possible during heat treatment is very important. Thus, induction is probably the best process for such parts. Among the other advantages of induction heat treatment of gears are the following:

- Gear teeth and roots can be selectively hardened
- Heating is rapid with minimum effect on adjacent areas
- Uniform hardening of all contact areas results in high wear resistance. The improvement of wear resistance often permits substitution of inexpensive steels, such as 1045 or 1335, for more highly alloyed steels

When using induction, however, extreme care is needed in positioning the gear in relation to the coil, particularly in setups in which all gear teeth are heated and hardened at once. In these instances, the coil goes entirely around the gear, and a quench ring concentric to it is used (Fig. 48a). A typical hardening pattern for this kind of arrangement is shown in Fig. 48(b). In such single-shot setups, a two-stage process is often preferable, however. In the first step, a relatively low frequency is used for heating of the root diameter of the gear and for partial heating of the flank areas between the roots and tooth tips. Then, the tooth tips themselves are heated with a much higher radio frequency. As with surface hardening of shafts, gears are usually rotated during processing to effect uniformity of heating and hardening. Part transfer between

stations in this and similar processes is carried out by specialized Systems or robots. In this way, a uniform or contoured hardness pattern which follows the outline of the gear is obtained. This hardness pattern improves not only the wear resistance of the teeth, but their bending strength as well. Modifications of single-shot techniques may be employed for preferential hardening of only certain portions of the teeth, such as tooth tips or flank regions, depending on specific applications. Unfortunately, as the gear becomes larger, the capacity of the induction generator needed for surface hardening increases dramatically, as shown in Table 12 for various gear geometries.

Table 12 Power requirements for induction hardening of gear teeth

Tooth	Diametral pitch	Approximate length of tooth profile		Surface area per tooth[(a)]		Power required per tooth[(b)], kW	Total power required[(c)], kW
		mm	in.^{2}	cm^2	in.^{2}		
A	3	50	2.0	12.9	2.0	20	800
B	4	38	1.5	9.7	1.5	15	600
C	5	33	1.3	8.4	1.3	13	520
D	6	25	1.0	6.5	1.0	10	400
E	7	23	0.9	5.8	0.9	9	360

(b) At a power density of 1.55 kW/cm^2 (10 kW/in.^{2}).

(c) For a gear having 40 teeth

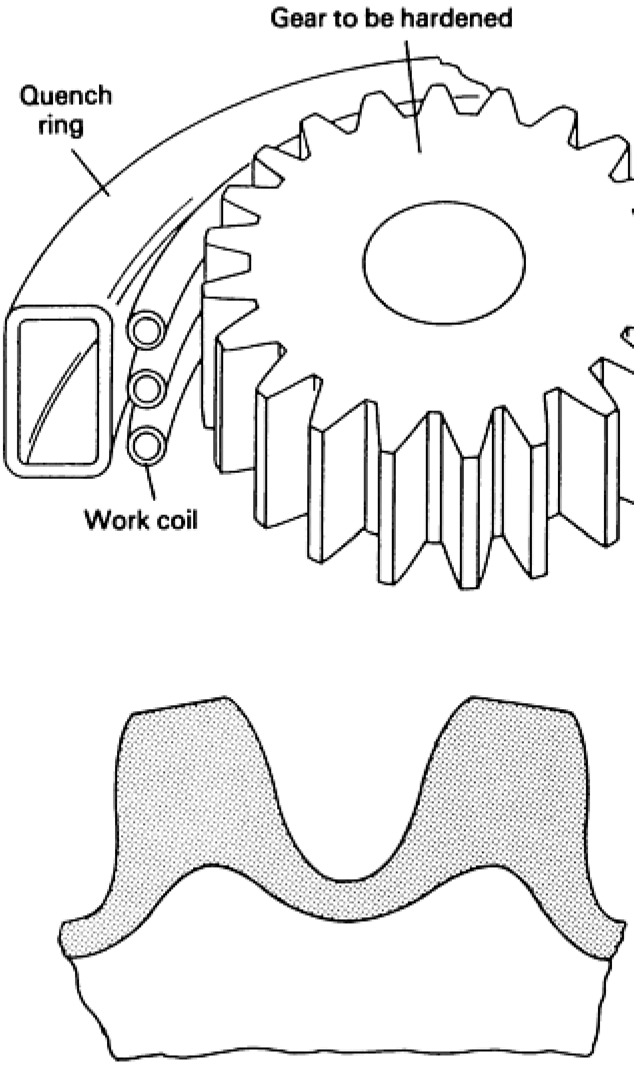

Fig. 48 Induction hardening of gear teeth by a single-shot technique. (a) Solenoid coil and concentric quench ring around gear to be hardened. (b) Schematic of case-hardness pattern obtained with such an arrangement

An alternative technique for surface hardening of gears is the so-called tooth-by-tooth technique. As the name implies, each tooth is individually heated and quenched. By this means, induction generators of modest capacity can be used for large gears which otherwise would require large coils and large amounts of power. A typical inductor for such a process consists of a copper coil that is slightly larger than the gear tooth (Fig. 49). If only flank and root hardening are desired, a coil whose outer corners are chamfered is employed (Fig. 50a). Without the chamfers, the tooth tips would be heated as well, often in a very nonuniform manner. Alternatively, auxiliary water sprays, which are used for quenching, may be adjusted to cool the tooth tips (Fig. 50b), or the coil can be shortened.

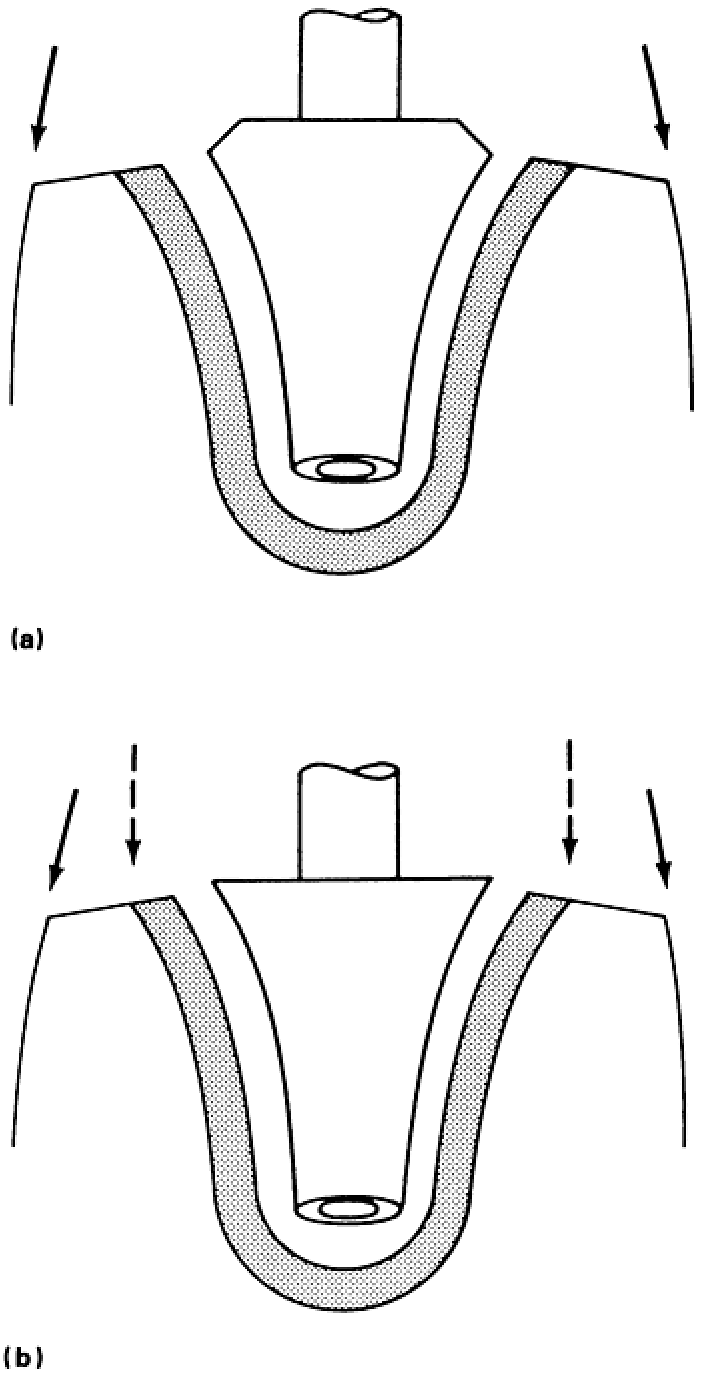

Fig. 50 Inductor designs for tooth-by-tooth hardening of gear flanks. (a) Inductor design with chamfered corners. (b) Inductor design without chamfers in which tooth-tip hardening is prevented by adjusting water sprays. In both sketches, arrows indicate direction of preferred water spray; solid arrows in (a) and dashed arrows in (b).

Valve seats in automobiles are yet another application of surface hardening by induction. Prior to the advent of catalytic converters and the need to use unleaded gasoline, wear resistance of valve seats was afforded by deposits of lead oxide. These deposits acted as a lubricant between the seat and valve. Without the lead oxide from gasoline, other means of preventing premature valve wear were required. In order to avoid the expense of hardened inserts, an induction heat-treating method by which all the seats in a single engine head can be processed at one time was developed. This is done with a specially designed machine in which the surfaces are heated rapidly and self-quenched to produce a case depth of 1.8 to 2 mm (0.06 to 0.08 in.) and a hardness of 50 to 55 HRC. Figure 51 shows the improvement over untreated parts that such processing affords. The durability of the induction hardened seats is even superior to that of conventional seats in engines which use leaded fuel.

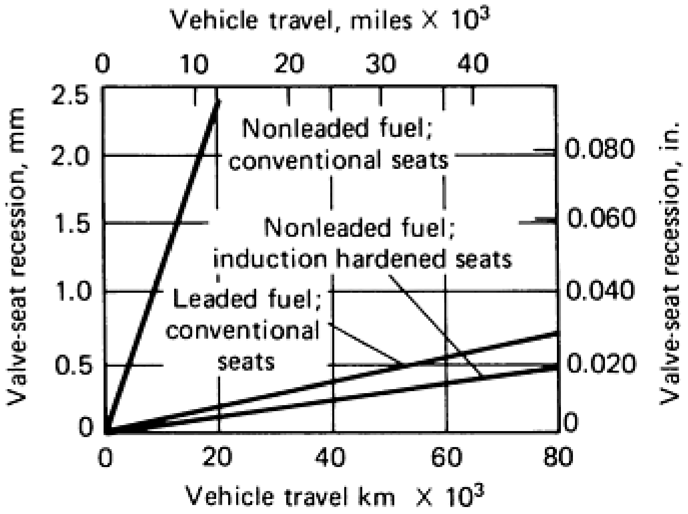

Fig. 51 Effect of induction surface hardening on wear of engine valve seats

Railroad Rails. Surface hardening of railroad rails is one of the more recent applications of heat treatment. The heads (top portions) of rails wear rapidly in curved sections where high-tonnage freight-car traffic is common. The abrasive action of the wheels combined with high stresses can result in a very short rail life, sometimes as little as one year or less. With the move toward heavier cars and increased speeds, these kinds of problems are becoming more severe.

Conventional railroad rails are manufactured from 1080 steel by hot (shape) rolling using a preheat temperature of 1290 °C (2350 °F). Following rolling, they are controlled cooled, and a finished product of only moderate hardness (250 HB $\approx$ 24.5 HRC) results. In the induction process, only the head of the rail is hardened since this is where failure takes place because of wear or deformation during service. A relatively thick case whose hardness decreases with depth (Fig. 52) is achieved by using a relatively low-frequency (approximately 1000 Hz) power source. In the actual process, rails are prebent (elastically) before heat treatment to offset distortions caused by heating and to eliminate the need for final straightening operations. The rails are then fed continuously through a U-shaped inductor and their surfaces heated to 1065 °C (1950 °F). Following heating, the surface is air quenched to 425 °C (800 °F), producing a bainitic microstructure. Residual heat left in the interior of the rail brings the surface layers back to a temperature of 595 °C (1100 °F), thereby bringing about autotempering. Finally, a controlled cold-water quench is applied to cool the rail to room temperature and to ensure straightness. Rails produced thereby have been found to last from $2\frac{1}{2}$ to 8 times as long as conventionally manufactured rails.

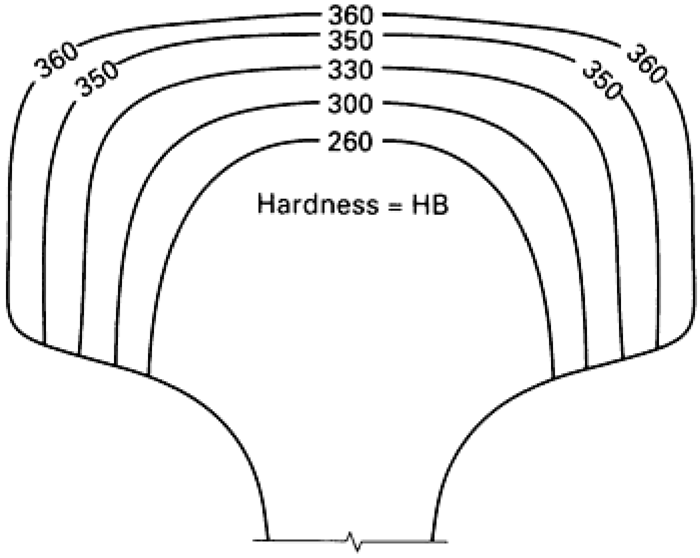

Fig. 52 Brinell hardness pattern in induction surface hardened railroad rail

Rolling-Mill Rolls. Induction hardening of rolling-mill rolls is analogous to induction hardening of rails in that relatively deep cases are produced. During service, roll life is limited by abrasive wear. As the diameter is reduced by wear, adjustments are made to bring the rolls closer together in order to maintain a given rolling reduction. These adjustments are sufficient until the rolls have worn approximately 40 mm (1.5 in.); once this amount of wear is exceeded, the rolls must be replaced. The objective of induction heat treatment is, therefore, to produce a hardened case approximately 20 to 40 mm (0.75 to 1.5 in.) deep. This is done employing a low-frequency (60 Hz) power supply.

In the scanning method of induction hardening, the roll, hanging vertically, is lowered into the induction coil, in which its surface temperature is gradually raised to 955 °C (1750 °F). By controlling the power input and feed rate, a temperature profile is developed such that the temperature ranges from 900 °C (1650 °F) at 40 mm (1.5 in.) below the surface to less than 260 °C (500 °F) at 40 mm (2 in.) below the surface. Following heating, the roll is quenched using water precooled to 5 °C (40 °F). Because roll steels usually contain 0.8 to 0.9% C and substantial amounts of nickel, chromium, molybdenum, and vanadium, they have high hardenability and develop high hardness to the entire depth to which the steel was austenitized. A typical hardness profile is shown in Fig. 53. Here, the drop in hardness beyond about 25 mm (1 in.) can be attributed to heat losses due to conduction, which could have resulted in the formation of pearlite or bainite prior to quenching, at which time the remaining austenite would have transferred to martensite.

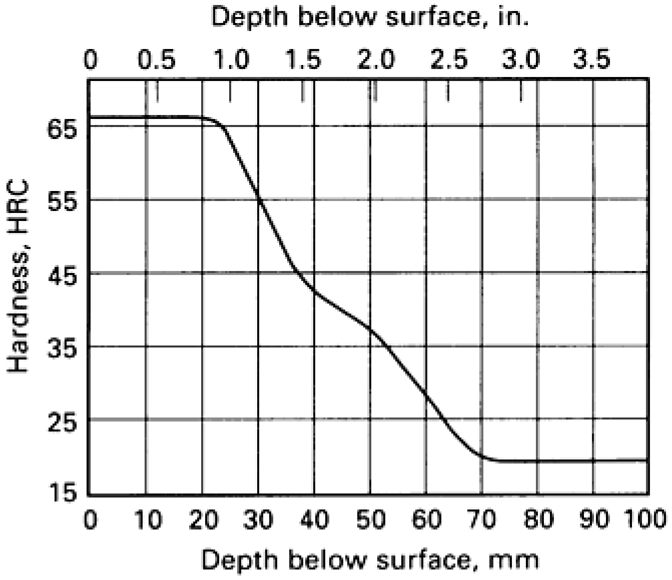

Fig. 53 Hardness pattern developed in rolling mill rolls induction hardened using a 60 Hz generator

Miscellaneous Applications. There are many other applications of induction surface hardening. These include uses in the ordnance, hand-tool, and automotive fields.

In the ordnance area, induction heating has been used for both surface hardening and through-hardening of armor-piercing projectiles. The induction process allows a very uniform bainitic microstructure to be obtained. During World War II, it was found that batch furnace heat treatment could not produce as uniform and high-quality a product at such a low cost as could the induction method.

Induction heating has also been found useful for selective through-hardening and surface hardening of heads for tools such as hammers, axes, picks, and sledges. These tools are usually made of 1078 steel. Lead baths were once used in the hardening of such parts, but use of lead baths has diminished because of health and safety regulations. Other applications include steels for automobile coil springs, leaf springs, and torsion bars and wheel spindles.

Through-Hardening Applications

Although not as common as surface hardening and tempering, through-hardening and tempering via induction methods have been found to be practical for a number of applications such as piping, structural members, saw blades, and garden tools.

Pipe-Mill Products. Probably the largest application of induction through-hardening (and tempering) involves piping or tubular goods used for oil wells and gas pipelines, for example. For these uses, relatively low-frequency induction generators are selected so that the reference depth is of the same order of magnitude as the wall thickness of the workpiece. Since the workpiece is hollow, there is no problem of loss of electrical efficiency arising from the eddy-current cancellation such as the losses which occur at the centers of solid bars. In fact, to a point, the efficiency of induction heating of tubular products increases as the wall thickness decreases, because the resistance of the material increases with decreasing wall thickness and becomes much larger than that of the coil. However, if the thickness is very small, the current developed in the workpiece goes down and relatively little I^2R heat is generated.

Pipe-mill products fall into two major categories: electric resistance welded (ERW) and seamless. The ERW pipe is made from steel strip which is formed and welded. After welding, the weld may be annealed to avoid cracking during shipment or subsequent operations, which may include reduction to obtain a smaller diameter or different wall thickness. In any case, ERW products tend to have a very uniform wall thickness, which is an important consideration in induction heating and heat treatment. Nonuniformities in wall thicknesses usually lead to temperature nonuniformities; thicker regions are heated to lower temperatures than thinner ones during induction heat treatment. In contrast to ERW pipe, seamless piping tends to have a much less uniform wall thickness. It is manufactured by piercing and extruding a heated, round-cornered square billet. To maintain quality, seamless piping for oil-country applications is typically required to have a wall thickness variation of no more than 12.5%. Because of its uniformity, ERW pipe is the preferred choice for induction heat treatment.

In a typical installation for heat treatment of piping, processing is carried out in a continuous line in which the steel is austenitized, quenched, tempered, and finally cooled to room temperature at successive stations. A typical arrangement is depicted in Fig. 54. In this system, each pipe is loaded onto an entry table and fed onto the conveyor as soon as the heat treatment of the pipe preceding it is completed. As each pipe passes through the austenitizing station (consisting of five coils), it is rotated on skewed rollers to ensure temperature uniformity. Also, because only a small portion of the pipe is heated at one time, distortion is readily controlled. Using 180-Hz current, pipes are heated uniformly through the thickness to approximately 900 °C (1650 °F). A suitable power density is chosen for this purpose as well. With a maximum generator capacity of 4500 kW, piping up to 405 mm (16 in.) in outside diameter can be handled by the austenitizing unit. For this largest diameter, the 1.5 m (5 ft) length of the heating section results in a maximum power density of roughly 0.23 kW/cm^2 (1.5 kW/in.^{2}), assuming 100% efficiency, when the total power of the generator is utilized.

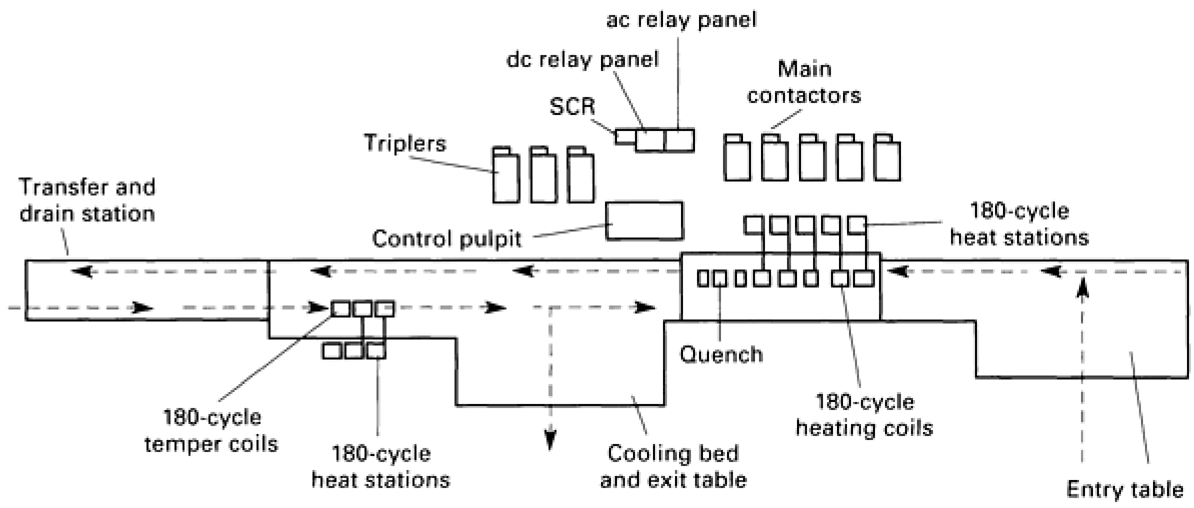

Fig. 54 Schematic diagram of equipment used for in-line induction through hardening and tempering of pipe-mill products. Pipe enters from the right, is austenitized, quenched, drained, and tempered. Following tempering, the pipe is transferred to cooling beds for air cooling.

After austenitizing, the pipe enters the quench ring several feet down the line. After the water has been drained off, the pipe moves to the tempering station which is powered by generators with a total capacity of 2700 kW and also at a frequency of 180 Hz. The power capacity for this operation is lower than that for austenitizing because the workpiece is heated to temperatures of only about 540 to 650 °C (1000 to 1200 °F). Following tempering, the pipe continues along the conveyor to cooling beds and is rotated during the entire cooling cycle to ensure straightness and lack of ovality.

Structural Members and Bar Stock. A process similar to hardening and tempering of pipe-mill products is used to heat treat structural members of uniform section thickness. In these cases, the structural member is passed through a series of induction preheating and heating stages for austenitizing and then is quenched while being restrained by a set of rolls which prevent distortion. The various coils for austenitizing are connected to generators of frequencies ranging from 180 Hz (preheating) to 10 kHz (final heating stages) in processing of steel shapes 6 to 13 mm (0.25 to 0.5 in.) in section thickness. After quenching, the structural shape is tempered in-line using induction heating frequencies of 180 to 3000 Hz and is prevented from distorting during subsequent cooling by another set of restraining rolls.

The above process is used to make high-strength structural members from 1025 steel strip in the form of U-channels, T's, and I-sections. For U-channels, a variety of coil designs are possible. These include hairpin, oval, pancake, and L-shape coils, all of which induce eddy currents whose paths lie in the plane of the structural member and which follow directions similar to those of the currents in the coil.

Miscellaneous Applications. Other induction hardening and tempering applications are often very specialized, requiring special coil designs and control of heating. Typical examples include hardening and tempering of circular-saw blade segments, garden trimmer blades, snow plow blades, and coil springs.

Process and Quality Control Considerations

Induction heat treatment precludes many of the problems associated with furnace methods. Among its advantages is the rapid heating that can be achieved. For this reason, induction heat treatment is particularly well-suited to high-volume continuous heat-treatment operations. With the advent of microprocessor technology, the controls necessary for such techniques have become readily available. The rate of heating is limited only by the power rating of the ac power supply. Because heating times are usually short, surface problems such as scaling and decarburization and the need for protective atmospheres can often be avoided. In addition, induction tends to be energy-efficient. With proper coil design and equipment selection, more than 80% of the electrical energy can be converted into heat for treatment of the workpiece. Such efficiencies are not possible with gas-fired furnaces, in which a fairly substantial proportion of the consumed energy is lost with the hot gases leaving the furnaces. Induction heating is also free of pollution.

Among the disadvantages of induction are those related to coil design and equipment selection, both of which must be tailored to the particular part to be heat treated and the temperature at which the heat treatment is to be carried out. In the

automotive and oil-drilling equipment industries, production rates are high and the induction heat-treating method finds wide application. In situations where only a few parts of a given design are to be made, induction heat treatment is usually not economically feasible.

Temperature Sensing. A kilowatt time meter can sense the amount of energy applied to the output of an induction heater, and providing all other conditions remain the same, it can be a good measure of the heat energy in the product. Besides temperature, energy usage can also be evaluated with kilowatt-time meters. However, the principal methods of temperature measurement utilize thermocouples, radiation sensing, or eddy current sensing. Each has its limitations.

Spring loaded thermocouples are used to measure and control the temperature of softer, nonferrous metals during an induction heating cycle. Thermocouples can be attached to parts, and measurement is then quite accurate, but only at the place where the thermocouple is attached. Because of the work involved in attaching and detaching, this temperature measurement technique is limited to test work or for very slow programmed heating applications such as stress relieving welds on installed piping systems.

Radiation Sensing. More typically, induction heating operations are monitored by sensing the energy radiated from the surface. Infrared systems of the two and three color variety are most widely used, but the work should be free of loose scale to obtain useful readings. Emissivity must not vary a great deal to obtain reliable readings and shiny surfaces are poor targets (see the article "Furnace Temperature Control" in this Volume for more information on temperature measurement by radiation sensing).

A basic disadvantage of temperature measurement by surface radiation is that the system only measures surface temperature; it tells nothing about the temperature profile, which is so important to surface hardening. The accuracy is also subject to vagaries in the surface condition of the metal.

Eddy Current Sensing. In the method of eddy current sensing, electrical conditions of the metal are sensed through the induction heating field, providing comparative sensing of both temperature and current depth in iron and steel, particularly when the metal is austenitized. The electrical resistivity (ρ) and the depth of current penetration (Eq 1) in a metal both increase with temperature, thus changing the eddy currents and heating pattern as the temperature rises. In addition, the magnetic permeability of ferromagnetic steel also changes with temperature, with the most dramatic change occurring at the Curie temperature where relative permeability drops to unity. Because the steep drop to a permeability of 1 occurs as the metal approaches its transformation to austenite, the sensing of this radical electrical change is most significant in hardening, and annealing or normalizing steel or cast iron.

By measuring the characteristics of the induction heating field (phase, amplitude, and frequency) in real time, the electrical and magnetic changes during heating can provide a signature that relates to the metal temperature and the temperature profile. This can then be used to critically monitor the process throughout the heating cycle. Eddy current sensing technology is thus a means for determining proper heating during the induction cycle. Improper part positioning, gross differences in microstructure, cracks, and other abnormalities may also be sensed, sometimes at the moment of power-on in which power can be removed immediately. Because the electrical load condition information during each cycle is fed into a computer, any trend to deviate from a normal signature overtime can be transmitted to a statistical computer program for analysis and correction.

Cost Factors in Induction Heat Treating. On just the basis of energy costs, induction heating seldom competes with gas or even oil. However, because of its ability to rapidly heat metal, savings may accrue from reduced processing time, increased production, reduced labor, or the ability to heat treat in a production line or automated manufacturing system. Surface and selective hardening may be energy competitive because a small portion of the metal is heated.

Hardening by induction may also enable one to use a plain carbon grade of steel instead of a more expensive alloy steel. The inherently short heating time of induction heating permits the use of higher austenitizing temperatures than with conventional heating practices. Consequently, it is generally possible to obtain satisfactory hardness with lower carbon steels using such higher temperatures.

Control of Surface Hardness. The ultimate surface hardness depends on the carbon content of steel. When the carbon content of the steel exceeds about 0.50%, additional carbon content has no effect on the hardness obtained; however, there is a pronounced effect on the ease of obtaining full hardness. During selective surface hardening, the quenching rate may be faster than a through heated material and a slightly higher hardness value may be achievable. Residual stresses from

selective heating and quench may also add a point or two to the readable hardness, which at one time was termed superhardness.

Low hardness values measured on an induction hardened part may be caused by any one of the following:

- Surface decarburization
- Lower carbon content than specified
- Inadequate austenitizing temperature
- Prior structure
- Retained austenite (mostly in high-carbon alloy steels)
- Unsatisfactory quenching

These problems are not unique to induction hardening, although the methods of correction may involve different options. In the event of inadequate austenitizing temperatures, for example, an adequate temperature can be achieved by increasing power density and/or heating time.

Distortion of Induction Hardened Steel. Steel parts that have been surface hardened by induction generally exhibit less total distortion or distortion more readily controllable than that for the same parts quenched from a furnace. The decrease in distortion is a result of the support given by the rigid, unheated core metal, and of uniform, individual handling during heating and quenching. In scanning, distortion is controlled further by heating and quenching only a narrow band of the steel at one time. Unless a part through hardened by induction is scanned, the distortion encountered will approach the distortion that is experienced in furnace hardening.

As in furnace heat treating, the distortion from induction hardening arises during austenitizing or quenching. Distortion during austenitizing usually results from relief of residual stresses introduced during forging, machining, and so forth, or from nonuniform heating. When the part is only surface austenitized and hardened, the cool metal in the core of the workpiece minimizes distortion. Small amounts of distortion in induction surface hardened parts with shallow cases are often eliminated by means of a subsequent mechanical sizing (for example, straightening) operation. Furthermore, the use of induction scanning, in which only a small portion of the workpiece is heated at any one time, is helpful in preventing problems of this type. Scanning is also helpful in keeping distortion levels low in through-hardening applications. In these instances, rotation of the part, provided that it is symmetrical, enhances the uniformity of heating and decreases the likelihood of non-uniformities in the final shape.

Distortion resulting from quenching is largely a function of the austenitizing temperature, the uniformity of the quench, and the quench medium. Higher austenitizing temperatures, which give rise to higher residual stresses, increase the amount of non-uniform contraction during cooling. Severe quenches such as water or brine, which also tend to produce high residual stresses, can lead to severe distortions as well. This problem can be especially troublesome when alloy steels are quenched in water. However, these steels usually have sufficient hardenability such that oil can often be employed instead.

In extreme cases, distortion may lead to cracking. This cracking is intimately related to part design, as well as to the residual stresses which are developed. Components with large discontinuities in cross section are particularly difficult to heat treat for this reason. In addition, there often is a limiting case depth beyond which cracking will occur; in these instances, tensile stresses near the surface of the induction hardened part, which balance the compressive residual stresses generated, can be blamed for the cracking problem.

Steel composition also plays a role in the tendency toward cracking in induction hardening applications. This tendency increases as the carbon or manganese content is increased. This is not to say, however, that critical levels of either element can be specified, because other factors such as case depth (in surface hardening applications), part design, and quench medium are also important. The effect of carbon content on the tendency toward quench cracking is greatest in through-hardened parts and arises because of its influence on the depression of the martensite-start (M_s) temperature and the hardness of the martensite.

Cold Treating and Cryogenic Treatment of Steel

Revised by Earl A. Carlson, Lindberg Heat Treating Company

Introduction

COLD TREATING of steel is widely accepted within the metallurgical profession as a supplemental treatment that can be used to enhance the transformation of austenite to martensite and to improve stress relief of castings and machined parts. Common practice identifies -84 °C (-120 °F) as the optimum temperature for cold treatment. There is evidence, however, that cryogenic treatment of steel, in which material is brought to a temperature of the order of -190 °C (-310 °F), improves certain properties beyond the improvement attained at cold-treatment temperatures. This discussion will explain the practices employed in the cold treatment of steel and will present some of the experimental results of using cryogenic treatment to enhance steel properties.

Cold Treating of Steel

Cold treatment of steel consists of exposing the ferrous material to subzero temperatures to either impart or enhance specific conditions or properties of the material. Increased strength, greater dimensional or microstructural stability, improved wear resistance, and relief of residual stress are among the benefits of the cold treatment of steel. Generally, 1 h of cold treatment for each inch of cross section is adequate to achieve the desired results.

All hardened steels are improved by a proper subzero treatment to the extent that there will be less tendency to develop grinding cracks and therefore they will grind much more easily after the elimination of the retained austenite and the untempered martensite.

Hardening and Retained Austenite

Whenever hardening is to be done during heat treating, complete transformation from austenite to martensite is generally desired prior to tempering. From a practical stand-point, however, conditions vary widely, and 100% transformation rarely, if ever, occurs. Cold treating may be useful in many instances for improving the percentage of transformation and thus for enhancing properties.

During hardening, martensite develops as a continuous process from start (M_s) to finish (M_f) through the martensite-formation range. Except in a few highly alloyed steels, martensite starts to form at well above room temperature. In many instances, transformation is essentially complete at room temperature. Retained austenite tends to be present in varying amounts, however, and when considered excessive for a particular application, must be transformed to martensite and then tempered.

Cold Treating versus Tempering. Immediate cold treating without delays at room temperature or at other temperatures during quenching offers the best opportunity for maximum transformation to martensite. In some instances, however, there is a risk that this will cause cracking of parts. Therefore, it is important to ensure that the grade of steel and the product design will tolerate immediate cold treating rather than immediate tempering. Some steels must be transferred to a tempering furnace when still warm to the touch to minimize the likelihood of cracking. Design features such as sharp corners and abrupt changes in section create stress concentrations and promote cracking.

In most instances, cold treating is not done before tempering. In several types of industrial applications, tempering is followed by deep freezing and retempering without delay. For example, such parts as gages, machineways, arbors, mandrils, cylinders, pistons, and ball and roller bearings are treated in this manner for dimensional stability. Multiple freeze-draw cycles are used for critical applications.

Cold treating is also used to improve wear resistance in such materials as tool steels, high-carbon martensitic stainless steels, and carburized-alloy steels for applications in which the presence of retained austenite may result in excessive wear. Transformation in service may cause cracking and/or dimensional changes that can promote failure. In some

instances, more than 50% retained austenite has been observed. In such cases, no delay in tempering after cold treatment is permitted, or cracking can develop readily.

Process Limitations. In some applications in which explicit amounts of retained austenite are considered beneficial, cold treating might be detrimental. Moreover, multiple tempering, rather than alternate freeze-temper cycling, is generally more practical for transforming retained austenite in high-speed and high-carbon/high-chromium steels.

Hardness Testing. Lower than expected HRC readings may indicate excessive retained austenite. Significant increases in these readings as a result of cold treatment indicate conversion of austenite to martensite. Superficial hardness readings, such as HR15N, can show even more significant changes.

Precipitation-Hardening Steels. Specifications for precipitation-hardening steels may include a mandatory deep freeze after solution treatment and prior to aging.

Shrink Fits. Cooling the inner member of a complex part to below ambient temperature can be a useful way of providing an interference fit. Care must be taken, however, to avoid the brittle cracking that may develop when the inner member is made of heat-treated steel with high amounts of retained austenite, which converts to martensite on subzero cooling.

Stress Relief

Residual stresses often contribute to part failure and frequently are the result of temperature changes that produce thermal expansion and phase changes, and consequently, volume changes.

Under normal conditions, temperature gradients produce nonuniform dimensional and volume changes. In castings, for example, compressive stresses develop in lower-volume areas, which cool first, and tensile stresses develop in areas of greater volume, which are last to cool. Shear stresses develop between the two areas. Even in large castings and machined parts of relatively uniform thickness, the surface cools first and the core last. In such cases, stresses develop as a result of the phase (volume) change between those layers that transform first and the center portion, which transforms last.

When both volume and phase changes occur in pieces of uneven cross section, normal contractions due to cooling are opposed by transformation expansion. The resulting residual stresses will remain until a means of relief is applied. This type of stress develops most frequently in steels during quenching. The surface becomes martensitic before the interior does. Although the inner austenite can be strained to match this surface change, subsequent interior expansions place the surface martensite under tension when the inner austenite transforms. Cracks in high-carbon steels arise from such stresses.

The use of cold treating has proved beneficial in stress relief of castings and machined parts of even or nonuniform cross section. The following are features of the treatment:

- Transformation of all layers is accomplished when the material reaches -84 °C (-120 °F)
- The increase in volume of the outer martensite is somewhat counteracted by the initial contraction due to chilling
- Rewarm time is more easily controlled than cooling time, allowing equipment flexibility
- The expansion of the inner core due to transformation is somewhat balanced by the expansion of the outer shell
- The chilled parts are more easily handled
- The surface is unaffected by low temperature
- Parts that contain various alloying elements and that are of different sizes and weights can be chilled simultaneously

Advantages of Cold Treating

Unlike heat treating, which requires that temperature be precisely controlled to avoid reversal, successful transformation through cold treating depends only on the attainment of the minimum low temperature and is not affected by lower temperatures. As long as the material is chilled to -84 °C (-120 °F), transformation will occur; additional chilling will not cause reversal.

Time at Temperature. After thorough chilling, additional exposure has no adverse effect. When heat is used, holding time and temperature are critical. In cold treatment, materials of different compositions and of different configurations may be chilled at the same time, even though each may have a different high-temperature transformation point. Moreover, the warm-up rate of a chilled material is not critical as long as uniformity is maintained and gross temperature-gradient variations are avoided.

The cooling rate of a heated piece, however, has a definite influence on the end product. Formation of martensite during solution heat treating assumes immediate quenching to ensure that austenitic decomposition will not result in the formation of bainite and cementite. In large pieces comprising both thick and thin sections, not all areas will cool at the same rate. As a result, surface areas and thin sections may be highly martensitic, and the slower-cooling core may contain as much as 30 to 50% retained austenite. In addition to incomplete transformation, subsequent natural aging induces stress and also results in additional growth after machining.

Aside from transformation, no other metallurgical change takes place as a result of chilling. The surface of the material needs no additional treatment. The use of heat frequently causes scale and other surface deformations that must be removed.

Equipment for Cold Treating

A simple home-type deep freezer can be used for transformation of austenite to martensite. Temperature will be approximately -18 °C (0 °F). In some instances, hardness tests can be used to determine if this type of cold treating will be helpful. Dry ice placed on top of the work in a closed, insulated container also is commonly used for cold treating. The dry ice surface temperature Is -78 °C (-109 °F), but the chamber temperature normally is about -60 °C (-75 °F).

Mechanical refrigeration units with circulating air at approximately -87 °C (-125 °F) are commercially available. A typical unit will have the following dimensions and operational features: chamber volume, up to 2.7 m^3 (95 ft^3); temperature range, 5 to -95 °C (40 to -140 °F); load capacity, 11.3 to 163 kg/h (25 to 360 lb/h); and thermal capacity, up to 8870 kJ/h (8400 Btu/h).

Although liquid nitrogen at -195 °C (-320 °F) may be employed, it is used less frequently than any of the above methods because of its cost.

Cryogenic Treatment of Steels

The value of cryogenic treatment of steel and other materials has been debated for many years; even today many metallurgical professionals have serious reservations about its value. Notwithstanding these concerns, it is the intent of this discussion to review some of the current literature and practices of those who believe that cryogenic treatment enhances steel properties.

Cryogenic Treatment Cycles

Typical cryogenic treatment consists of a slow cool-down (~2.5 °C/min, or 4.5 °F/min) from ambient temperature to liquid nitrogen temperature. When the material reaches approximately 80 K (-315 °F), it is soaked for an appropriate time (generally 24 h). At the end of the soak period, the material is removed from the liquid nitrogen and allowed to warm to room temperature in ambient air. The temperature-time plot for this cryogenic treatment is shown in Fig. 1. By conducting the cool-down cycle in gaseous nitrogen, temperature can be controlled accurately and thermal shock to the material is avoided. Single-cycle tempering is usually performed after cryogenic treatment to improve impact resistance, although double or triple tempering cycles are sometimes used.

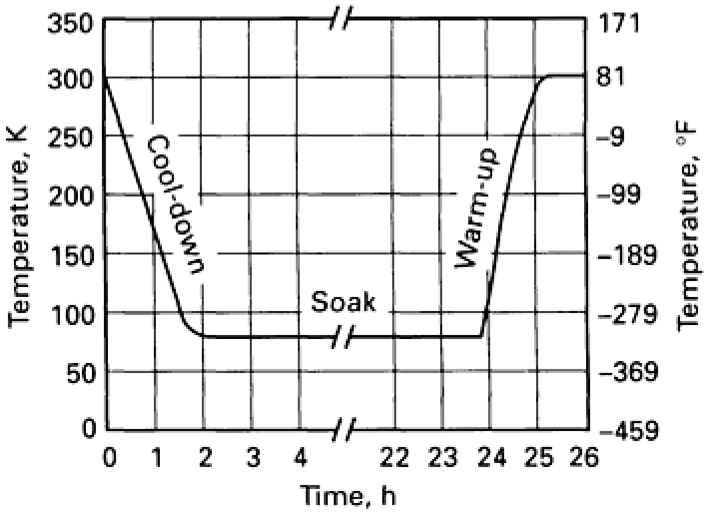

Fig. 1 Plot of temperature versus time for the cryogenic treatment process. Source: Ref 1

Kinetics of Cryogenic Treatment

There are several theories concerning reasons for the effects of cryogenic treatment. One theory involves the more nearly complete transformation of retained austenite into martensite. This theory has been verified by x-ray diffraction measurements. Another theory is based on the strengthening of the material brought about by precipitation of submicroscopic carbides as a result of the cryogenic treatment. Allied with this is the reduction in internal stresses in the martensite that happens when the submicroscopic carbide precipitation occurs. A reduction in microcracking tendencies resulting from reduced internal stresses is also suggested as a reason for improved properties.

The absence of a clear-cut understanding of the mechanism(s) by which cryogenic treatment improves performance has hampered its widespread acceptance by metallurgists. Nonetheless, it is important to review the studies done to determine the effects of cryogenic treatment on the performance of steel in a variety of applications.

Case Studies of Cryogenically Treated Steels

Resistance to abrasive wear was investigated in a parametric study. Five tool steels were tested after conventional heat treatment, after cold treatment at -84 °C (-120 °F), and after being cryogenically treated at -190 °C (-310 °F). Figure 2 and Table 1 show the results of these abrasive wear tests. Cold treatment at -84 °C (-120 °F) improved the wear resistance by 18 to 104%, but the cryogenic treatment results show 104 to 560% improvement.

Table 1 Wear resistance as a function of cryogenic soak temperature for five high-carbon steels. (Data taken in the Department of Mechanical Engineering, Louisiana Tech University, Ruston, Louisiana, April 9-30, 1973).

Alloy	Wear resistance, R_W[(a)]		
	Untreated	Soaked	
		-84 °C (-120 °F)	-190 °C (-310 °F)
52100	25.2	49.3	135
D2	224	308	878

A2	85.6	174.9	565
M2	1961	2308	3993
O1	237	382	996

Source: Ref 2

(a) $R_W = FV/WH_V$, where F is the normal force in newtons, N, pressing the surfaces together; V is the sliding velocity in mm/s; W is the wear rate in mm^3/s; and H_V is the Vickers hardness in MPa. R_W is dimensionless.

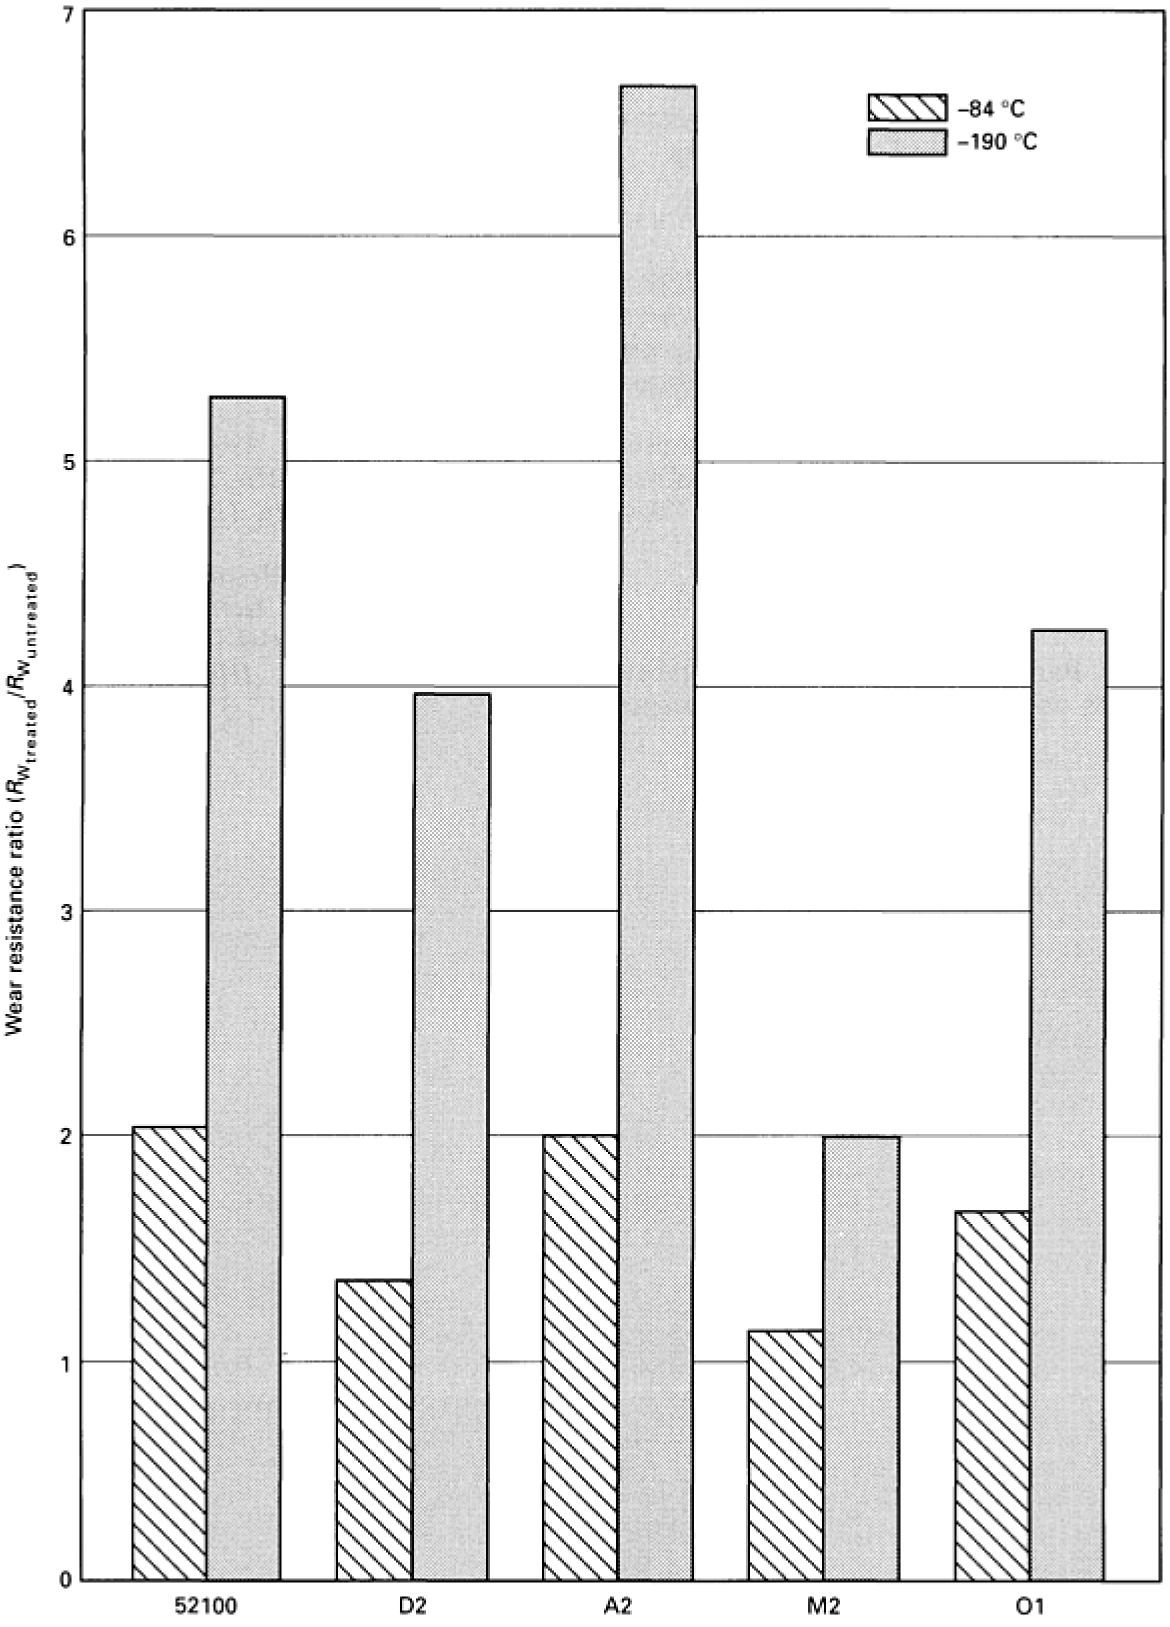

Fig. 2 Comparison of wear-resistance ratios for five high-carbon steels soaked at -84 °C (-120 °F) and at -190 °C (-310 °F). The study also showed that soaking at temperatures below -84 °C (-120 °F) does not significantly change the hardness of the material. The samples were soaked to ensure that their mass was at -84 °C (-120 °F) and -190 °C (-310 °F). Source: Ref 2

Corrosion resistance to water-saturated hydrogen sulfide gas was determined on conventionally processed and cryogenically treated stainless steel and tool steel samples. The results are shown in Table 2. The decrease in corrosion

rate ranged from a modest 1.035 to a significant 1.786. The mechanism Suggested by these data is a refinement in grain boundaries, which limits the diffusion of hydrogen sulfide into the metal. Type 316, an austenitic stainless steel, is susceptible to intergranular corrosion, and apparently refinement of the grain boundaries did not have as much of an effect on the corrosion rate.

Table 2 Corrosion rate of five high-carbon steels exposed for 30 days to a water-saturated hydrogen sulfide gas at a pressure of 2 atm. Test coupons measured 64 × 64 × 1.6 mm (2.5 × 2.5 × 0.062 in.) with a 9.5 mm ($\frac{3}{8}$ in.) hole in the center of the coupon.

These two scientifically designed studies serve to highlight the effects of cryogenic treatment. Many other case studies with varying results appear in technical journals and engineering publications. The variability of results listed in these articles does not disprove the effectiveness of the cryogenic treatment; however, it does provide a cautionary note to anyone considering cryogenic treatment. The need for study of any potential application should be apparent, and a careful technical and cost-effectiveness analysis should be made before embarking on such a program.

Equipment for Cryogenic Treatment

Liquid nitrogen systems have become the customary method for achieving cryogenic temperatures. The two types of systems are described below.

The heat-exchanger system passes liquid nitrogen through a heat exchanger, and the exhaust gas from the unit is piped into the main gaseous-nitrogen header line. The chamber atmosphere is drawn over the heat-exchanger coils by a fan. In some versions of the system, the cooling is boosted by spraying liquid nitrogen directly into the chamber.

The direct spray system sprays liquid nitrogen directly into the chamber, while a fan circulates the gases over the work. In this system, the spent gas cannot be recovered for use as a furnace atmosphere. The equipment design does not permit the liquid nitrogen to come into direct contact with the work, thereby reducing the probability of thermal shock.

In both systems, temperature controllers are used to control the flow of liquid nitrogen (through a solenoid valve) and to monitor the work temperature. Temperature charts of the cycle provide a record of the processing.

Heat Treating of Ultrahigh-Strength Steels

Bruce A. Becherer and Thomas J. Witheford, Teledyne Vasco Corporation

---

Introduction

ULTRAHIGH-STRENGTH STEELS are heat treated by use of equipment and techniques similar to those employed for heat treating constructional alloy steels. With ultrahigh-strength steels, emphasis is placed on the maximum section size that a given alloy will respond to during heat treatment, and thus machining is generally done prior to heat treatment to optimize final property response. The ultrahigh-strength steels ordinarily are quenched and tempered to specific hardnesses, but for critical applications it may be necessary to pull tensile specimens to ensure that a required combination of strength and ductility has been achieved. In still other instances, it may be necessary to conduct impact or fracture-toughness tests to ensure that a required level of resistance to brittle fracture has been attained.

The majority of ultrahigh-strength steels are available in varying quality levels. The quality level is usually dictated by the method of primary or secondary melting used in the manufacture of that alloy. Recent improvements in refining techniques such as argon-oxygen decarburization (AOD) along with vacuum induction melting (VIM) as primary melting techniques are used. Remelting is typically performed with vacuum arc remelting (VAR) techniques to further enhance microstructural cleanliness. Currently some of the grades are being processed by electroslag remelting (ESR). Although heat treatment of the different quality level materials is similar, the premium quality provides increased fracture toughness, tensile ductility, and fatigue life at a given strength level. Some property improvements are given in this article.

Types of High-Strength Steels

Ultrahigh-strength steels, which are classified in Volume 1 of this *ASM Handbook* series as those commercial structural steels capable of a minimum yield strength of 1380 MPa (200 ksi), include several distinctly different families of steels. Three types of ultrahigh-strength steels are:

- Medium-carbon low-alloy steels
- Medium-alloy air-hardening steels
- High-alloy hardenable steels

Of these steels, this article covers only the heat treatment of the medium-carbon low-alloy steels, medium-alloy air-hardening steels, and high-fracture-toughness 9Ni-4Co steels listed in Table 1 . This article does not cover 18 Ni maraging steels, which are described in the article "Heat Treating of Maraging Steels" in this Volume. Ultrahigh-strength steels of the stainless type (martensitic, martensitic precipitation hardenable, semiaustenitic precipitation hardenable, and cold-rolled austenitic steels) are covered in the article "Heat Treating of Stainless Steels" in this Volume.

(a) Phosphorus and sulfur contents may vary with steelmaking practice. Usually, these steels contain no more than 0.035 P and 0.040 S; 9Ni-4Co steels and premium-quality VAR steels are typically specified to have 0.010 max P and 0.010 max S.

(b) ASTM A 681; composition ranges used by some producers are narrower.

In addition to the steels discussed in this article, many other proprietary and standard steels are used for essentially the same types of applications but at strength levels slightly below the arbitrary lower limit of 1380 MPa (200 ksi) established above for the ultrahigh-strength class of constructionalsteels. Medium-alloy steels such as 4330V and 4335V (vanadium-modified versions of the corresponding AISI standard steels) are among the more widely used steels for yield strengths of 1240 to 1380 MPa (180 to 200 ksi), The medium-carbon low-alloy 8630 steel is also used for yield strengths around 1240 MPa (180 ksi). Finally, certain proprietary steels such as Hy Tuf (a silicon-modified steel similar to 300M) exhibit excellent toughness at strengths to or slightly above 1380 MPa. Hy Tuf has about the same toughness as a maraging steel in this strength range. For properties and other information on steels and strength ranges not discussed here, the reader is referred to sources such as *Aerospace Structural Metals Handbook* (Ref 1) and to producer data sheets.

Decarburization Control. During the heat treatment of high-strength steels, decarburization is very critical. Total decarburization is not acceptable, whereas partial surface decarburization to a depth of 0.075 to 0.125 mm (0.003 to 0.005 in.) is often permitted. Decarburization control can be achieved by the use of:

- Copper plating
- Controlled atmospheres: endothermic (-40 °C dew point), vacuum, or inert gas
- Salt bath heating (limited to maximum of 45 min for 0.075 mm, or 0.003 in., partial decarburization)

More information on this topic is provided in the article "Control of Surface Carbon Content in Heat Treating of Steel" in this Volume. Restoration of carbon is discussed in the article "Evaluation of Carbon Control in Processed Parts" in this Volume.

Heat treatments associated with machining, forming, or welding operations include stress relieving, spheroidizing, or heat treatments to allow adequate machinability. Stress relief, which is used after machining, forming, or welding operations, can be performed either before or after hardening and tempering. Table 2 lists the typical temperatures for stress relief prior to hardening and tempering. Stress relief at about 25 °C (50 °F) below the tempering temperature can also be performed after hardening and tempering.

Table 2 Typical heat-treatment temperatures of various medium-carbon low-alloy steels with yield strengths above 1380 MPa (200 ksi)

Note: See the section. "Medium-Carbon Low-Alloy Steels" for possible variations in heating and cooling procedures.

(a) Typical hold time at indicated austenitizing temperatures is about 1 h minimum or 15 to 20 min for each 25 mm (1 in.) of section thickness followed by air cooling (AC), water quenching (WQ), or oil quenching (OQ).

(b) Typical hold time at annealing temperatures is 1 h for each 25 mm (1 in.) of section thickness followed by furnace cooling to about 480 to 540 °C (900 to 1000 °F) at a rate of about 15 °C/h (30 °F/h) but no more than 25 °C/h (50 °F/h).

(c) Minimum tempering times can vary from $\frac{1}{2}$ to 3 h depending on desired properties; snap temper at 175 °C (350 °F) if tempering is not started within 1 h.

(d) These high-temperature stress reliefs are performed prior to hardening and tempering and are used for enhancing machinability or postweld treatment. For stress relief after hardening and tempering, stress relief at 25 °C (50 °F) below the tempering temperature can be used for

machining stress or cold forming.

(e) See the section "Medium-Carbon Low-Alloy Steels" for specification of any intermediate temperatures and cooling procedures.

(f) See text for less-restrictive temperature ranges.

Prior to machining, usual practice for medium-carbon low-alloy steels is to normalize at 870 to 925 °C (1600 to 1700 °F) and temper at 650 to 675 °C (1200 to 1250 °F), or, if the steel is a deep air-hardening grade, to anneal by furnace cooling from 815 to 845 °C (1500 to 1550 °F) to about 540 °C (1000 °F). These treatments impart moderately hard microstructures suitable for machining. If blanks for parts are produced by flame cutting, they are annealed before forming or machining.

Spheroidizing. A very soft spheroidized structure can be obtained by full annealing. Such a structure is not as well suited for machining as the normalized and tempered structure. However, for severe cold-forming operations such as spinning, deep drawing, and wiredrawing, the soft and ductile spheroidized structure is preferred. Spheroidizing treatments are described in the text of this article.

Weld Stress Relief. Welded parts, especially if complex, are Stress relieved immediately after welding. Typical stress-relief temperatures for medium-carbon low-alloy ultrahigh-strength steels are listed in Table 2. Welded parts are stress relieved (and often normalized) prior to hardening and tempering.

Hydrogen Bakeout after Plating. Although hydrogen bakeout is not a standard heat-treatment procedure, it is necessary when ultrahigh-strength steels are exposed to hydrogen, such as in pickling or electroplating operations. Steel parts exposed to hydrogen are susceptible to hydrogen embrittlement when the parts have been heat treated to tensile strengths greater than about 1400 MPa (200 ksi). Ductility can be restored after pickling or electroplating of ultrahigh-strength steels by baking at 185 to 195 °C (365 to 385 °F) for at least 8 h, and for 24 h if thicker than 38 mm ($1\frac{1}{2}$ in.), as soon as possible after pickling or plating.

Medium-Carbon Low-Alloy Steels

The medium-carbon low-alloy steels considered in this article are types 4130, 4140, 4330 Mod, 4340, 6150, 8640, and two modifications of 4340, namely, 300M and D-6A. These steels are generally supplied by the mill in either the normalized and tempered or annealed condition and are readily hot forged. To avoid stress cracks resulting from air hardening (especially for geometries with significant variation in section size), the forged part may be slowly cooled in a furnace or in an insulating medium. As previously mentioned, decarburization control is also critical in the heat treatment of these steels.

Alloy 4130 is a water-hardening alloy steel of low to intermediate hardenability. The following standard heat treatments apply to type 4130 steel:

- *Normalizing:* Heat to 870 to 925 °C (1600 to 1700 °F) and hold for a minimum of 1 h or 15 to 20 min per 25 mm (1 in.) of maximum section thickness; air cool. Tempering at 480 °C (900 °F) or above is often done after normalizing to decrease yield strength
- *Annealing:* Heat to 830 to 870 °C (1525 to 1600 °F) and hold for a period that depends on section thickness (Table 2) or furnace load; furnace cool at a rate of about 15 °C/h (30 °F/h) to 480 °C (900 °F) and then air cool
- *Hardening:* Heat to 845 to 870 °C (1550 to 1600 °F) and hold, and then water quench, or heat to 860 to

885 °C (1575 to 1625 °F) and hold, and then oil quench. Holding time depends on section thickness and is typically 1 h minimum or 15 to20 min per 25 mm (1 in.) of maximum section thickness

- *Tempering:* Temper at least $\frac{1}{2}$to 2 h at 200 to 700 °C (400 to 1300 °F); air cool or water quench. Tempering temperature and time at temperature depend mainly on desired hardness or strength
- *Spheroidizing:* Heat to 760 to 775 °C (1400 to 1425 °F) and hold 4 to 12 h; cool slowly

Properties. Table 3 summarizes the typical properties obtained by tempering water-quenched and oil-quenched 4130 steel bars at various temperatures. Because 4130 steel has low hardenability, section thickness must be considered when heat treating to high hardness or strength. Effects of mass on typical properties of heat-treated 4130 steel are indicated in Table 4.

75	3	710	103	540	78	22.0	60.0	217

Note: Round bars oil quenched from 845 °C (1550 °F) and tempered at 540 °C (1000 °F); 12.83 mm (0.505 in.) diam tensile

Steel alloy 4140 is similar in composition to 4130 except for a higher carbon content, which imparts greater hardenability and strength. The following standard heat treatments apply to 4140 steel:

- *Normalizing:* Heat to 845 to 925 °C (1550 to 1700 °F) and hold for 1 h minimum or 15 to 20 min per 25 mm (1 in.) of maximum section thickness; air cool. More restrictive normalizing temperatures are listed in Table 2
- *Annealing:* Heat to 830 to 870 °C (1525 to 1600 °F) and hold for a period that depends on section thickness (Table 2) or furnace load; furnace cool at a rate of about 15 °C/h (30 °F/h) to 480 °C (900 °F) and then air cool
- *Hardening:* Heat to 830 to 870 °C (1525 to 1600 °F) and hold; oil quench. (For water quenching, which is rarely used because of the likelihood of cracking, hardening temperatures are 815 to 845 °C, or 1500 to 1550 °F.) Holding time is typically 1 h minimum or 15 to 20 min per 25 mm (1 in.) of maximum section thickness. Polymer quenchants, which preferably should have cooling capabilities similar to that of oil, are less likely than oil to catch fire
- *Tempering:* Temper at least $\frac{1}{2}$ to 2 h at 175 to 230 °C (350 to 450 °F) for "ultra-high" strength, or 385 to 705 °C (725 to 1300 °F) for yield strength below 1380 MPa (200 ksi); air cool or water quench. Tempering temperature and time at temperature depend mainly on desired hardness. To avoid blue brittleness, 4140 usually is not tempered between 230 and 370 °C (450 to 700 °F)
- *Spheroidizing:* Heat to 760 to 775 °C (1400 to 1425 °F) and hold 4 to 12 h; cool slowly

Properties. Table 5 summarizes the mechanical properties obtained by tempering oil-quenched 4140 steel at various temperatures. Because 4140 is not a deep-hardening steel, section size should be considered, especially when specifying heat treatment for high strength levels. The effects of mass on hardness and tensile properties of 4140 steel are shown in Table 6.

Table 5 Typical mechanical properties of heat-treated 4140 steel

4330 Mod Steel. Type 4330 Mod is a deep-hardening, vanadium-modified steel with improved toughness. Vanadium forms a stable, high-melting-point carbide that acts to pin grain-boundaries, prohibiting grain growth during hot-working operations. The following standard heat treatments apply to 4330 Mod steel:

- *Normalizing:* Heat to 870 to 925 °C (1600 to 1700 °F) for a minimum of 1 h or 15 to 20 min per 25 mm (1 in.) of maximum thickness, and then air cool
- *Annealing:* Heat to 830 to 870 °C (1525 to 1600 °F) for 1 h per 25 mm (1 in.) of maximum thickness, furnace cool (approximately 15 °C/h, or 30 °F/h) to 480 °C (900 °F), and then air cool
- *Hardening:* Heat to 845 to 870 °C (1550 to 1660 °F) for 1 h minimum or about 15 min per 25 mm (1 in.) of maximum thickness, quench in warm oil at 25 to 60 °C (75 to 140 °F), and air cool
- *Tempering:* Temper at least 2 h at 260 to 595 °C (500 to 1100 °F) depending upon desired tensile strength. For ultimate tensile strength of 1515 to 1655 MPa (220 to 240 ksi), temper between 260 and 370 °C (500 to 700 °F)
- *Stress relieving:* After being straightened, formed, or machined, parts may be stress relieved at 650 to 675 °C (1200 to 1250 °F) prior to hardening. Stress relief of hardened material should not exceed tempering temperatures

Properties. Table 7 summarizes the tensile and impact properties obtained by tempering oil-quenched 4330 Mod steel at various temperatures. Through hardening of 4330 Mod steel up to 50 mm (2 in.) in diameter can be achieved by the above practice.

Table 7 Typical properties of heat-treated 4330 Mod steel

Tempering temperature		**Tensile strength**		**Yield strength**		**Elongation in 50 mm (2 in.), %**	**Reduction in area, %**
°C	**°F**	**MPa**	**ksi**	**MPa**	**ksi**		
290	550	1620	235	1345	195	11	51
315	600	1550	225	1297	188	13	55
370	700	1440	209	1248	181	15	59
480	900	1330	193	1185	172	17	60
595	1100	1228	178	1145	166	18	62

4340 Steel. Type 4340, the most popular steel in this class, is a deep-hardening steel. In thin sections, the steel is air hardening, although in practice it is usually oil quenched. The following standard heat treatments apply to 4340 steel:

- *Normalizing:* Heat to 870 to 925 °C (1600 to 1700 °F) and hold for 1 h minimum or 15 to 20 min per 25 mm (1 in.) of maximum section thickness, and then air cool
- *Annealing:* Heat to 830 to 860 °C (1525 to 1575 °F) and hold for a period that depends on section thickness (Table 2) or furnace load; furnace cool at a rate of about 15 °C/h (30 °F/h) to 480 °C (900 °F) and then air cool
- *Hardening:* Heat to 800 to 845 °C (1475 to 1550 °F) and hold 15 min for each 25 mm (1 in.) of thickness (minimum, 15 min); quench in warm oil at 25 to 60 °C (75 to 140 °F). Polymer quenchants (such as Glycol), which preferably have the same cooling capability as oil, are less likely to catch fire than oil quenchants
- *Tempering:* Temper at least 2 h at 455 to 650 °C (850 to 1200 °F); air cool. Double tempering is recommended to optimize yield strength and impact properties. Temperature and time at temperature depend mainly on desired strength or hardness. Tempering below 455 °C (850 °F) is not recommended because of susceptibility to temper embrittlement
- *Spheroidizing:* Preheat to 690 °C (1275 °F) and hold 2 h, increase temperature to 750 °C (1375 °F) and hold 2 h, cool to 650 °C (1200 °F) and hold 6 h, furnace cool to about 600 °C (1100 °F), and finally air cool to room temperature. An alternative schedule is to heat to 730 to 750 °C (1350 to 1375 °F) and hold several hours, and then furnace cool to room temperature
- *Stress relieving:* After straightening, forming, or machining, parts may be stress relieved at 650 to 675 °C (1200 to 1250 °F) prior to hardening. Stress relief of hardened material should not exceed tempering temperatures

Properties. Through hardening of 4340 steel can be achieved by oil quenching round sections up to 75 mm (3 in.) in diameter, and by water quenching larger sections (to the limit of hardenability). The influence of section size on tensile properties of oil-quenched and water-quenched 4340 is indicated by the data in Table 8. However, at this carbon level the possibility of cracking increases significantly for water quenching.

Table 8 Effects of mass on mechanical properties of 4340 steel

Sources: *Alloy Dig.* and Ref 2

(a) Austenitized at 845 °C (1550 °F); tempered at 425 °C (800 °F).

(b) 75 mm (3 in.) diam bar austenitized at 800 °C (1475 °F); 100 and 150 mm (4 and 6 in.) diam bars austenitized at 815 °C (1500 °F). All sizes tempered at 650 °C (1200 °F). Test specimens taken at midradius.

Hardness of type 4340 as a function of tempering temperature is plotted in Fig. 1. Typical mechanical properties of oil-quenched 4340 are given in Table 9. Additional data on mechanical properties (notch toughness and fracture toughness) of this steel tempered to different hardnesses are given in Table 10.

Alloy 300M is a silicon-modified (1.6% Si) 4340 steel that is slightly higher in carbon and molybdenum and also contains vanadium. Silicon is added to allow higher tempering temperatures, thereby improving toughness. The steel exhibits deep hardenability. Because of its high silicon and molybdenum contents, 300M is more prone to decarburization than the steels so far described; and during heat treating, care should be exercised to avoid decarburization. The following standard heat treatments apply to 300M steel:

- *Normalizing:* Heat to 915 to 940 °C (1675 to 1725 °F) and hold for 15 to 20 min per 25 mm (1 in.) of section thickness; air cool. If normalizing is done to enhance machinability, it should be tempered at 650 to 675 °C (1200 to 1250 °F)
- *Hardening:* Austenitize at 855 to 885 °C (1575 to 1625 °F). Oil quench to below 70 °C (160 °F); or quench in salt at 200 to 210 °C (390 to 410 °F), hold 10 min, and then air cool to 70 °C (160 °F) or below. For optimum dimensional stability, aus-bay quench into a furnace or salt bath at 525 °C (975 °F), equalize at temperature, quench in oil at 60 °C (140 °F) or salt at 205 °C (400 °F), and air cool
- *Tempering:* Temper 2 to 4 h at 300 ± 15 °C (575 ± 25 °F) double tempering is recommended. This procedure produces the best combination of high yield strength and high impact properties. Tempering above or below 300 °C (575 °F) results in severe deterioration of properties
- *Spheroidizing:* Heat to temperatures no higher than 730 °C (1350 °F) and hold for a period that depends on section thickness or furnace load. Temperatures above 730 °C (1350 °F) result in possible decarburization and transformation. Cool to 650 °C (1200 °F) at a rate no faster than 5.5 °C/h (10 °F/h), cool to 480 °C (900 °F) no faster than 10 °C/h (20 °F/h), and finally air cool to room temperature
- *Annealing:* Same schedule as for spheroidizing

Properties. Variations in hardness and mechanical properties of 300M with tempering temperature are presented in Table 11. This steel has deep hardenability; therefore, heat-treated bars 75 mm (3 in.) in diameter have essentially the same tensile properties as bars 25 mm (1 in.) in diameter. Reductions in tensile strength, ductility, and impact strength, however, are observed in heat-treated bars 145 mm ($5\frac{3}{4}$ in.) in diameter. Variations in properties of 300M with section size are presented in Table 12.

Table 11 Typical mechanical properties of 300M steel

D-6A and D-6AC. D-6A was designed by Ladish Company for use at room temperature at tensile strengths of 1800 to 2000 MPa (260 to 290 ksi). It is deeper hardening than 4340. The alloy is called D-6A when produced by air melting in an electric furnace and D-6AC when produced by air melting followed by VAR. Except for improvements in steel cleanliness and mechanical properties of D-6AC caused by melting practice (see Table 13), the characteristics of the two steels are similar.

Table 13 Typical fracture toughness of D-6AC with either EAF-VAR or EAF-AOD-VAR steel-making methods

5-Heat average	1448	210	1345	195	14	52	122	111
5-Heat range	1435-1462	208-212	1330-1365	193-198	14-15	51-53	114-127	104-116

Note: All samples longitudinal direction after normalized at 900 °C (1650 °F), austenitized at 865 °C (1615 °F) 1 h, salt quenched at 163 °C (325 °F), and double tempered at 570 °C (1085 °F). Each heat tested at 3 locations

The following standard heat treatments apply to D-6A and D-6AC steels:

- *Normalizing:* Heat to 870 to 955 °C (1600 to 1750 °F) and hold for 15 to 20 min per 25 mm (1 in.) of section thickness; air cool. More restrictive normalizing temperatures are listed in Table 2
- *Annealing:* Heat to 815 to 860 °C (1500 to 1575 °F) and hold for a period that depends on section thickness (Table 2) or furnace load; furnace cool to 540 °C (1000 °F) at a rate no faster than 28 °C/h (50 °F/h), and then air cool to room temperature. Alternatively, normalizing followed by a 690 to 705 °C (1275 to 1300 °F) temper (with 1 h hold for each inch of section thickness) will result in hardness/machinability comparable to annealing at lower overall furnace time
- *Hardening:* Austenitize at 845 to 940 °C (1550 to 1725 °F) for $\frac{1}{2}$ to 2 h. Sections no larger than 25 mm (1 in.) in thickness or diameter can be air cooled. Larger sections can be oil quenched to 65 °C (150 °F) or salt quenched to 205 °C (400 °F) and then air cooled. For optimum dimensional stability, aus-bay quench into a furnace or salt bath at 525 °C (975 °F), equalize the temperature, and then quench in an oil bath held at 60 °C (140 °F), or quench in 205 °C (400 °F) salt (marquenching) and air cool (see Fig. 2). The cooling rate during quenching significantly affects fracture toughness. For high fracture toughness (with some associated reduction in ultimate tensile strength), especially in heavy sections, austenitize at 925 °C (1700 °F), aus-bay quench to 525 °C (975 °F), equalize temperature, and oil quench to 60 °C (140 °F)
- *Tempering:* Immediately after hardening, temper 2 to 4 h in the range 315 to 650 °C (600 to 1200 °F), depending on desired strength or hardness. Double tempering is recommended to optimize yield strength and impact toughness

- *Spheroidizing:* Heat to no more than 730 °C (1350 °F) because of excessive decarburization and possible transformation. Hold at temperature for 5 to 6 h; furnace cool to 690 °C (1275 °F) and hold 10 h; furnace cool to 650 °C (1200 °F) and hold 8 h; air cool to room temperature
- *Stress relieving:* Heat to a temperature from 540 to 675 °C (1000 to 1250 °F) and hold for 1 to 2 h; air cool. For hardened material, stress relieve at about 25 °C (50 °F) below the tempering temperature

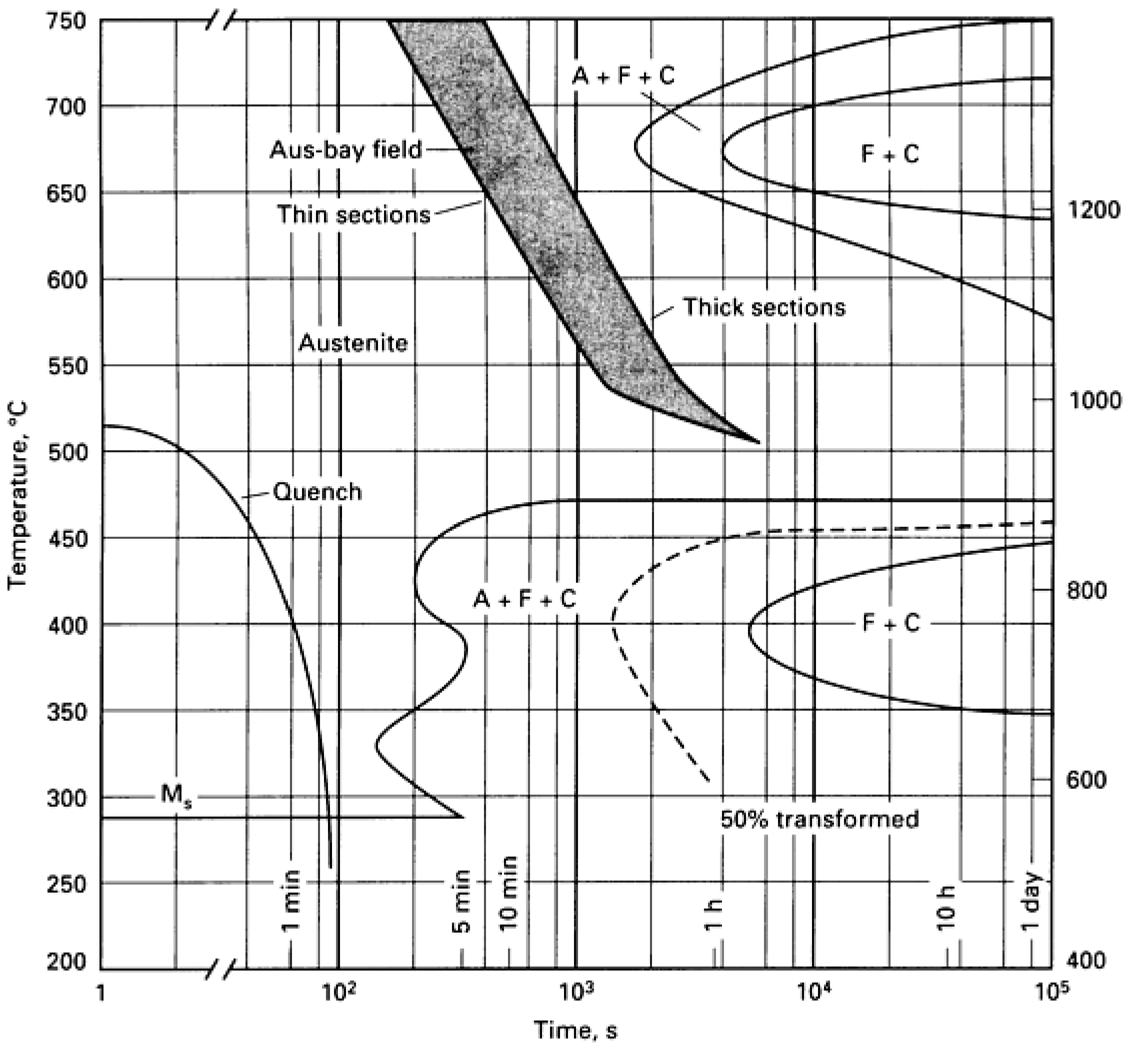

Fig. 2 Aus-bay quenching for improved dimensional stability. D-6AC has an isothermal transformation diagram characterized by a deep, wide austenitic bay region. Because of this bay, heat treaters can cool parts of varying cross sections to below 540 °C (1000 °F) at the indicated rates, hold them in the bay until all sections are at the intermediate temperature, and then quench them in hot oil or a salt bath. Cooling curves around the aus-bay region indicate the procedure.

Properties. Typical room-temperature hardness of D-6A steel bar as a function of tempering temperature is plotted in Fig. 3; other typical mechanical properties of D-6AC bar are given in Table 14. Tensile properties of heat-treated D-6AC billet material are given in Table 15. Fracture toughness levels for products with varying quench rates are given in Table 16.

6150 Steel. Type 6150 can be considered an ultrahigh-strength steel, although as a constructional steel it is not as popular as the other steels in this class. It is a shallow-hardening steel. Parts made of 6150 can be readily welded; after welding, parts should be normalized, and then hardened and tempered to the desired hardness.

The following heat treatments apply to 6150 steel:

- *Normalizing:* Heat to 870 to 955 °C (1600 to 1750 °F) and hold for about 15 to 20 min per 25 mm (1

in.) of section thickness; air cool

- *Annealing:* Heat to 845 to 900 °C (1550 to 1650 °F) and hold for a period that depends on section thickness (Table 2) or furnace load; furnace cool at a rate of about 15 °C/h (30 °F/h) to 480 to 540 °C (900 to 1000 °F) and then air cool. More restrictive temperatures are listed in Table 2
- *Hardening:* Austenitize at 845 to 900 °C (1550 to 1650 °F); oil quench
- *Tempering:* Temper at least $\frac{1}{2}$ to 2 h at 200 to 650 °C (400 to 1200 °F); oil quench. The spring temper is at 385 to 480 °C (725 to 900 °F)
- *Austempering:* Austenitize in a salt bath at 845 to 900 °C (1550 to 1650 °F); quench in a salt bath at 230 to 315 °C (450 to 500 °F), hold 20 to 30 min, and then oil quench or air cool to room temperature
- *Martempering:* Austenitize in a salt bath at 845 to 870 °C (1550 to 1600 °F); quench in a salt bath at 230 to 260 °C (450 to 500 °F), equalize, and then air cool or quench to room temperature. Temper to desired hardness
- *Spheroidizing:* Heat to no more than 730 °C (1350 °F) because of danger of decarburization; hold until heated through, furnace cool to 650 °C (1200 °F) and hold several hours, followed by furnace cooling to about 425 °C (800 °F) before air cooling to room temperature

Properties. Typical mechanical properties of small-diameter round sections of 6150 tempered at various temperatures are given in Table 17. Hardness and Izod impact energy as functions of tempering temperature are plotted in Fig. 4. The effects of section size on tensile properties and hardness are given in Table 18.

Type 8640 steel was designed especially for maximum hardenability and the best combination of properties with minimum alloying additions. It is an oil-hardening steel but may be water hardened if precautions are taken to prevent cracking.

The following standard treatments apply to 8640 steel:

- *Normalizing:* Heat to 870 to 925 °C (1600 to 1700 °F) and hold for about 15 to 20 min per 25 mm (1 in.) of section thickness; air cool
- *Annealing:* Heat to 845 to 870 °C (1550 to 1600 °F) and hold for a period that depends on section thickness (Table 2) or furnace load; furnace cool at a rate of about 15 °C/h (30 °F/h) to 480 to 540 °C (900 to 1000 °F) and then air cool
- *Hardening:* Austenitize at 815 to 845 °C (1500 to 1550 °F); quench in oil or warm water at 45 to 60 °C (110 to 140 °F)
- *Tempering:* Temper at least $\frac{1}{2}$ to 2 h at 200 to 650 °C (400 to 1200 °F). Temperature and time at temperature depend on desired hardness
- *Spheroidizing:* Heat to 700 to 720 °C (1300 to 1325 °F) and hold several hours; furnace cool

Properties. Variations in typical properties of heat-treated round sections of 8640 with tempering temperature are given in Table 19. Variations in properties with section size (mass effect) are given in Table 20.

Medium-Alloy Air-Hardening Steels

Heat treatments for ultrahigh-strength steels H11 Mod and H13, which are also known as 5% Cr hot-work die steels, are discussed in this section. These steels are similar in composition, heat treatment, and many properties. They have deep hardenability and can be hardened through in large sections by air cooling. Air hardening results in minimal residual stresses after hardening. Both H11 Mod and H13 are secondary hardening steels, and thus develop optimum properties when tempered at temperatures above the secondary hardening peaks at about 510 °C (950 °F). These high tempering temperatures provide substantial stress relief and stabilization of properties so that steels can be used to advantage at elevated temperatures. This also enables heat-treated parts to be warm worked or preheated for welding at temperatures as high as 55 °C (100 °F) below the prior tempering temperature.

Because H11 Mod and H13 are air-hardening steels, forged parts must be cooled slowly after forging to prevent stress cracking. After forging, parts should be charged into a furnace at about 790 °C (1450 °F), soaked until the temperature is uniform, and then slowly cooled, either in the furnace or in an insulating medium such as ashes, lime, mica, or silocel. When the forgings have cooled, they should be spheroidize annealed. Weldments, especially heavy-section weldments, should be cooled slowly in a furnace heated to the preheating temperature or in an insulating medium immediately after welding. After being cooled, weldments should be given a full spheroidizing anneal.

H11 Mod. This steel is a modification of the martensitic hot-work die steel H11, the significant difference being the slightly higher carbon content of H11 Mod. The following standard heat treatments apply to H11 Mod steel:

- *Normalizing:* This method is generally not recommended. For effective homogenization, heat to about 1065 °C (1950 °F), soak 1 h for each 25 mm (1 in.) of thickness, and air cool. Anneal immediately after the steel reaches room temperature. There is a possibility that H11 Mod may crack during this treatment, especially if the surface is significantly decarburized
- *Annealing:* Heat to 845 to 900 °C (1550 to 1650 °F) in a furnace, preferably one with controlled atmosphere, and hold to equalize temperature; cool very slowly in the furnace to about 480 °C (900 °F) and then more rapidly to room temperature. This treatment should produce a fully spheroidized microstructure free of grain-boundary carbide networks
- *Hardening:* Preheat to 760 to 815 °C (1400 to 1500 °F) and then raise the temperature to 995 to 1025 °C (1825 to 1875 °F) and hold 20 min plus 5 min for each 25 mm (1 in.) of thickness (minimum, 25 min); air cool in still air. This can be done conveniently in a neutral salt bath or a controlled-atmosphere furnace. For a few applications, oil quenching from the low end of the hardening temperature range may be done. Air cooling, which produces less distortion than oil quenching, is more commonly employed
- *Tempering:* Temper at the secondary hardening peak temperature of about 540 °C (1000 °F) for maximum hardness and strength, or preferably above the secondary peak to temper back to a lower hardness or strength with improved ductility and toughness. A minimum of 2 h at temperature should be

allowed, but it is preferable to double temper parts (2 h at temperature, cool to room temperature, and then 2 h more at ~15 °C, or 25 °F, above the previous temperature). Triple tempering is even more desirable, especially for critical parts. For high-temperature applications, parts should be tempered at a temperature above the maximum service temperature to guard against unwanted changes in properties during service

- *Stress relieving:* Heat to 650 to 675 °C (1200 to 1250 °F); cool slowly to room temperature. This treatment is often used to achieve greater dimensional accuracy in heat-treated parts by stress relieving rough-machined parts, finish machining them, and finally heat treating to the desired hardness
- *Nitriding:* For increased wear resistance, finish-machined and heat-treated parts may be nitrided. The nitriding operation can be considered as the second temper of a double-tempering operation. The parts should be gas or liquid nitrided at about 525 °C (980 °F). The nitrided case depth depends on time at temperature. For example, gas nitriding in 20 to 30% dissociated ammonia for 8 to 48 h normally produces a case depth of about 0.2 to 0.35 mm (0.008 to 0.014 in.)

Properties. Variation of hardness with tempering temperature for H11 Mod is plotted in Fig. 5. Variations in typical room-temperature longitudinal mechanical properties with tempering temperature are given in Table 21. As an indication of the deep air hardenability of this steel (to depths greater than 300 mm, or 12 in.), the transverse tensile strength and ductility obtained in large billets of air-melted and VAR H11 Mod are given in Table 22, which also shows improvement in ductility resulting from VAR. Each value is the average of four tests: two from the top and two from the bottom of the ingot.

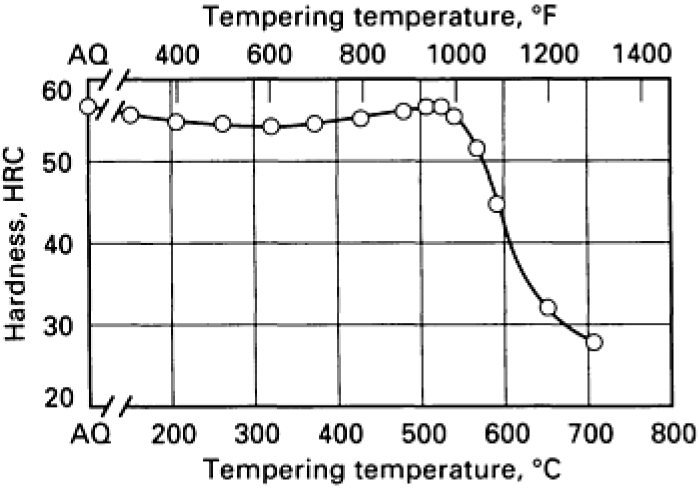

Fig. 5 Variation for hardness with tempering temperature for H11 Mod steel. All specimens air cooled from 1010 °C (1850 °F) and double tempered, 2 + 2 h at temperature. AQ, as-quenched

H13 Steel. The main difference in composition between H11 Mod and H13 is the higher vanadium content of the latter (see Table 1). This leads to a greater dispersion of hard vanadium carbides, which results in higher wear resistance. Parts made of H13 can be nitrided for additional wear resistance. H13 also has a slightly wider range of carbon content than H11 Mod. The carbon content of H13 may be nearer the high or low side of the accepted range, depending on the producer, and for a given heat treatment the properties will vary correspondingly.

The following standard heat treatments apply to H13 steel:

- *Normalizing:* This is not recommended for H13. Some improvement in homogeneity can be obtained by preheating to about 790 °C (1450 °F), heating slowly and uniformly to 1040 to 1065 °C (1900 to 1950 °F) and holding 1 h for each 25 mm (1 in.) of thickness, and then air cooling. Just before or just as the steel reaches room temperature, it should be recharged into a furnace and given a full spheroidizing anneal. There is a risk of cracking during this treatment, especially if it is done in a furnace where the atmosphere is not controlled to prevent surface decarburization
- *Annealing:* Heat uniformly to 845 to 900 °C (1550 to 1650 °F) in a controlled-atmosphere furnace, or with the part in a neutral compound, to prevent decarburization, and hold to equalize temperature; cool very slowly in the furnace to about 480 °C (900 °F) and then cool more rapidly to room temperature. This treatment should result in a fully spheroidized microstructure free from grain-boundary carbide networks
- *Hardening:* Preheat to 790 to 815 °C (1450 to 1500 °F) and then raise the temperature uniformly to 995 to 1025 °C (1825 to 1875 °F) and soak 20 min plus 5 min for each 25 mm (1 in.) of thickness (minimum, 25 min); air cool in still air. For a few applications oil quenching from the low side of the

hardening temperature can be done, but this is at risk of distortion or cracking. Air cooling is preferred and is usually done from the high side of the hardening temperature range

- *Tempering.* Temper at the secondary hardening peak of about 510 °C (950 °F) for maximum hardness and strength, but it is preferable to temper at a higher temperature to a lower level of hardness or strength with improved toughness and ductility. Double tempering--2 h at temperature, air cool, and then 2 h more at temperature--is recommended; for critical parts, triple tempering is more desirable
- *Stress relieving:* Heat to 650 to 675 °C (1200 to 1250 °F) and soak 1 h or more; cool slowly to room temperature. This treatment is often used to achieve greater dimensional accuracy in heat-treated parts by stress relieving rough-machined parts, then finish machining, and finally heat treating to the desired hardness
- *Nitriding:* Finish-machined and heat-treated parts can be nitrided. Because it is carried out at about the normal tempering temperature, nitriding can serve as the second temper in a double-tempering treatment. The nitrided case depth depends on time at temperature. For example, gas nitriding at 510 °C (950 °F) for 10 to 12 h produces a case depth of 0.10 to 0.13 mm (0.004 to 0.005 in.). For selective nitriding, copper plating is preferred for stopping off areas that are not to be nitrided; stopoffs containing lead should be avoided because lead has been found to embrittle H13 steel

Properties. The properties presented in this section are for H13 with a carbon content in the middle of the composition range (see Table 1). Somewhat different properties should be expected when the carbon content is near the high end or the low end of the range.

Variation of hardness with tempering temperature for H13 is plotted in Fig. 6. Typical room-temperature longitudinal mechanical properties of bars tempered to different hardness levels are given in Table 23. H13 has deep hardenability, although it is slightly less than that of H11 Mod. For example, an H13 bar 330 mm (13 in.) in diameter and 2745 mm (108 in.) long, when fast air cooled from 1010 °C (1850 °F), has an as-quenched hardness of 45 HRC.

9Ni-4Co Steels

During the 1960s, Republic Steel Corporation introduced a family of four HP 9-4 (9Ni-4Co) steels having high fracture toughness when heat treated to very high strength levels. Of these, HP 9-4-20 and HP 9-4-30 are commercially available. They nominally contain 0.20 and 0.30% C, respectively (see Table 1 for chemical compositions). The attainable strength increases with increases in carbon content, but decreases in toughness and weldability correspond. The high nickel content of 9% provides deep hardenability and toughness, and the 4% Co prevents retention of excessive austenite in heat-treated parts. Double tempering is recommended to ensure complete austenite transformation. The carbide-forming elements chromium and molybdenum also impart hardenability, but the amounts of these carbide formers are adjusted to provide a fairly flat response to tempering without pronounced secondary hardening and its attendant reduction in toughness.

HP 9-4-20, although it has good weldability and fracture toughness, cannot develop a yield strength of 1380 MPa (200 ksi), which was selected as the criterion for ultrahigh-strength steels discussed in this article. Therefore, only HP 9-4-30 is discussed further.

HP 9-4-30 steel has deep hardenability and can be fully hardened to martensite in sections up to 150 mm (6 in.) thick. Heat-treated parts can be readily welded without preheat or postheat treatment. After welding, parts may be stress relieved at about 540 °C (1000 °F) for 24 h.

The following heat treatments apply to HP 9-4-30 steel:

- *Normalizing:* Heat to 885 to 915 °C (1625 to 1675 °F) and hold 1 h for each 25 mm (1 in.) of thickness (minimum, 1 h); air cool
- *Annealing:* Heat to 620 °C (1150 °F) and hold 24 h; air cool. An alternative procedure consists of annealing at 705 °C (1300 °F) for 2 h, air cooling to room temperature, and annealing a second time at 650 °C (1200 °F) for 4 h, followed by air cooling to room temperature
- *Hardening:* Austenitize at 800 to 860 °C (1475 to 1575 °F) and hold 1 h for each 25 mm (1 in.) of thickness (minimum, 1 h); water or oil quench.Complete the martensitic transformation by refrigerating at least 1 h at -87 to -60 °C (-125 to -75 °F); let warm to room temperature
- *Tempering:* Temper at 200 to 600 °C (400 to 1100 °F), depending on desired strength; double tempering preferred. The most widely used tempering temperature is double tempering (2 h or more at temperature) from 540 to 575 °C (1000 to 1075 °F)
- *Stress relieving:* This is usually required only after welding of restrained sections. Heat to 540 to 575 °C (1000 to 1075 °F) and hold 24 h; air cool to room temperature

Properties. Room-temperature mechanical properties of HP 9-4-30 double tempered at three different temperatures are presented in Table 24. The data for material double tempered at 540 °C (1000 °F) represent the minimum mechanical properties for this condition; properties listed for the other conditions can be considered typical.

Table 24 Room-temperature mechanical properties of HP 9-4-30 steel

Property	**Typical value for hardness of**		**Minimum value[(c)]**

	(15-20 ft · lb)	(18-25 ft · lb)	(18 ft · lb)
Fracture toughness (K_{1c})	66-99 MPa $\sqrt{m}$	99-115 MPa $\sqrt{m}$	. . .

(a) Oil quenched from 845 °C (1550 °F), refrigerated to -73 °C (-100 °F), and double tempered at 205 °C (400 °F).

(b) Same heat treatment as (a) except double tempered at 550 °C (1025 °F).

(c) For sections forged to 75 mm (3 in.) or less in thickness (or to less than 0.016 m^2 or 25 $in.^2$, in total cross-sectional area), quenched to martensite and double tempered at 540 °C (1000 °F)

AF 1410

In the late 1970s the U.S. Air Force sponsored development work for improved submarine hull steels. From this work, AF 1410 evolved as an ultrahigh-strength steel with particularly high fracture toughness. AF 1410 is typically manufactured via VIM followed by VAR to achieve the required low levels of impurities. For improved or finer grain size, producers often recommend forging reductions of 40% below 900 °C (1650 °F). This grade is typically supplied in normalized and overaged condition for best machinability. The steel is then renormalized and austenitized or double austenitized, air cooled/quenched, cooled to -75 °C (-100 °F), and aged to attain maximum properties.

The microstructure of AF 1410 consists of iron-nickel lath martensite with carbides from age precipitation for strengthening. Quenching from the austenitizing temperature produces a highly dislocated lath martensite that has a high toughness, as measured by the Charpy V-notch impact test. Aging produces a complex series of changes in carbide structure. At approximately 425 °C (800 °F), Fe_3C is precipitated. At 455 °C (850 °F), iron-chromium-molybdenum M_2C carbide is obtained, which at 480 °C (900 °F) will begin to produce a pure molybdenum-chromium M_2C carbide. By raising the temperature to 510 °C (950 °F), the M_2C will begin to coarsen; at 540 °C (1000 °F) M_2C will begin to be replaced by M_6C, which has little strengthening effect.

The secondary hardening, which is due to the aging, produces a maximum tensile strength when aged at 480 °C (900 °F) using a 5-h aging time and a minimum impact energy when aged at 425 °C (800 °F), as shown in Fig. 7. When aged in the temperature range between 425 and 540 °C (800 and 1000 °F), the impact energy exhibits a maximum at about 508 °C (947 °F), as shown in Fig. 8. At aging temperatures above 540 °C (1000 °F), both the tensile strength and the impact energy decrease rather rapidly.

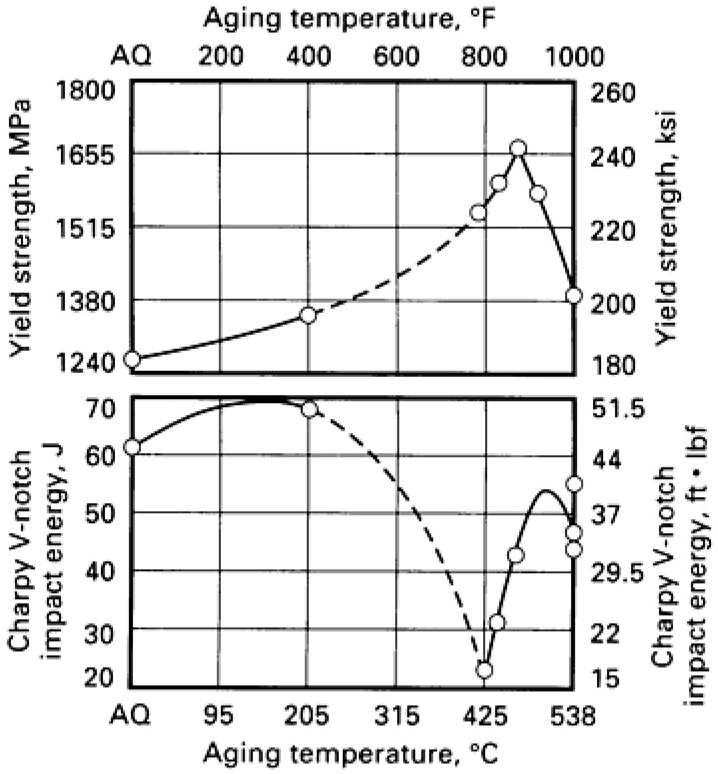

Fig. 7 Effect of aging temperature on impact energy (bottom) and yield strength (top) of AF 1410 steel (VIM/VAR plate 15 mm, or $\frac{5}{8}$ in., thick). Heat treatments: Heat at 900 °C (1650 °F) for $\frac{1}{2}$ h and water quench; heat at 815 °C (1500 °F) for $\frac{1}{2}$ h and water quench; age for 5 h at indicated temperatures and air cool. AQ, as-quenched. Source: Ref 1

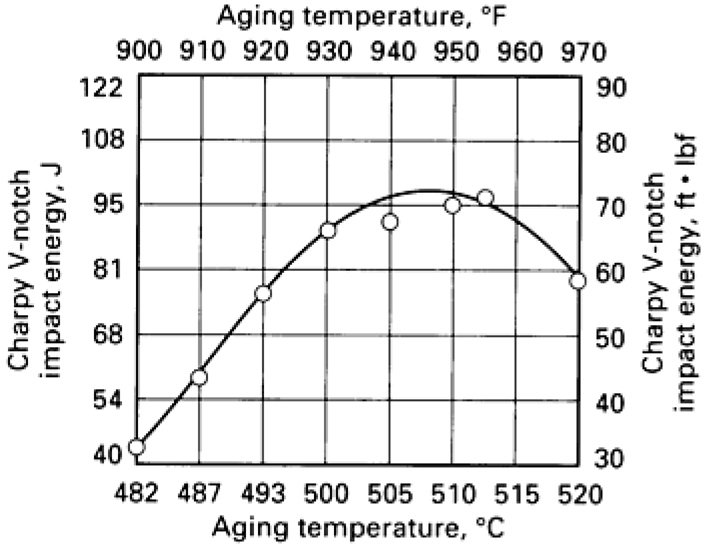

Fig. 8 Effect of aging temperature on impact energy of AF 1410 steel (VIM/VAR plate 15 mm, or $\frac{5}{8}$ in., thick). Heat treatments: See Fig. 7

The steel is subject to austenite reversion during aging. At normal aging temperatures, the retained austenite is generally less than 1% by volume. However, 540 °C (1000 °F) or higher will produce large amounts of austenite, and these will weaken the matrix of the steel. The best combination of strength and ductility results from a 480 to 510 °C (900 to 950 °F) age.

Heat Treatments. The heat treatments that apply to AF 1410 steel are:

- *Normalizing and overaging:* The material is normally normalized and overaged for best machinability. Heat between 880 and 910 °C (1620 and 1675 °F) and hold 1 h for each 25 mm (1 in.) of thickness; air cool and overage at 675 °C (1250 °F) for 5 h minimum
- *Annealing:* Usually, normalizing and overaging are used to soften and stress relieve the product. A stress relief of 675 °C (1250 °F) can be applied to relieve mechanical stresses
- *Hardening:* Renormalize and austenitize at 800 to 860 °C (1475 to 1575 °F) and hold 1 h for each 25 mm (1 in.) of thickness; oil, water, or air cool depending on section size. An alternative method, originally believed to improve toughness, involves double austenitizing, first at 870 to 900 °C (1600 to 1650 °F) with holding times of 1 h for each 25 mm (1 in.) of section thickness. Then cool with oil, water, or air, and reaustenitize as with the single austenitizing treatment
- *Quenching:* Air cooling from the austenitizing temperature will produce tensile strength, toughness, and fatigue strength essentially equal to oil or water quenching in section sizes up to 75 mm (3 in.). Refrigeration treatment of -73 °C (-100 °F) might be optional, although large forgings often fail to attain properties if not subjected to the subzero treatment. The aim is to reduce the amount of retained austenite
- *Aging:* Age at 480 to 510 °C (900 to 950 °F) 5 to 8 h. Air cooling is normally employed

Properties. Tensile strength and impact energy properties for VIM/VAR bar product austenitized and aged from various cycles are shown in Table 25. Figures 9, 10, and 11 augment Table 25 in allowing an estimate of the effect of a given aging treatment on properties by using Larson-Miller parameters. Tensile strength properties and impact energy for VIM/VAR plate quenched in air, water, or vermiculite and cooled following austenitizing are shown in Table 26. The heat treatments showed some effect on the tensile and impact properties for both 15 mm ($\frac{5}{8}$ in.) and 75 mm (3 in.) VIM/VAR plate.

Introduction

MARAGING STEELS are highly alloyed low-carbon iron-nickel martensites that possess an excellent combination of strength and toughness superior to that of most carbon-hardened steels (Fig. 1). As such, they constitute an alternative to hardened carbon steels in critical applications where high strength and good toughness and ductility are required. Hardened carbon steels derive their strength from transformation-hardening mechanisms (such as martensite and bainite formation) and the subsequent precipitation of carbides during tempering. In contrast, maraging steels derive their strength from the formation of a very low-carbon, tough, and ductile iron-nickel martensite, which can be further strengthened by subsequent precipitation of intermetallic compounds during age hardening. The term marage was coined based on the age hardening of the martensitic structure.

Historical Development

Age hardening of martensite, or maraging, depends on the occurrence of a thermal hysteresis of phase transformations, whereby the reversion of martensite to austenite during reheating occurs at a higher temperature range than the temperature range for martensite formation during cooling. Although knowledge of this thermal hysteresis in Fe-Ni alloys was observed as early as 1927 (Ref 2), the first extensive research toward development of commercial iron-nickel maraging steels was conducted in the late 1950s by the International Nickel Company (currently Inco Ltd.). This research culminated in the development of the 20 and 25% Ni maraging steels. In addition to nickel, these two alloys contained 0.3% Al, 1.4% Ti, and 0.4% Nb, which resulted in precipitation hardening of the low-carbon martensitic structure when aged at 425 to 510 °C (800 to 950 °F). Both alloys were reported to exhibit good combinations of strength and ductility at

hardness levels of 53 to 56 HRC (Ref 3, 4); however, as reported by Hall (Ref 5), these alloys were abandoned because of their brittleness at extremely high strength levels.

Subsequent work on the iron-nickel system by Decker, Eash, and Goldman (Ref 6) revealed that the martensite formed in this binary system could be hardened to appreciable levels through the addition of cobalt and molybdenum. A nickel level of 18% was chosen for this alloy system because nickel levels significantly greater than 18% resulted in the retention of austenite in the as-quenched condition. By the early 1960s, three new maraging steels based on the Fe-18Ni-Co-Mo quaternary alloy system were introduced. These were the 18 Ni Marage 200, 250, and 300 alloys, which are capable of achieving yield strengths of approximately 1380, 1725, and 2000 MPa (200, 250, and 290 ksi), respectively, in combination with excellent ductility and toughness. The nominal compositions of these grades are shown in Table 1. In general, the strength levels attained by these alloys are determined by the cobalt, molybdenum, and titanium contents of each alloy. These three alloys replaced the phased-out 20 and 25% Ni maraging steels.

Table 1 Nominal compositions of standard commercial maraging steels

Grade	**Composition[(a)], wt%**				
	Ni	**Mo**	**Co**	**Ti**	**Al**
18 Ni Marage 200	18	3.3	8.5	0.2	0.1
18 Ni Marage 250	18	5.0	7.75	0.4	0.1
18 Ni Marage 300	18	5.0	9.0	0.65	0.1
18 Ni Marage 350	18	4.2[(b)]	12.5	1.6[(b)]	0.1

(a) The carbon content for all grades is restricted to 0.03% max.

(b) Some producers use a combination of 4.8% Mo and 1.4% Ti, nominal.

Based on the success and excellent properties of the 18 Ni Marage 200, 250, and 300 alloys, a modified version of the 18 Ni Marage 250 alloy was developed for use in casting applications in 1963 (Ref 7). In the mid- to late-1960s research was initiated at Inco Ltd. to develop maraging steels with strength levels in excess of 2100 MPa (300 ksi); as a result of this work, the 18 Ni Marage 350 steel was developed. Because of the high strength of this alloy, it is designated as an ultrahigh-strength maraging steel. As can be seen by its composition (Table 1), the 18 Ni Marage 350 alloy is essentially a modified version of the 300 grade that contains higher cobalt and titanium levels and a slightly reduced molybdenum content (Ref 8).

A number of cobalt-free maraging steels and a low-cobalt-bearing maraging steel have recently been developed (Table 2). The driving force for the development of these particular alloys was the cobalt shortage and resultant price escalation of cobalt during the late 1970s and early 1980s.

Table 2 Nominal compositions of cobalt-free and low-cobalt-bearing commercial maraging steels

Grade	**Composition[(a)], wt%**

	Ni	Mo	Co	Ti	Al	Nb
Cobalt-free 18 Ni Marage 200	18.5	3.0	. . .	0.7	0.1	. . .
Cobalt-free 18 Ni Marage 250	18.5	3.0	. . .	1.4	0.1	. . .
Low-cobalt 18 Ni Marage 250	18.5	2.6	2.0	1.2	0.1	0.1
Cobalt-free 18 Ni Marage 300	18.5	4.0	. . .	1.85	0.1	. . .

(a) The carbon content for all grades is restricted to 0.03% max.

Physical Metallurgy

As previously mentioned, the good strength and toughness of maraging steels (Fig. 1) are achieved by the age hardening of an extremely ductile, low-carbon martensitic structure with relatively good strength (Table 3). During the aging of the martensitic structure, the basic objective is to form a uniform distribution of fine intermetallic precipitates, which serve to strengthen the martensitic matrix. Another basic objective during the aging of maraging steels is to minimize or eliminate the reversion of metastable martensite into austenite and ferrite.

Table 3 Typical range of mechanical properties developed in unaged 18 Ni maraging steels after solution annealing [815 °C (1500 °F), 1 h, air cooled]

Alloy	Yield strength		Tensile strength		Elongation, %	Reduction in area, %	HRC
	MPa	ksi	MPa	ksi			
18 Ni Marage 200	760-807	110-117	965-1000	140-145	17-18	72-79	28-30
18 Ni Marage 250	725-895	105-130	1000-1140	145-165	8-16	55-70	28-35
18 Ni Marage 300	760-895	110-130	1000-1170	145-170	6-15	45-60	30-37

Fortunately, the kinetics of the precipitation reactions that cause hardening of iron-nickel maraging steels are such that considerable age hardening--that is, approximately 20 HRC points (1035 MPa, or 150 ksi)--occurs before the onset of the reversion reactions that produce austenite and ferrite. The iron-nickel maraging steels also exhibit a thermal hysteresis in phase transformations that prevents or minimizes martensite-to-austenite reversion during aging heat treatment. This thermal hysteresis and phase behavior are illustrated in the two phase diagrams of Fig. 2, which depict the iron-rich end of the iron-nickel binary system. Figure 2(a) is the metastable diagram plotting the austenite-to-martensite transformation upon cooling and the martensite-to-austenite reversion upon heating. Figure 1(b) is the equilibrium diagram showing that at higher nickel contents the equilibrium phases at low temperatures are austenite and ferrite.

Martensite Formation

The martensite of maraging steels is normally a low-carbon body-centered cubic (bcc) lath martensite containing a high dislocation density but no twinning. The metastable phase diagram of Fig. 2(a) indicates the typical behavior of maraging steels during cooling from the solution-annealing (austenitizing) temperature. During cooling after solution annealing, the elevated-temperature face-centered cubic (fcc) austenite transforms to a bcc martensitic structure by a diffusionless shear reaction without decomposing into the equilibrium structures. This transformation of austenite to metastable martensite does not occur until the martensite start (M_s) temperature is reached, and the M_s temperature must be high enough so that a complete transformation to martensite occurs before the steel cools to room temperature. Most grades of maraging steels have M_s temperatures of about 200 to 300 °C (390 to 570 °F) and are fully martensitic at room temperature. The resultant martensitic structure is relatively strong and extremely ductile (Table 3).

Alloying elements alter the M_s temperature significantly, but do not alter the characteristic that transformation is largely independent of cooling rate. In maraging steels, fully martensitic structures are formed even during very slow cooling of heavy sections from the solution-annealing temperature. Consequently, there is no apparent lack of hardenability in maraging steels. This behavior is illustrated by the continuous cooling transformation (cct) diagrams for 18 Ni Marage 200, 250, 300, and 350 that appear in Fig. 3. As these cct diagrams indicate, the classical diffusion-controlled bainitic and pearlitic transformations that occur in carbon-base martensitic steels are not present in the 18 Ni maraging steels.

(d) 18 Ni Marage 350. The Vickers hardness appears in the circles at the end of each cooling curve. The horizontal lines at the bottom of each graph represent the percentage of material transformed to martensite at a given time and temperature. Source: Ref 13

Martensite Morphology. One of two possible types of martensite might form in the iron-nickel alloy system depending on the nickel content of the material in question. At sufficiently high cooling rates, martensite will form in iron containing 5 to 10% Ni (Ref 14), and the addition of nickel in excess of 10% lowers the cooling rate necessary to form martensite in iron and ensures the formation of a completely martensitic structure. This particular type of martensite is referred to as lath martensite, and it will form in iron containing up to 25% Ni. If the nickel content is increased above 25%, the lath martensitic structure is replaced by a twinned martensite. Maraging steels typically transform from austenite to bcc lath martensite following cooling/quenching from the solution-annealing temperature, which is typically around 815 °C (1500 °F). Work on a series of Fe-7Co-5Mo-0.4Ti maraging alloys (18 Ni Marage 250) containing various nickel levels revealed that a lath martensitic structure was obtained for nickel levels as high as 23%. However, nickel contents in excess of 23% resulted in the formation of a twinned martensite (Ref 15). Generally, a lath martensitic structure is preferred in maraging steels because, following aging, this structure is tougher than a twinned martensitic structure.

Lath martensite consists of three subgrain structures, two of which are visible using standard optical metallographic techniques and one that requires transmission electron microscopy (TEM) for proper resolution. The lath martensitic structure of maraging steels consists of several martensitic packets within each prior austenitic grain and numerous blocks within each packet. Generally, the packets and blocks are planar, lie along one direction, and are parallel to each other. Packets are the predominant structure of lath martensite followed by the block structures that appear as discrete areas within each packet. These microstructural features can be resolved using standard optical metallographic techniques. The typical packet/block structure of 18 Ni Marage 250 is shown in Fig. 4(a). The substructure of each individual block of lath martensite consists of a series of fine parallel laths as shown by TEM (Fig. 4b). These martensitic laths are characterized by a high density of tangled dislocations. The orientation relationship between the lath martensite in 18 Ni maraging steels and the parent austenite from which it forms has been identified as the Kurdjumov-Sachs type: $(111)_{\gamma}//(011)_M$, $[110]_{\gamma}//[111]_M$ (Ref 16, 17).

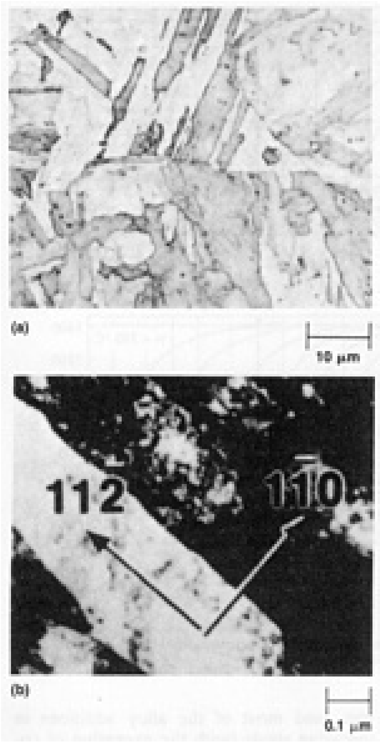

Fig. 4 Photomicrographs detailing the packet, block, and lath substructures of lath martensite in 18 Ni Marage 250. (a) Optical photomicrograph of the packet-block structure of lath martensite. (b) TEM photomicrograph of lath substructure of a block

The high density and uniform distribution of dislocations within the lath substructure promote an improved age-hardening response in maraging steels by providing a large number of preferred nucleation sites for the intermetallic precipitates that are formed in these alloys during aging. Additionally, these same dislocations also increase the diffusion rates of solute atoms by providing preferred diffusion paths. Both of these factors promote a uniform distribution of fine precipitates.

Effect of Alloying Elements on M_s and Martensite Morphology. Alloying elements have significant effects on the M_s temperature, and most of the alloy additions in maraging steels (with the exception of cobalt) suppress the M_s temperature. Most grades of maraging steel have M_s temperatures of the order of 200 to 300 °C (390 to 570 °F) and are fully martensitic at room temperature. In terms of martensite morphology, a high M_s temperature favors the formation of the desirable lath martensite morphology.

Maraging steels require careful use of M_s-suppressing alloy additions (such as nickel, molybdenum, and titanium) because these elements lower the M_s temperature and thereby promote the formation of a twinned martensite if used in excess. However, because nickel, molybdenum, and titanium are also responsible for the age-hardening mechanisms, cobalt is an important ingredient of maraging steels. One of the roles of cobalt in maraging steels is to raise the M_s temperature (Ref 18) so that greater amounts of other alloying elements (that is, titanium and molybdenum, which lower the M_s temperature) can be added while still allowing complete transformation to martensite before the steel cools to room temperature. Moderate levels of cobalt (6 to 8 wt% Co) are very useful in the design of maraging steels with strength levels in excess of 2100 MPa (300 ksi), since it helps to maintain a high enough M_s temperature in the presence of a high alloy content. Cobalt is also extremely important in maraging steels due to the influences it exerts on these alloys during the age-hardening reaction.

In the absence of cobalt, other elements such as nickel, molybdenum, and titanium must be maintained or reduced to levels to ensure an adequately high M_s temperature. Nickel lowers the M_s temperature of iron (Fig. 2a), and this effect becomes more pronounced at nickel levels in excess of 17.5% (Ref 8, 15). This is the reason nickel levels in excess of approximately 18% are no longer used in maraging steels. Molybdenum strongly depresses the M_s temperature (Ref 8, 18, 19), and chromium also exerts a negative influence on the M_s temperature of maraging steels; however, its effect is not as strong as that of nickel and molybdenum. The presence of titanium in an Fe-18Ni-8Co-5Mo maraging alloy promotes a reduction in the M_s temperature at all levels (Ref 8). The addition of up to 0.2% Al gives rise to a slight increase in the

M_s, which is then unaffected by subsequent additions (Ref 15). This effect, coupled with the deoxidizing capabilities of aluminum, is responsible for the use of approximately 0.1% Al in most maraging steels.

Retained austenite is generally not a problem in most commercially available grades of maraging steel, and, as a result, refrigeration treatments are not needed prior to aging. However, retained austenite can occur within localized regions that contain a high concentration of M_s-depressing elements such as nickel, molybdenum, chromium, and titanium. This microconstituent is generally associated with segregation, and as such, is found in heavily banded microstructures. The presence of retained austenite is generally considered to be unacceptable because this phase can result in significant variations in tensile strength, ductility, and toughness (particularly in the transverse orientation).

Martensite Aging

When the martensitic structure of maraging steels is reheated, two things can happen, depending on the temperature. If the alloy is reheated above the austenite start temperature, A_s, the previously formed martensite will transform back to austenite of the same composition by a diffusionless shear reaction. However, if the alloy is reheated to a temperature below the A_s, the martensite will initially age harden, followed by decomposition (reversion) into the equilibrium ferrite and austenite compositions. The rate at which this reversion reaction occurs is dependent upon the temperature to which the alloy is reheated. The rate of this reversion reaction at temperatures in the range of 455 to 510 °C (850 to 950 °F) is slow enough to allow considerable precipitation hardening to occur before the reversion reaction begins to dominate. This phenomenon of sluggish austenite reversion coupled with rapid age hardening forms the basis for the aging heat treatments of maraging steels.

The hardening of maraging steels during aging has been attributed to two different mechanisms. The first mechanism involves short-range ordering in the cobalt-bearing solid solution, and the second mechanism involves the precipitation of nickel-rich intermetallic compounds in the lath martensitic structure. While these two mechanisms occur separately, they are closely interrelated. According to the literature, the short-range ordering reaction occurs first, and it exerts a very significant influence on the subsequent precipitation reaction.

Ordering Reactions. The ordering reaction in maraging steels has been studied quite extensively by several investigators (Ref 20, 21, 22, 23). Neutron diffraction experiments performed on an Fe-22.7Ni-19.3Co maraging steel have revealed the presence of B2-type long-range ordering in this material upon aging (Ref 20). Similar experiments (Ref 21, 22) performed on maraging alloys with reduced nickel and cobalt levels (that is, Fe-18Ni-8 to 12% Co) have failed to reveal the presence of this long-range ordered structure. However, a neutron diffraction study performed on 18 Ni Marage 350 (Fe-18Ni-12Co-4.2Mo-0.1Al-1.5Ti) (Ref 22) revealed that a high degree of short-range ordering exists in this alloy after aging at 510 °C (950 °F) for 3 h. Based on this study, it was postulated that this short-range ordering phenomenon resulted in the formation of iron- and cobalt-rich regions and nickel-rich regions.

Rack and Kalish (Ref 23) believe that this short-range ordering reaction influences the subsequent precipitation-hardening reaction. Because the useful precipitates formed in maraging steels during aging are nickel-rich intermetallic compounds, the precipitation of the nickel-molybdenum and nickel-titanium compounds occurs primarily in the nickel-rich regions that were formed in the short-range ordered structure. Additionally, the formation of iron- and cobalt-rich regions would tend to stabilize these same precipitates because the strong interatomic attraction between iron and cobalt inhibits the diffusion of iron to the nickel-rich regions. This in turn delays the replacement of the metastable nickel-rich precipitates by equilibrium iron-rich precipitates.

Rack and Kalish's theory is quite logical based on the aging reactions that occur in maraging steels. Increased aging temperatures and/or times are necessary for the equilibrium iron-rich phases to displace the metastable nickel-rich phases, and an increase in either or both of these parameters would provide the necessary driving force for the diffusion of iron to the nickel-rich regions, which contain the metastable nickel-molybdenum and the nickel-titanium precipitates.

Precipitation Reactions. The precipitation reactions that occur in maraging steels are rather complex, and a significant amount of research has been devoted to the study of this phenomenon. The alloy elements that are involved in the precipitation reactions in maraging steels can be grouped into three broad categories (Ref 16):

- Beryllium and titanium are classified as strong hardeners
- Aluminum, niobium, manganese, molybdenum, silicon, tantalum, tungsten, and vanadium are classified as moderate hardeners

- Cobalt, copper, and zirconium are classified as weak hardeners

However, of these 13 elements, only 3 are utilized in the commercially available maraging grades. Two of these elements are titanium and molybdenum, both of which form precipitates, and the third is cobalt. Although cobalt does not form a precipitate, it participates indirectly in the age-hardening reaction through a phenomenon referred to as the cobalt/molybdenum interaction (see the section "Cobalt/Molybdenum Interaction" in this article).

The titanium- and molybdenum-bearing phases that are precipitated in this alloy system during aging are usually nucleated at dislocations or at lath boundaries. Nucleation on these two structural inhomogeneities tends to result in a uniform distribution of these phases. In general, these precipitates are coherent with the matrix; in addition, precipitate-free zones and coarsegrain-boundary precipitates are generally not found in these alloys.

The molybdenum-bearing precipitate commonly associated with the 18 Ni Marage 200, 250, 300, and 350 alloys is the metastable orthorhombic Ni_3Mo phase. These precipitates are rod shaped, they typically measure 25 Å wide × 500 Å long in the peak aged condition, and their long axis has been observed to lie parallel to the <111> directions of the bcc lath martensitic matrix (Ref 24). The strengthening that is imparted to the matrix is derived from the distorted matrix lattice that surrounds each Ni_3Mo precipitate. This effect is illustrated in Fig. 5.

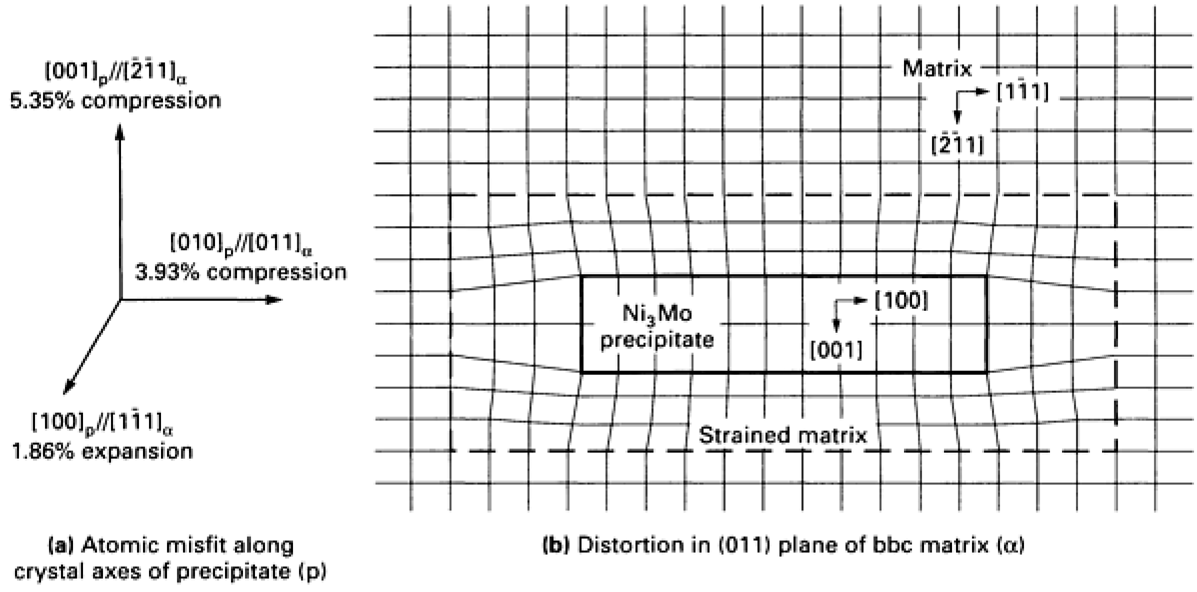

Fig. 5 Diagrams showing (a) the atomic misfit along the crystal axes of Ni_3Mo precipitate (p), and (b) the distortion that Ni_3Mo causes in the bcc matrix (α) of 18 Ni maraging steels. Source: Ref 24

Molybdenum also plays the necessary supplemental role of minimizing localized grain-boundary precipitation by lowering the diffusion coefficients of a number of elements in solid solution. Precipitation of these grain-boundary phases severely impairs the toughness of most molybdenum-free ferrous alloys. Work by Schmidt (Ref 25) has shown that discrete particles of austenite are also present on the grain and subgrain boundaries in molybdenum-free 18 Ni Marage 300. It has been theorized that the precipitation of these discrete particles of austenite at the grain and subgrain boundaries results in a nickel-depleted zone, which adversely affects the toughness and ductility of the molybdenum-free 18 Ni Marage 300 alloy on a localized scale.

Titanium-bearing precipitates are commonly associated with the 18 Ni Marage 200, 250, and 300 alloys. Titanium is used as a supplemental hardener because levels in excess of approximately 1.2% generally result in reduced ductility, both before and after aging (Ref 17). Titanium-rich precipitates identified as Ni_3Ti have been reported in 18 Ni Marage 250 and cobalt-free 18 Ni Marage 250 by Vasudevan, Kim, and Wayman (Ref 26) and in 18 Ni Marage 300 and cobalt-free 18 Ni Marage 300 by Vanderwalker (Ref 27). The η-Ni_3 Ti has a DO_{24} ordered hexagonal structure (Ref 28), and unlike Ni_3Mo,

Ni_3Ti is a stable phase. This titanium-bearing precipitate distorts the bcc martensitic matrix in a manner similar to that achieved with the molybdenum-bearing, Ni_3Mo precipitate.

Nucleation Rates. It has generally been observed that no incubation period accompanies the precipitation reaction in maraging steels. This behavior is evident in Fig. 6, which shows that significant hardening occurs after very short aging times (less than one minute). The lack of an incubation period implies the lack of a free-energy barrier to nucleation in these alloys. Peters and Cupp (Ref 29) attributed this lack of a free-energy barrier to two factors: the high degree of solute supersaturation and heterogeneous nucleation on dislocations. Cahn (Ref 30) has shown that both of these factors can effectively reduce the free-energy barrier to nucleation. Floreen (Ref 16) has also theorized that the good structural fit between A_3B precipitates and the bcc martensitic matrix is also responsible for the lack of a free-energy barrier and the low activation energies associated with 18% Ni maraging steels.

Figures 6 and 7 both indicate that the aging response of maraging steels is influenced by aging time. For example, Fig. 7 shows that the electrical resistivity of maraging alloys decreases as the aging time increases up to approximately 100 h. Because electrical resistivity is directly related to the amount of an alloy in solid solution, the electrical resistivity is influenced by the precipitation of compounds during aging. At aging times in excess of 100 h, the electrical resistivity increases. A similar effect on hardness (Fig. 6) can be observed. Aging times up to approximately 100 h promote an increase in aged hardness in Fe-18Ni-5Mo-8Co and Fe-18Ni-5Mo maraging alloys, after which a decrease is observed. This phenomenon is known as austenite reversion, which accompanies the formation of equilibrium precipitates in overaged maraging steels. (See the section "Austenite Reversion" in this article.)

Cobalt/Molybdenum Interaction. Cobalt does not directly enter into the aging reaction because it does not form a precipitate. However, this element does contribute to the aging reaction indirectly through a phenomenon referred to as the cobalt/molybdenum interaction. Numerous authors have reported that a synergistic effect exists between cobalt and molybdenum (Ref 6, 21, 31, 32). In these studies, the increases in strength from cobalt and molybdenum additions were greater than the sum of the strength increases produced by individual additions of these two elements. For example, in a study performed by Floreen and Speich (Ref 31), the addition of 8% Co to ternary Fe-8Ni-*X* (where *X* = aluminum, beryllium, manganese, niobium, silicon, or titanium) alloys resulted in a 140 to 310 MPa (20 to 45 ksi) increase in the 0.2% offset yield strength of the quaternary alloy over that of the ternary, which is equivalent to the solid-solution-strengthening effect of cobalt. However, when 8% Co was added to a ternary Fe-18Ni-5Mo maraging alloy, the yield strength of the quaternary alloy was 515 MPa (75 ksi) greater than that of the ternary alloy.

This synergistic effect of cobalt on the strength of molybdenum-bearing maraging steels occurs because cobalt reduces the solubility of molybdenum in the bcc matrix and thus enhances the precipitation of Ni_3Mo. Consequently, a finer, more uniform distribution of Ni_3Mo precipitates is formed when cobalt additions are present. This theory, proposed by Peters and Cupp (Ref 29), is supported by electrical resistivity measurements and TEM work. Figure 7 indicates that the amount of molybdenum in solid solution during the age-hardening reaction is less for the alloy system containing 8% Co. Transmission electron microscopy work performed by Miller and Mitchell (Ref 33) and Floreen and Speich (Ref 31) has also shown that additions of cobalt promote a finer dispersion of Ni_3Mo precipitates. A finer distribution of precipitates will reduce the interparticle spacing, which, in turn, will increase the yield strength of the alloy system.

Austenite reversion in maraging steels is caused by nickel enrichment of the bcc matrix. As was mentioned, Ni_3Mo, which has an orthorhombic Cu_3Ti-type structure (Ref 28), is one of the primary precipitates responsible for the age-hardening reaction in maraging steels; however, this phase is metastable. Formation of Ni_3Mo depletes the matrix of nickel, and, based on the stoichiometry of this phase, this depletion occurs at a ratio of three nickel atoms for every molybdenum atom. Because of its better fit with the bcc martensitic matrix, the formation of Ni_3Mo is initially favored over that of Fe_2Mo. As the orthorhombic Ni_3Mo precipitates grow, the coherency strains between the precipitate and the matrix also increase. Eventually, the coherency strains increase to the point where the stability of the Ni_3Mo is upset. At this point the Ni_3Mo phase dissolves and is replaced by Fe_2Mo. TEM and microprobe analysis of extraction replicas by Miller and Mitchell (Ref 34) and by Fleetwood, Higginson, and Miller (Ref 35) has confirmed the presence of Fe_2Mo in overaged maraging steels. Thus, as the metastable Ni_3Mo precipitates dissolve, the matrix becomes enriched in nickel because of

the resolution of nickel, and this enrichment in nickel is further enhanced due to a depletion in iron as the Fe_2Mo phase nucleates and grows.

Austenite reversion in maraging steels cannot be eliminated entirely when these alloys are reheated to temperatures below the A_s for prolonged periods, because the martensite that is formed during solution annealing is metastable and the system wants to decompose to the equilibrium austenite and ferrite structures via diffusion-controlled reactions. However, the rate at which this reversion reaction occurs can be modified to a certain extent by the alloy content of the steel.

Peters (Ref 36) performed an extensive study on the effect of various molybdenum, cobalt, and titanium contents on the volume percent of austenite formed during aging of ternary Fe-18Ni-*X* (*X* = molybdenum, cobalt, or titanium) alloys. Additions of molybdenum in excess of approximately 1% accelerated the formation of reverted austenite. This behavior is attributed to an increase in Ni_3Mo, which in turn promotes increased Fe_2Mo formation and subsequent nickel enrichment of the matrix. In contrast to this behavior, cobalt additions up to approximately 8% retard the reversion reaction; however, further additions of cobalt tend to accelerate the formation of reverted austenite. This phenomenon has been attributed to:

- The effect of moderate cobalt levels (6 to 8%) on raising the M_s temperature
- The subsequent lowering of M_s accompanied by cobalt additions in excess of 8%

Titanium, like moderate additions of cobalt, tends to delay the onset of austenite reversion in maraging steels, although the mechanism responsible for this effect is quite different from that associated with cobalt. Titanium forms a very stable precipitate that contains significant quantities of nickel (that is, Ni_3Ti), and the formation of these stable precipitates results in a nickel-depleted matrix.

Based on the arguments presented in the preceding paragraph, care must be taken to avoid segregation in the more highly alloyed maraging grades. For example, Schmidt (Ref 25) observed bands of austenite in an Fe-18.5Ni-9.1Co-6.75Mo-0.65Ti-0.11Al maraging alloy. Microprobe analysis of these bands revealed that they were enriched in cobalt and molybdenum, and the austenite contained in this segregated region was determined to be a mixture of retained and reverted austenite. This particular specimen was aged at only 480 °C (900 °F) for 8 h. The underlying point is that segregation, particularly of the elements cobalt and molybdenum, should be minimized in these grades to minimize both retained and reverted austenite formation because these two microconstituents can severely damage both mechanical and physical properties.

Heat Treatment of Maraging Steels

Solution Annealing. The martensitic matrix of maraging steels is prepared for later age hardening through a heat-treating procedure commonly referred to as a solution anneal. Solution annealing entails heating the alloy significantly above the austenite finish (A_f) temperature, holding a sufficient time to place the alloying elements in solid solution, and then cooling to room temperature. The most common solution-annealing cycle for the 18 Ni Marage 200, 250, and 300 alloys involves heating to 815 °C (1500 °F) for 1 h followed by air cooling.

Maraging steels are generally purchased in the solution-annealed condition for machining applications and reannealing is usually unnecessary. Product for forging applications is generally purchased in the unannealed condition because heating would negate the prior thermal-annealing cycle. It is suggested that machining follow solution annealing. If solution annealing must be performed after final machining, the use of vacuum, atmosphere-control air circulating, neutral salt bath, or fluidized bed furnaces may be necessary to minimize surface damage.

Generally, endothermic atmospheres are used in conjunction with atmosphere-control air-circulating furnaces. If vacuum furnaces are used to solution anneal maraging steels, a slight positive pressure of an inert gas, such as nitrogen or argon, should be used to minimize the possible loss of alloying elements at low vacuum levels. In addition, a neutral fluidizing gas should be usedin conjunction with a fluidized bed furnace to minimize surface damage. It may be necessary to solution treat sheet and strip products in dry hydrogen or dissociated ammonia to maintain surface integrity.

When maraging steels are required in long lengths, with a high degree of straightness, double solution-annealing treatments are sometimes applied with an intermediate straightening operation. These treatments are often performed with the product in a vertical orientation to prevent sagging. The initial solution-annealing temperature tends to be in the 815 to 980 °C (1500 to 1800 °F) range where residual stresses are more fully relieved. The product is then cooled to room temperature and straightened. This is followed by a lower-temperature vertical solution anneal in the 790 to 815 °C (1450 to 1500 °F) range to remove straightening stresses while minimizing distortion. If the product were straightened after annealing, it could return to the prior out-of-straightness condition upon aging because of a shape memory effect of the low-carbon iron-nickel lath martensite.

Castings generally receive pretreatments of 1150 °C (2100 °F) for 1 h followed by air cooling and reheating to 595 °C (1100 °F) for 1 h with another air cool. This pretreatment is a homogenizing cycle before solution annealing. The 595 °C (1100 °F) step forms reverted austenite that provides nucleation sites for recrystallization when the solution anneal is then

applied. The solution-annealing treatment that follows the homogenization and overaging cycles is similar to that for wrought product.

Effect of Annealing Time and Temperature on Aged Properties. Solution-annealing temperature has only a small effect on the strength of the aged material. This behavior is graphically depicted in Fig. 8 for Marage 250 and 300, with additional values for Marage 300 contained in Table 4. The data show that peak strength occurs with an 800 to 815 °C (1475 to 1500 °F) solution anneal, and strength is reduced up to 135 MPa (20 ksi) with higher and lower temperatures in the 760 °C (1400 °F) to 980 °C (1800 °F) range. Tensile ductility increases slightly with annealing temperatures from 760 to 815 °C (1400 to 1500 °F) and remains relatively unchanged with temperatures up to 980 °C (1800 °F). Table 4 also suggests that higher strength can be obtained with shorter annealing times.

Table 4 Effect of solution-annealing treatment on the aged properties of 18 Ni Marage 300 alloy

Solution heat treatment[(a)]	**Aged[(a)] strength**						**Aged[(a)] tensile ductility**	
	0.2% yield		**Tensile strength**		**Shear strength[(b)]**		**Elongation in 25 mm (1 in.), %**	**Reduction in area, %**
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**		
815 °C (1500 °F) for 15 min	2080	302	2095	304	1160	168	9.1	56
871 °C (1600 °F) for 15 min	2000	290	2027	294	1117	162	9.2	55
927 °C (1700 °F) for 15 min	1965	285	2005	291	1103	160	8.8	54
815 °C (1500 °F) for 1 h	2000	290	2040	296	1117	162	9.4	56

(a) All solution heat treatments followed by an aging heat treatment of 480 °C (900 °F) for 3 h.

(b) Double-shear-type test

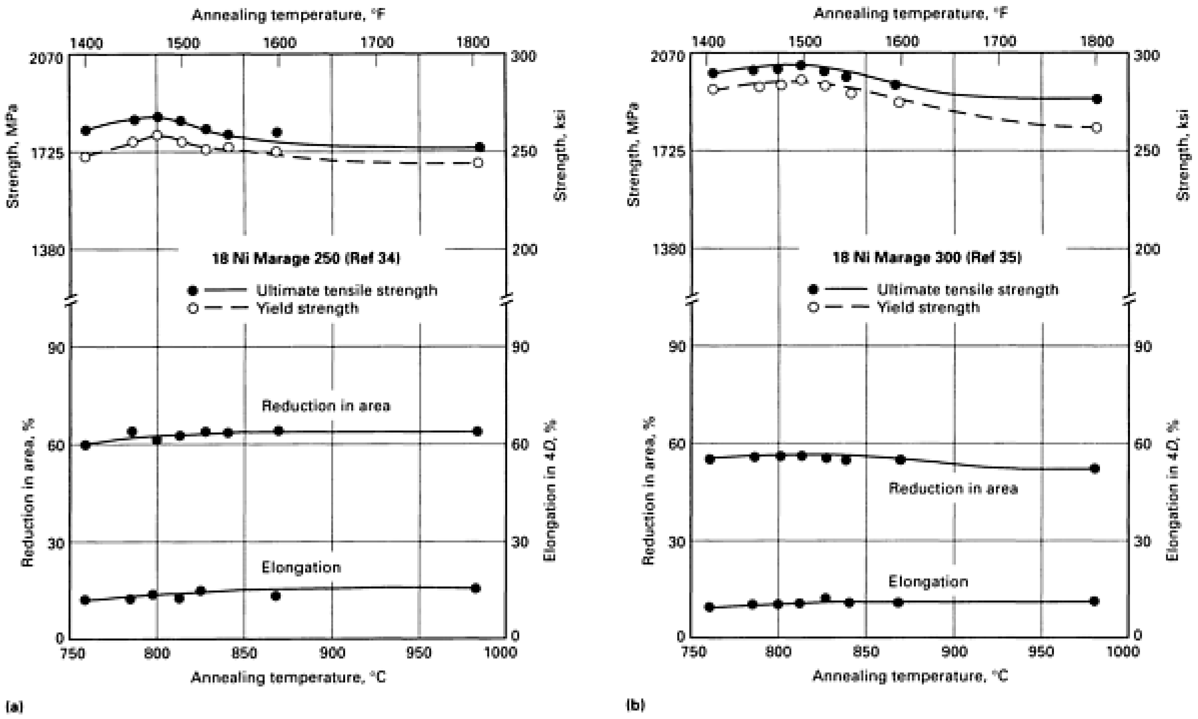

Fig. 8 Influence of solution-annealing temperature on the aged tensile properties of consumable vacuum-melted 18 Ni Marage 250 and 300. Heat treatment: Solution annealed for $\frac{1}{2}$ h at indicated temperatures, air cooled, and then aged at 480 °C (900 °F) for 3 h. Sources: Ref 10, 11

Lower strength and ductility with solution-annealing temperatures from 760 to 800 °C (1400 to 1475 °F) are attributed to incomplete solution of hardening elements. The reduction in strength associated with solution-annealing temperatures above 815 °C (1500 °F) is attributed to coarsening of the grain/packet structure. This grain growth and the subsequent reduction in strength are minimized by boron contents between 0.001 and 0.003%.

Maraging steels are usually solution annealed at a given temperature for 1 h. Table 4 indicates a benefit to strength from shorter solution-annealing times; however, care must be taken to ensure complete solution of hardening elements. Therefore, 1-h solution-annealing times are generally favored, and excessively long times are discouraged. Even boron-containing maraging steels will exhibit grain growth if exposed for more than 6 h at 955 °C (1750 °F).

The cooling rate following solution annealing is of little consequence because it has little to no effect on either the microstructure or mechanical properties (Table 5) of maraging steels. However, it is essential that parts be cooled to room temperature prior to age hardening. If parts are not completely cooled to room temperature prior to age hardening, untransformed or retained austenite may be present in the structure that could result in slightly lower than expected hardness and strength. Maraging steels are not susceptible to cracking during quenching to room temperature following solution annealing because of the extremely ductile nature of the bcc lath martensite.

Table 5 Data showing the relative insensitivity of tensile properties (a) of 18 Ni Marage 250 to variations in cooling medium following solution annealing

Cooling medium	Tensile properties[(a)]					
	0.2% yield		Tensile strength		Elongation (4*D*), %	Reduction in area, %
	MPa	ksi	MPa	ksi		

Brine	1855	269	1895	275	10.7	50.2
Air	1835	266	1875	272	10.6	50.8
Vermiculite	1835	266	1882	273	10.7	49.1

(a) Data represent transverse, midradius specimens removed from a 181 mm (7.125 in.) double-octagon billet. Heat treatment: 955 °C (1750 °F), 1 h, quench to room temperature plus; 790 °C (1450 °F), 1 h, quench to room temperature plus; 455 °C (850 °F), 9 h, air cool to room temperature.

Thermal embrittlement of maraging steels is due to the precipitation of TiC and possibly of Ti(C, N) films at austenite grain boundaries. This phenomenon is easily avoided with proper thermal handling and is, hence, quite rare. Thermal embrittlement occurs by heating maraging steels to temperatures in excess of 1175 °C (2150 °F), wherein carbon is taken into solution, followed by cooling slowly through or holding within the temperature range of 750 to 1090 °C (1380 to 2000 °F), where the carbon is then reprecipitated as a grain-boundary film.

It is permissible to heat maraging steels to temperatures in excess of 1175 °C (2150 °F) and rapidly cool or hot work through the 750 to 1090 °C (1380 to 2000 °F) range. The former time/temperature cycle will not permit time for grain-boundary carbide precipitation, whereas the latter will continually change grain-boundary location as a result of dynamic recrystallization. After a material has been heated above 1175 °C (2150 °F) and successfully cooled to room temperature, it may be heated into the 750 to 1090 °C (1380 to 2000 °F) range without problems because any carbides and possibly carbonitrides will have precipitated as discrete, stable particles during previous cooling to below 750 °C (1380 °F), and thus cannot reprecipitate as a film on reheating. In general, there is no reason to heat maraging steels over 1175 °C (2150 °F) except for initial raw material production, and therefore, no reason for an end user to cause thermal embrittlement.

Grain Refinement Using Thermal Cycling. Thermal cycling of maraging steels between the martensite finish (M_f) temperature and a temperature considerably in excess of the solution-annealing temperature can be used to refine the grain structure of coarse-grained maraging steels For example, Saul, Roberson, and Adair (Ref 37) were able to refine an ASTM grain size of 00/1 to an ASTM grain size of 6/7 in 18 Ni Marage 300 following three thermal cycles between room temperature and 1025 °C (1880 °F) The strains produced by the diffusionless shear transformations of martensite to austenite and of austenite to martensite provide the driving force for recrystallization during these thermal cycles. Grain sizes finer than ASTM 6 or 7 cannot be achieved by this process, and the process becomes less effective as the starting grain size becomes finer.

Age Hardening. A typical age-hardening treatment after solution annealing usually consists of reheating the alloy into the temperature range of 455 to 510 °C (850 to 950 °F), holding at this temperature for 3 to 12 h, and air cooling to room temperature. In typical treatments at 480 °C (900 °F), the 18 Ni Marage 200, 250, and 300 grades are held 3 to 8 h, whereas the 18 Ni Marage 350 grade is usually held 6 to 12 h at 480 °C (900 °F). The 18 Ni Marage 350 grade can also be aged for 3 to 6 h at 495 to 510 °C (925 to 950 °F). The use of marage steels in applications such as die casting tooling requires the use of an aging temperature of approximately 530 °C (985 °F) to provide an overaged structure that is more thermally stable.

Table 6 contains typical mechanical properties of the standard 18 Ni maraging steels following aging, and Table 7 contains a comparison of the typical mechanical properties associated with the 18 Ni Marage 250, low cobalt-bearing 18 Ni Marage 250 and cobalt-free 18 Ni Marage 250 grades. The standard aging treatments listed in Table 6 produce contraction in length of 0.04% in 18 Ni Marage 200, 0.06% in 18 Ni Marage 250, and 0.08% in both 18 Ni Marage 300 and 350. These very small dimensional changes during aging allow many maraging steel components to be finish machined in the annealed condition and then age hardened. When precise dimensions must be held, an allowance for contraction can be made and finish machining should be performed after aging.

Table 6 Typical mechanical properties of standard 18 Ni maraging steels in the age-hardened condition

Grade	Heat treatment[(a)]	Yield strength		Tensile strength		Elongation in 50 mm (2 in.), %	Reduction in area, %	Fracture toughness	
		MPa	ksi	MPa	ksi			MPA $\sqrt{m}$	ksi $\sqrt{in}$
18 Ni Marage 200	A	1400	203	1500	218	10	60	155-240	140-220
18 Ni Marage 250	A	1700	247	1800	260	8	55	120	110

(b) L-S orientation (that is, tensile load applied along longitudinal axis and crack propagation along the short transverse axis)

Temperature and time exert a significant influence on the properties that are developed in maraging steels during age hardening. These effects are clearly illustrated by the graphs in Fig. 9(a) and 9(b) for 18 Ni Marage 250. Hardening is initially very rapid as shown by the substantial increases in hardness and tensile strength that occur after only a few minutes at the age-hardening temperature. As aging time increases, eventually a point is reached where hardness and strength begin to decrease due to coarsening of the precipitates and formation of reverted austenite. Reverted austenite

generally begins to form as rather small particles at prior austenite grain boundaries and at packet and lath martensite boundaries. As shown in Fig. 9(a) and 9(b), the time at which overaging begins to occur is a function of temperature and generally obeys known time/temperature kinetic relationships such as the familiar Larson-Miller parameter. Figure 9(a) also indicates that significantly higher-aged hardness levels can be achieved in 18 Ni maraging steels by aging at lower than normal temperatures for extended periods. Unfortunately, the times associated with aging temperatures in the 400 to 425 °C (750 to 800 °F) range are on the order of 300 to 1000 h and generally are not viable for commercial production.

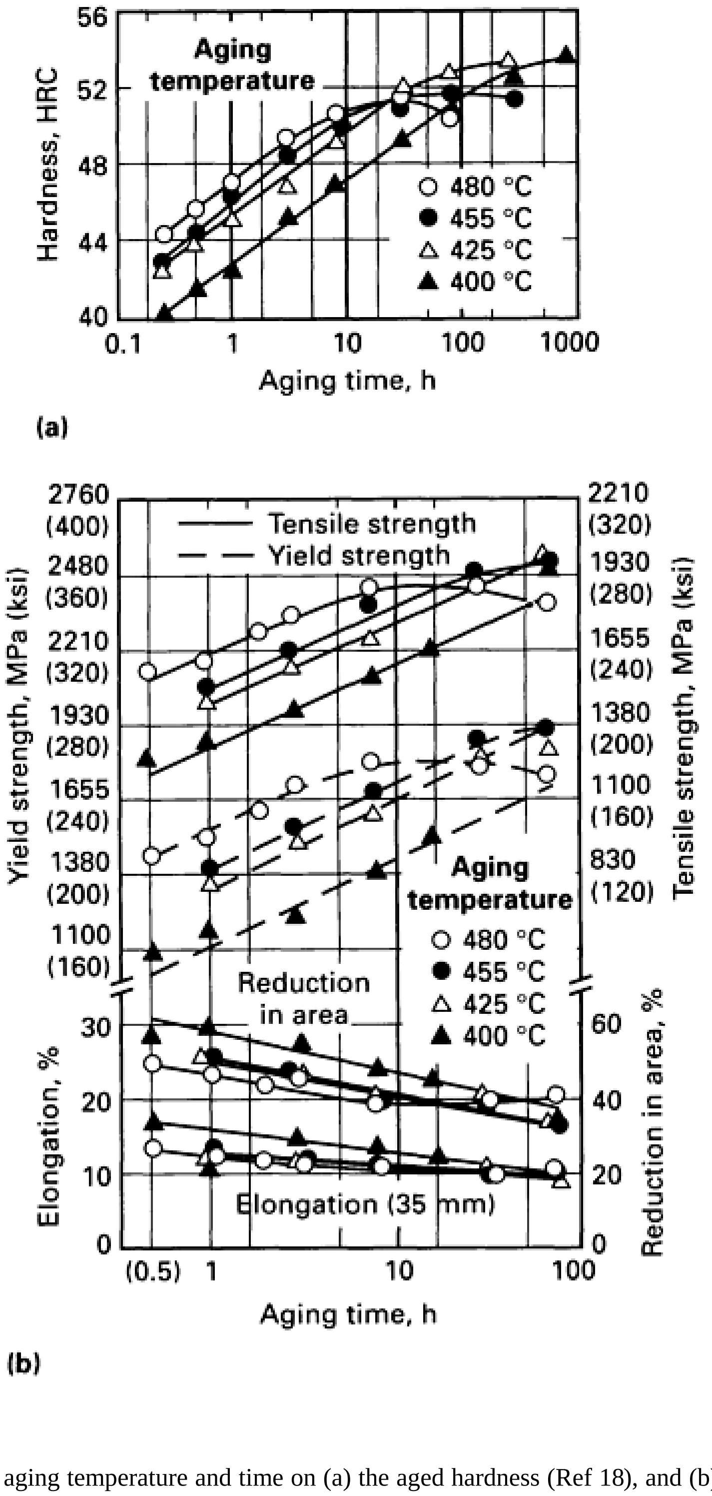

Fig. 9 Graphs showing the effect of aging temperature and time on (a) the aged hardness (Ref 18), and (b) the longitudinal tensile properties (Ref 37) of 18 Ni Marage 250 air-melted plate. Heat treatment: Solution heat treated at 815 °C (1500 °F) for 1 h, air cooled, and aged

Overaging. Great effort has been devoted to examining the properties of overaged maraging steels. The general belief is that an overaged microstructure should have good resistance to both fracture and stress-corrosion cracking (scc) as a result of the inherent lower strength and the potential crack-blunting ability of finely distributed austenite particles. In many instances this has been found to be so, and impressive improvements in plane-strain fracture toughness (K_{Ic}) or

threshold stress intensity for stress-corrosion cracking (K_{Iscc}) have been achieved with only modest reductions in yield strength of an overaged structure (Fig. 10). Unfortunately, however, there appears to be more heat-to-heat variability when overaging heat treatments are used. This variability is the result of a greater sensitivity of austenite formation to minor changes in composition and processing. Even the most homogeneous-looking structures contain minor alloy segregation that is manifested in the form of alloy-rich and alloy-lean bands. The alloy-rich bands tend to overage more rapidly than their alloy-lean counterparts. It is therefore difficult to recommend specific overaging heat treatments that will produce consistent mechanical properties. Generally, if a specific yield strength is required, it is better to use a maraging steel in which the required strength can be produced by conventional aging than to use an overaged steel of higher strength.

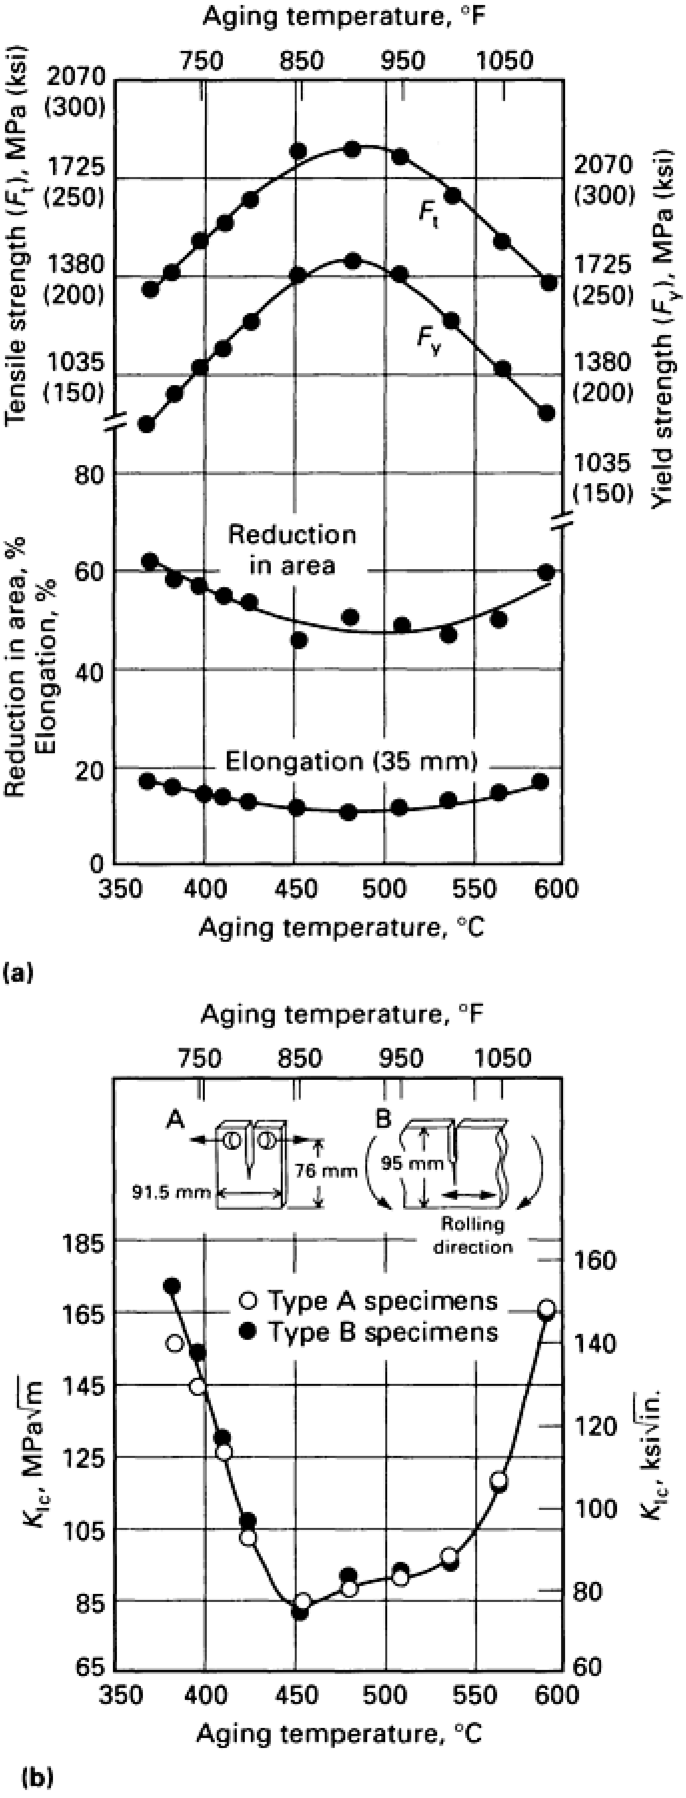

Fig. 10 Effect of aging temperature on (a) the longitudinal tensile properties, and (b) the plane-strain fracture toughness (L-T orientation) of 18 Ni Marage 250 consumable vacuum-melted plate. Heat treatment: Solution heat treated at 815 °C (1500 °F) for 1 h, air cooled, and aged

at indicated temperatures for 6 h. Sources: Ref 10, 38

Cold Working and Aging. The yield and ultimate tensile strengths of maraging steels can be increased by up to 15% by cold working prior to aging (see Table 8). This is accomplished by cold working previously solution-annealed material with up to a 50% reduction prior to aging. There is a concurrent loss in ductility and toughness. Some directionality of properties also occurs, with ductility being downgraded slightly more in the direction perpendicular to cold working. Cold reductions in excess of 50% should be avoided because delamination of the product may occur.

Table 8 Effect of cold work on Marage 250 fasteners

Alloy	Cold work, %	Yield strength		Tensile strength		Shear strength[a]		Elongation in 25 mm (1 in.), %	Reduction in area, %
		MPa	ksi	MPa	ksi	MPa	ksi		
18 Ni Marage 250	0	1800	261	1820	264	1025	149	8.6	57
	25	1875	272	1910	277	1070	155	6.5	49
	50	2020	293	2055	298	1140	165	5.2	44

	25	1903	276	1937	281	1062	154	6.7	48

(a) Double-shear-type test

Nitriding. Considerable surface hardening can be achieved by nitriding maraging steels in dissociated ammonia. Hardness levels equivalent to 65 to 70 HRC can be achieved at depths up to 0.15 mm (0.006 in.) after nitriding for 24 to 48 h at 455 °C (850 °F). Nitriding at this temperature allows simultaneous age hardening to occur. Salt bath nitriding for 90 min at 540 °C (1000 °F) has also been performed successfully; however, such treatment must be very carefully controlled to avoid excessive overaging. Both the fatigue strength and the wear resistance of maraging steels are improved by nitriding.

Postweld Heat Treatment. Welding exposes base metal to a range of temperatures, from molten metal within the weld, to ambient temperature some distance away. The area adjacent to the weld tends to be coarse grained as a result of the grain growth that accompanies the high temperatures in this portion of the heat-affected zone. Further away, the region that was heated between 595 and 745 °C (1100 and 1375 °F) tends to be overaged. Mechanical properties can be recovered for the most part by reaging the component. This should be considered a minimum requirement. Better properties can be obtained if the component is resolution annealed and aged; however, this may lead to distortion of the part. The most common practice is to simply reage after welding.

Baking is a low-temperature thermal exposure in the 150 to 200 °C (300 to 400 °F) range for hydrogen removal. Hydrogen embrittlement can occur in maraging steels when they are exposed to electrochemical operations such as plating. Because hydrogen pickup is difficult to detect, components exposed to such an environment should be baked for a period of 3 to 10 h. Mechanical properties, other than those that are deleteriously affected by hydrogen embrittlement, will not be affected by this low-temperature treatment.

Surface Treatment. Grit blasting is the most efficient technique for removing heat-treat oxide. Maraging steels can be chemically cleaned by pickling in sulfuric acid or by duplex pickling in hydrochloric acid and then in nitric and hydrofluoric acid. As with conventional steels, care must be taken to avoid overpickling. The sodium hydride cleaning of maraging steels should be avoided to minimize problems with crack formation. Grease and oils can be removed by cleaning in trichloroethane-type solutions.

Heat Treating of Powder Metallurgy Steels

Howard A. Ferguson, Metallurgical Consultant

Introduction

ATTAINING CONSISTENT RESULTS has always been a challenge in the heat treatment of sintered powder metallurgy (P/M) steel components. Unlike hardenability in wrought steel, where the response is controlled primarily by chemistry and grain size, hardenability in P/M steel is significantly influenced by interconnected porosity. Interconnected porosity is a network of connecting pores in a sintered object that permits a fluid or gas to pass through the object; also referred to as interlocking or open porosity. Because P/M is a net-shaped process, dimensional change or distortion occur that may affect the function or fit of the part. If a P/M part has been slack quenched, to reharden it without degrading the strength and toughness of the part is difficult.

In P/M, hardenability is influenced not only by porosity but also by prior processing variables such as graphite segregation and the degree of sintering. When P/M parts are quenched from the austenitic range, the external surfaces may be exposed to much higher cooling rates than are the interior surfaces, resulting in mixed microstructures and inconsistent hardness readings. These variations increase with the part design complexity. The next section briefly reviews the relationship between porosity and properties.

Effect of Porosity on Material Properties

The mechanical properties of wrought, fully dense steel are determined by chemical composition, microstructure, and surface characteristics. When porosity is uniformly distributed throughout a metal, the response to external stress can affect other physical, mechanical, and electrical properties. The degree of porosity in a metal affects the following material properties:

- Density
- Conductivity (thermal and electrical)
- Magnetic permeability
- Saturation induction
- Tensile strength, yield strength, and elongation
- Fatigue impact strength
- Modulus of elasticity
- Poisson's ratio
- Apparent hardness

- Hardenability
- Surface roughness

Approximate mathematical relationships [per Metal Powder Industries Federal (MPIF) Standard 35] between porosity and some physical properties are expressed as:

$$\textit{Density} = (\text{Theoretical density of metal}) \text{ x } \left(1\text{-}\frac{\%\text{porosity}}{100}\right)$$

$$\textit{Conductivity} = (\text{Theoretical conductivity of metal}) \text{ x } \left(1\text{-}2\frac{\%\text{porosity}}{100}\right)$$

Fatigue strength
= 0.40 × U.T.S., determined experimentally

$$\text{Modulus of elasticity of sintered steel} = (\text{Modulos of elasticity of wrought steel}) \text{ x } \left(1\text{-}\frac{\%\text{porosity}}{100}\right), \text{valid when \% porosity} < 50$$

Additional information is available in the article "Ferrous Powder Metallurgy Materials" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Relationship between Porosity and Hardenability

Maximum hardness is achieved in any steel composition with a fully martensitic microstructure. This microstructure can only be produced, however, if the diffusion-dependent transformation of austenite can be suppressed by sufficiently rapid cooling. A number of factors affect cooling rates throughout a given shape and the response of a given steel composition to those cooling rates. Hardenability for a wrought material can be defined as the capacity of the microstructure of a metal to be transformed from austenite to martensite at a given depth when cooled rapidly. The core hardenability depends directly upon the thermal conductivity of the steel to dissipate the heat content.

As has been shown, thermal conductivity in P/M parts is determined by the percent of porosity in the workpiece material. This porosity acts as an insulator and slows heat transfer. The quantity of heat (Q) (in kg-cal/kg) that can be removed from a porous steel upon quenching can be expressed by the relationship:

$$Q = M\,(1 - \varepsilon)\; C(\Delta T) \qquad \textbf{(Eq 1)}$$

where M (1 - ε) is the mass of the sintered steel with percent of porosity (ϵ), which has the same surface for heat exchange as a fully dense part of equal shape, and C is the average heat capacity of the material. This property is not influenced by the porosity. ΔT is the temperature differential occurring during cooling. Therefore:

$$\frac{Q}{M.\Delta T} = (1 - e)C \qquad \textbf{(Eq 2)}$$

As porosity approaches zero, hardenability increases linearly, as shown in Fig. 1. This figure shows the results of a series of Jominy tests in which test specimens made from atomized iron containing 0.90% graphite were pressed and sintered at various density levels. The lowest-density specimen contained 24% porosity, whereas the highest-density specimen contained approximately 9% porosity.

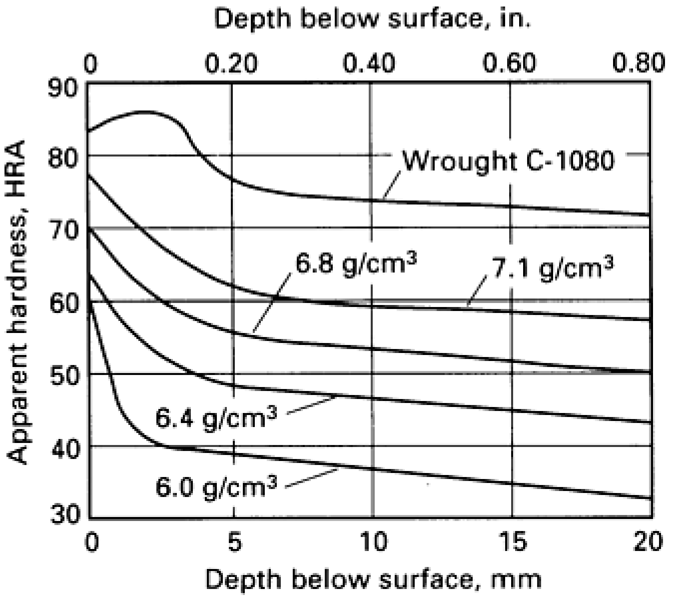

Fig. 1 Effect of metal powder density on the hardenability of P/M steels. The four test specimens, made from an atomized iron metal powder containing 0.90% graphite, had densities ranging from 6.0 g/cm^3 (0.217 lb/in.^{3}) (24% porosity) to 7.1 g/cm^3 (0.256 lb/in.^{3}) (9% porosity) and compositions similar to the wrought C-1080 with which they are being compared.

The test specimens, along with a test bar machined from wrought C-1080 steel having a composition similar to that of the P/M steel, were austenitized at 870 °C (1600 °F) for 30 min in a protective neutral atmosphere and then end quenched in a water column, according to the Jominy test described in ASTM A 255. Hardness readings were taken every 2.5 mm (0.10 in.) from the quenched end and plotted as shown in Fig. 1. This graph dramatically illustrates that the hardenability of P/M steels is limited by the influence of porosity on thermal conductivity.

Influences of Porosity on Case Depth

At porosity levels above 8%, the pores are interconnected by small channels. This allows gases to penetrate quite rapidly. Upon case hardening with gases containing a high carbon potential, this interconnected porosity allows diffusion of carbon into the internal pore surfaces as well as to the external surface of the part. If it is assumed that total porosity (ε_t) is the sum of both open porosity (ε_o) and closed porosity (ε_c):

$$\varepsilon_t = \varepsilon_o + \varepsilon_c \qquad \textbf{(Eq 3)}$$

The inverse of ε is a measure of the resistance to penetration of the gases, and the ratio:

$$R = \frac{1}{(e_0 - e_c)\, x\, e_0} \qquad \textbf{(Eq 4)}$$

is an indication of the maximum resistance that the gas can meet in its passage through the interconnected porosity. Plotting this resistance index (*R*) against total porosity, we see a curve as shown in Fig. 2. This curve can be verified by experiment.

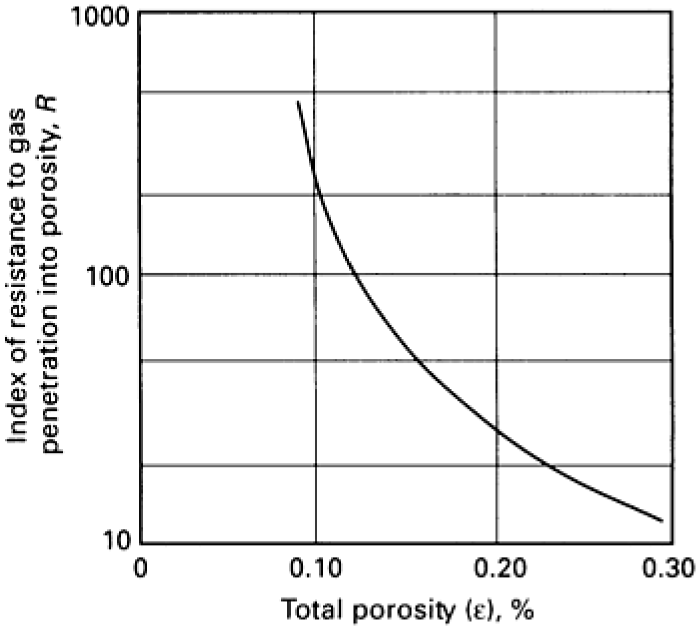

Fig. 2 Resistance to gas penetration of a P/M steel as a function of metal powder density

The photographs shown in Fig. 3 are microstructures of P/M test specimens that were carbonitrided. The 25 mm (1 in.) diam slugs were pressed and sintered to increasing density levels from atomized iron with 0.20% graphite added. Upon sintering, the chemistry of the P/M slugs approximated that of AISI/SAE C1018 carbon steel. A test specimen was also machined from C1018 bar stock, and all specimens were then carbonitrided at 870 °C (1600 °F) for 60 min and oil quenched. As is shown, increasing density was accompanied by a proportional decrease in carbon penetration, to approximately 7.0 g/cm^3 (0.253 lb/in.^{3}). At this point, the interconnected pores began to close off, preventing the gases from penetrating into the internal volume of the part.

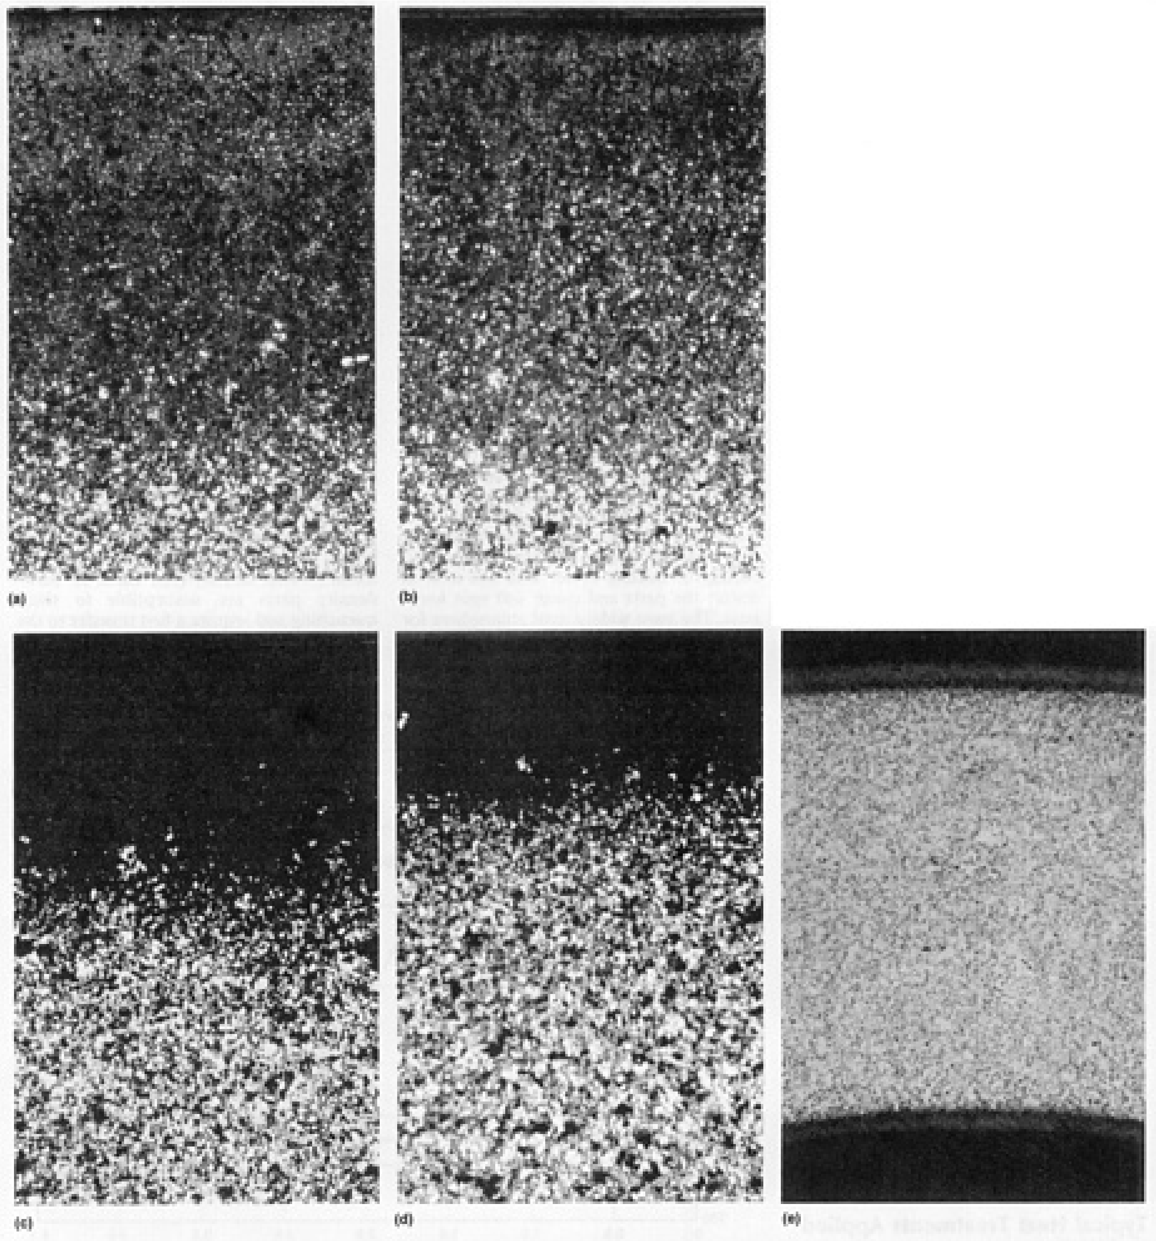

Fig. 3 Microstructures showing relationship of density to carbon penetration in carbonitrided P/M steels having composition similar to carbonitrided C1018 steel. (a) Density, 6.0 g/cm^3 (0.217 lb/in.^{3}); carbon penetration, 3.6 mm (0.140 in.). (b) Density, 6.4 g/cm^3 (0.231 lb/in.^{3}); carbon penetration, 3.3 mm (0.130 in.). (c) Density, 6.8 g/cm^3 (0.246 lb/in.^{3}); carbon penetration, 1.8 mm (0.070 in.). (d) Density, 7.0 g/cm^3 (0.253 lb/in.^{3}); carbon penetration, 1.0 mm (0.040 in.). (e) Density, 7.87 g/cm^3 (0.284 lb.in.^{3}) (wrought) C1018; carbon penetration, 0.3 mm (0.012 in.). All 25×

By plotting depth below surface against density (Fig. 4), it became evident that for optimum control of case-hardening processes, P/M parts should be specified at 7.0 g/cm^3 (0.253 lb/in.^{3}) or higher.

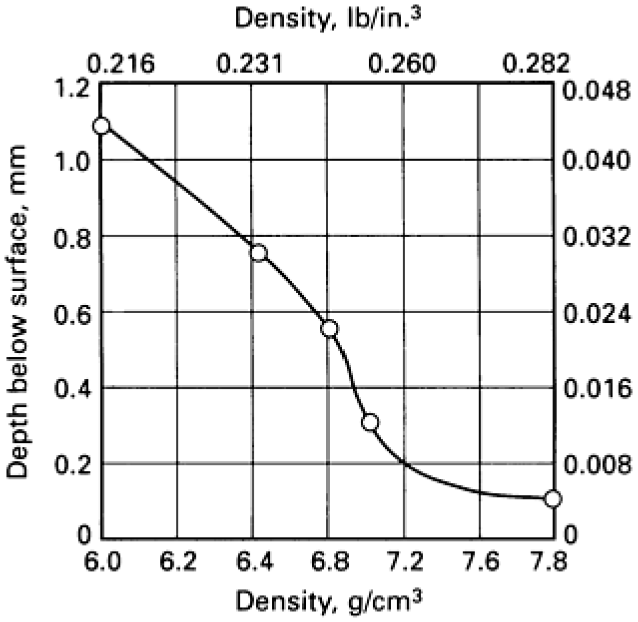

Fig. 4 Effect of metal powder density on the case depth of a carbonitrided P/M steel. Hardening sequence: carbonitrided at 70 °C (1600 °F) for 30 min, oil quenched, and tempered 1 h at 205 °C (400 °F)

These test specimens were then micro-hardness tested. From the graph shown in Fig. 5 it is apparent that many problems can occur when case hardening low-density parts. Because of the fast penetration of carburizing gases, a controlled carbon potential cannot be sustained at the surface of the part. This would allow soft spots to occur upon quenching.

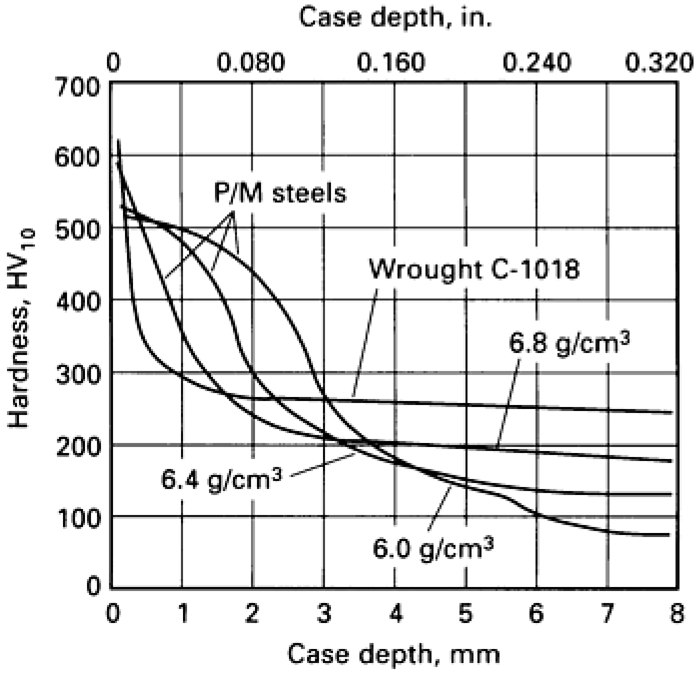

Fig. 5 Plot of hardness versus case depth as a function of metal powder density in P/M steels carbonitrided 30 min at 870 °C (1600 °F) and then oil quenched. P/M steel composition is similar to that of wrought C1018.

The primary purpose of case hardening low-carbon steels is to provide a hard, wear-resistant surface while maintaining a soft ductile core. This combination imparts optimum wear resistance and toughness properties to these materials. When

carbon penetration is uncontrolled, parts can exhibit extreme embrittlement and excessive dimensional distortion upon quenching.

Effect of Alloy Content on Hardenability

It is known that by increasing the carbon content of steel, tensile strength and hardness are gained in proportion to the added carbon. In wrought steel, this ratio is maintained to approximately 1.4% C.

In P/M steels, ultimate tensile strength is reached at the eutectoid composition of 0.9% C. By increasing carbon content above this level, carbide networks begin to form at grain boundaries and porosity channels. This causes embrittlement and loss of rupture strength. As alloying agents such as nickel, molybdenum, chromium, and copper are added, the optimum carbon content is lowered. These elements tend to reduce the critical cooling rate. In sintered steels, the most common alloying agents are copper and nickel.

Copper Content. Additions of copper increase both hardness and tensile strength in the sintered condition. Upon heat treatment, it increases depth of hardness but severely reduces toughness and elongation. The relationship existing among modulus of rupture, copper additions, and combined carbon is shown in Fig. 6. As carbon content increases, rupture strength increases proportionately to an optimum level and then begins to decrease.

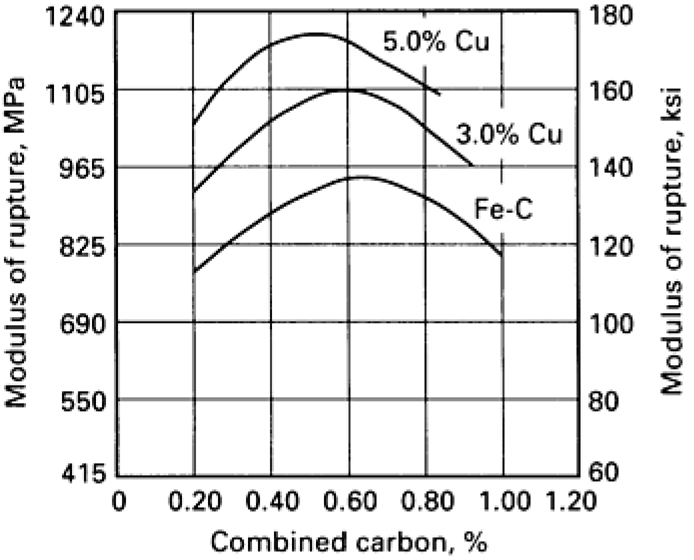

Fig. 6 Plot of combined carbon content versus modulus of rupture as a function of copper content (0 to 5%) in P/M steels. Metal powder density of steel is 6.6 g/cm^3 (0.238 lb/in.^{3}). Samples neutral hardened for 30 min at 870 °C (1600 °F)

In the plain iron-carbon compositions, peak strength occurs near the eutectoid composition in the as-sintered condition and at approximately 0.65% C in the heat-treated condition. By adding copper to the iron-carbon compositions, there exists a significant increase in strength with increasing copper content to approximately 5% Cu. Upon heat treatment however, optimum strength is found at a lower carbon content as the copper content is increased.

Nickel Content. Nickel increases tensile properties of as-sintered P/M steels approximately one-half as much as copper but provides significantly higher strengths after heat treatment due to higher hardenability. This is because of the heterogeneous nature of blended nickel alloys. Copper, which melts at approximately 1040 °C (1905 °F), forms a liquid phase upon sintering at 1120 °C (2050 °F), creating a homogeneous iron-copper alloy. Nickel, having a higher melting point than the sintering temperature, will alloy only by solid-state diffusion. This produces a duplex microstructure consisting of partially alloyed iron surrounding nickel-rich islands. Upon heat treatment the matrix transforms to martensite, but the nickel-rich areas remain austenitic. This results in a strengthening of the matrix with some ductility and toughness retained.

Nickel-Copper Content. Figure 7 shows the influence of increasing nickel and copper contents on hardenability of P/M steels. Here Jominy bars were made with increasing levels of copper and nickel, holding carbon content at 0.50%. All

bars were pressed to a 6.7 g/cm^3 (0.24 lb/in.^{3}) density and austenitized at 850 °C (1560 °F) for 2 h. By adding copper to the iron-carbon alloy, a dramatic increase in surface hardness is seen with a relatively small increase in hardenability. By adding nickel to the iron-copper-carbon alloy, we see a slight gain in surface hardness but a significant improvement in hardenability. Many components made today that require optimum heat-treated properties contain both nickel and copper additions to a low-carbon, high-density steel.

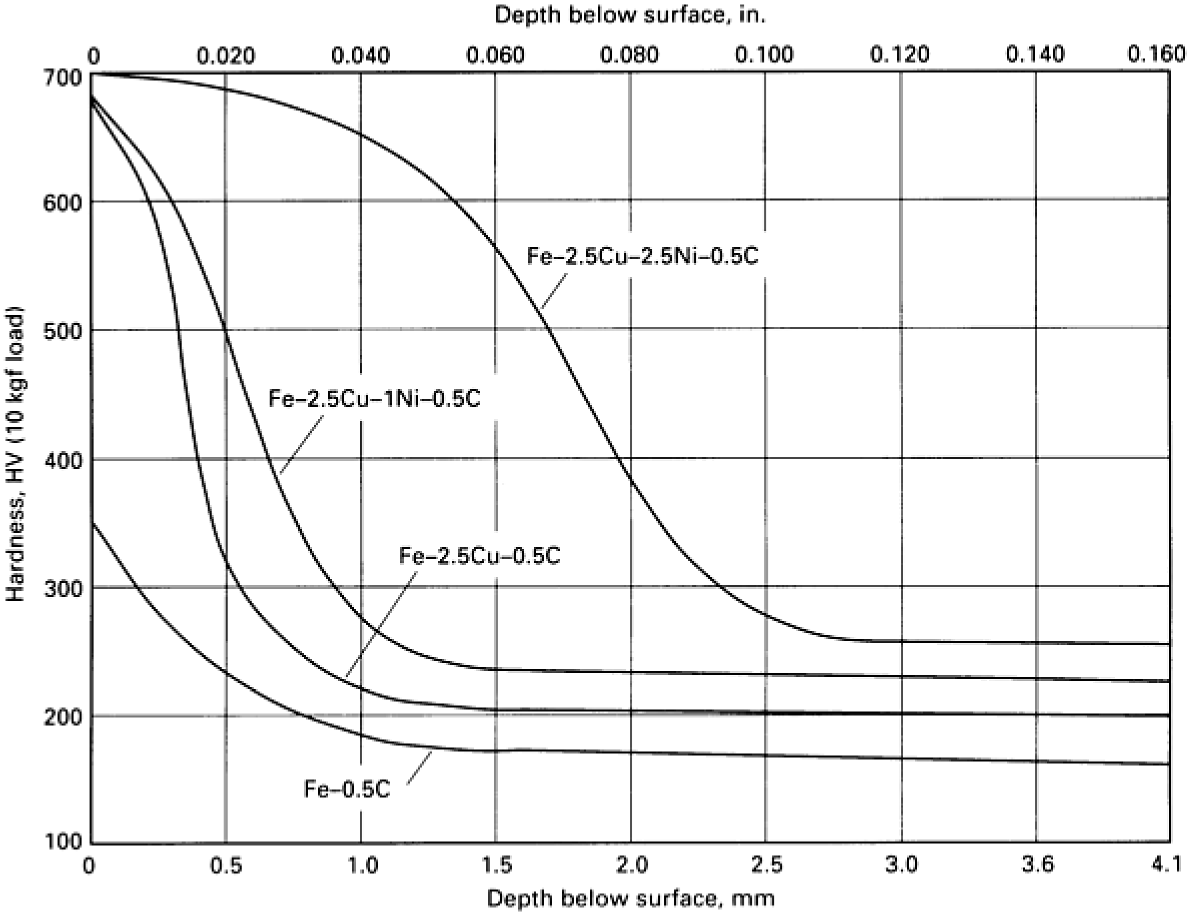

Fig. 7 Effect of copper and nickel additions on the hardenability of iron-carbon P/M steels. Metal powder density was 6.7 g/cm^3 (0.242 lb/in.^{3}). Specimens carburized 2 h at 850 °C (1560 °F)

Effect of Materials and Processing on Heat-Treated Properties

Conventional blended alloys as previously described with a single compaction at 410 to 620 MPa (30 to 45 tsi) and a conventional sinter at 1120 °C (2050 °F) provide typical heat-treated properties listed in Table 1. Further details of the range of properties obtainable by heat treating P/M copper and nickel steels made from elemental powders are given in Table 2.

Table 1 Comparison of the mechanical properties of conventional blended P/M alloys versus prealloyed P/M alloys

P/M alloy	Sintering temperature		Ultimate tensile strength		Yield strength		Elongation, %	Hardness, HRC	Fatigue strength		Impact resistance (Unnotched Charpy test)

(b) All mixes contained 0.5% zinc stearate [$Zn(C_{18}H_{35}O_2)_2$]; sintered in endogas at 1125 °C (2050 °F) for 30 min. Heat treatment: austenitized at 815 °C (1500 °F) for 15 min, quenched in oil at 65 °C (150 °F), tempered at 175 °C (350 °F) for 60 min.

Prealloyed Powders. To attain higher properties, special materials or processes must be employed. The first consideration is to use a prealloyed powder that provides more uniform hardenability. The most commonly used prealloy on the market is similar to the AISI/SAE 4600 composition. The nominal composition of this prealloy is 0.20% Mn, 1.8% Ni, 0.50% Mo, and a balance of iron.

Traditionally, prealloyed powders have been harder to compact than mixed elemental powders based on atomized iron. Recent improvements in compressibility of low-alloy steel powders have enabled higher densities to be reached with compaction pressures of 485 to 620 MPa (35 to 45 tsi). Properties of heat-treated nickel-molybdenum P/M steels (MPIF designations FL-4205 and FL-4605) for a wide range of densities are given in Table 2.

By alloying the iron prior to atomization, the hardenability can be significantly improved when compared to a similar blended alloy. However, this increases the particle hardness and reduces compressibility of the powder. To increase the hardenability of these materials, additional operations that would increase density need to be employed.

Re-pressing. Probably the most common method is re-pressing. Dependent on part shape, this can be done in tools similar to the compacting tools, allowing for size change upon sintering. A fully sintered 4600-type prealloy composition would require a 550 to 690 MPa (40 to 50 tsi) re-press to attain 90% of theoretical density. For complex-shaped parts, a process that includes pressing, presintering, re-pressing, and sintering is frequently used. This will provide density levels to approximately 94% of theoretical.

The improvement in hardenability of the 4600-type prealloy is shown in Fig. 8. Here it is compared to an iron-carbon and an iron-nickel-carbon blended alloy with equivalent carbon content and density. The Jominy bars were made by pressing the various alloys at 415 MPa (30 tsi) and sintering at 1120 °C (2050 °F). As shown, the prealloy density was slightly lower than the preblended alloys. The prealloy was then repressed at 550 MPa (40 tsi) to show the improvement in hardenability due to repressing. The 4600 prealloy with 0.50% combined carbon, sintered and re-pressed to 90% of theoretical density and heat treated in the same manner as the blended alloy shown above, will develop the typical heat-treated properties listed in Table 1.

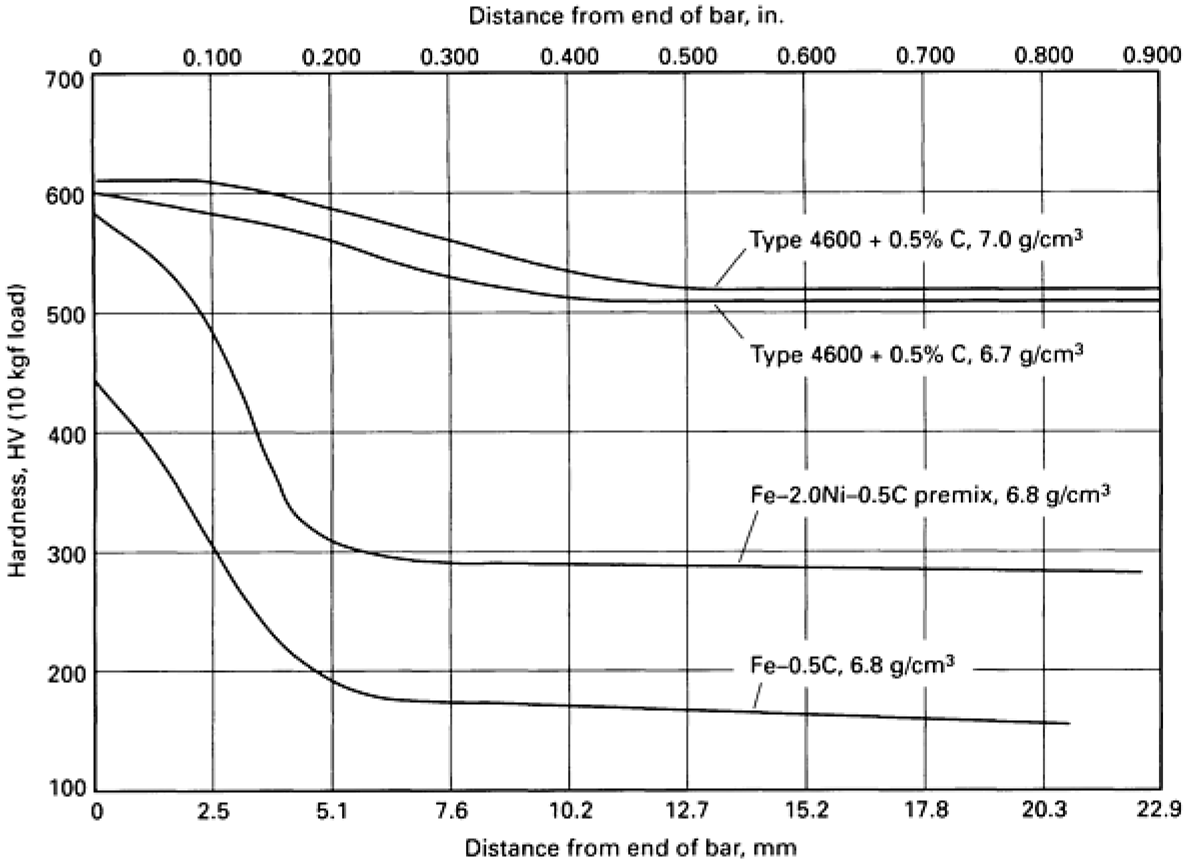

Fig. 8 Effect of prealloying on the hardenability of P/M steels. Two type 4600 prealloyed P/M steels with different metal powder densities are compared with two preblended P/M alloys having different compositions but identical densities. All four steels sintered at 1120 °C (2050 °F)

High-Temperature Sintering. Most P/M sintering is done in mesh belt furnaces with a temperature capability to 1150 °C (2100 °F) Special pusher- and walking-beam furnaces are now being used that can provide temperatures to 1380 °C (2515 °F) These temperatures can also be attained in batch-type vacuum furnaces. By sintering at higher temperatures, more uniformity in alloying is realized along with improved pore rounding and coalescence. This can provide added hardenability and more consistent heat-treating properties. Properties of an AISI/SAE 4600-type alloy with 0.5% C, sintered at 1260 °C (2300 °F) and subsequently heat treated, are listed in Table 1.

Typical Heat Treatments Applied to P/M Parts

Neutral Hardening. Many P/M parts heat treated today are neutral hardened. These alloys contain 0.50 to 0.80% C and have densities exceeding 88% of theoretical. They are hardened primarily for wear resistance and improved core strength.

These parts are normally hardened in belt-type or batch-type sealed quench furnaces. Because they are net-shaped parts, they must not touch or impinge upon one another during the heating cycle. This will tend to distort the parts and cause soft spot hardness. The most widely used atmosphere for these furnaces is endothermic gas, with both methane and air additions to control carbon potential (see the article "Furnace Atmospheres" in this Volume). Because these gases can rapidly penetrate the porosity, carbon diffusion is quite rapid. Therefore, short time cycles at relatively low temperatures are used.

Metal Powder Density Determines Hardening Variables. A general rule of thumb for selection of hardening cycles when maximum wear resistance and core strength are desired is to determine the heat-treating cycle on the basis of the metal powder density (see Table 3). Low-density parts are susceptible to slack quenching and require a fast transfer to the quench. The ideal furnace for these parts would be a mesh belt or shaker hearth where the parts can fall freely into the quench. In these furnaces, it is recommended that a high temperature and a slightly carburizing atmosphere be used to counterbalance the loss of control at the quench end of these furnaces.

Table 3 Recommended P/M steel hardening cycles for obtaining maximum combination of wear resistance and core strength based on metal powder density

Density		Quenching					Tempering temperature	
		Temperature		Time at temperature, min	Transfer time, s	Medium		
g/cm^3	lb/in.^{3}	°C	°F				°C	°F
6.4-6.8	0.231-0.246	870-890	1600-1635	30-45	<8	Fast oil	. . .	. . .
6.8-7.2	0.246-0.260	850-870	1560-1600	45-60	<12	Fast oil	150-180	300-355

Medium- to high-density parts suited to batch-type sealed quench furnaces where temperature uniformity and carbon content of the atmosphere are better controlled. Here lower temperatures can be used that minimize part distortion, and atmosphere carbon content can be neutral to the part. The one drawback to batch-type furnaces is the longer transfer time to the quench. Many of the new batch furnaces on the market have automated internal handling equipment to transfer the hot load to the quench. These are not suitable for many P/M parts because of the excessive time delay in reaching the quench.

Quenching Mediums. Also recommended is a fast oil, an oil defined as having a General Motors' quenchometer rating of 10 s or less. Load size is also a critical factor in attaining uniform hardness upon quenching. Most sealed quench furnaces are designed to quench out 0.5 kg (1 lb) of parts per gallon of quench oil. For P/M parts it is recommended that 0.5 kg (1 lb) of parts require 11 to 15 L (3 to 4 gal) of quench oil.

Overloading is probably the most common problem in attaining uniform heat-treated properties. When these parts are quenched, the gases entrained in the porosity are rapidly expelled, creating an extended vapor phase around the parts and thereby reducing the critical cooling rate.

Carburizing is normally specified in parts with a large cross-sectional thickness to attain maximum fatigue and impact properties. The material usually specified for carburizing contains hardenability agents such as nickel, molybdenum, and copper with relatively low carbon content. To develop optimum dynamic properties at porosity levels between 10 to 15%, a combined carbon level of 0.30 to 0.35% is recommended. As porosity is reduced below 10%, combined carbon can be reduced to 0.15 to 0.25% C. Because improved dynamic properties are also associated with high densities, it is recommended that combined carbon be adjusted to a level best suited for re-pressing after sintering Additional information is available in the articles "Gas Carburizing," "Pack Carburizing," "Liquid Carburizing and Cyaniding," and "Vacuum Carburizing" in this Volume.

Wrought Steel. In wrought steel, carburizing is normally characterized by a surface hardness range and an effective case depth. Microhardness measurements can accurately show the hardness profile in wrought steel but can be erratic when used on P/M steels.

P/M Steels. Here subsurface porosity can influence the microhardness readings, resulting in false hardness readings. It is recommended that at least three hardness readings be taken at each level below the surface and averaged to determine effective case depth.

Carburizing of P/M steels is usually done at temperatures between 900 to 930 °C (1650 to 1705 °F). Time cycles are normally short because of the rapid diffusion of carbon through the interconnected porosity. Therefore, atmosphere carbon potentials need to be somewhat higher than those required for wrought steels of similar composition.

Carbonitriding is probably the more common case-hardening treatment used on P/M parts. Here process temperatures are lower (800 to 850 °C, or 1470 to 1560 °F) and ammonia additions to approximately 10% are made. Ammonia dissociates on the parts, allowing nitrogen to diffuse into the surfaces. This retards the critical cooling rate upon quenching and provides a more consistent martensite transformation. It also produces a more consistent surface hardness, which improves wear resistance and toughness of the P/M steel. Because lower temperatures can be used, carbonitriding provides better control of distortion compared to carburizing. Care must be taken when adding ammonia, however, since excessive nitrogen diffusion into the internal pore surfaces can cause embrittlement.

Carbonitriding is a shallow case-hardening treatment. Case depths greater than 0.51 mm (0.020 in.) deep are seldom specified. For this reason, cycle times are relatively short, usually on the order of 30 to 60 min. As in neutral hardening, carbon control is a critical aspect of the treatment. Normally carbon potentials of 1.0 to 1.2% are specified to maintain the carbon profile in the part. Additional information is available in the article "Carbonitriding" in this Volume.

Tempering is usually required after case hardening when densities exceed 90%. In this case, significantly high stresses that could initiate cracking are developed upon quenching. As porosity increases, this stress level is reduced to a level at which a posttemper is not necessary. However, judgment should be used when deciding whether tempering is required. If a substantial amount of retained austenite is formed upon carbonitriding, a temper is advisable.

If the part has thin cross sections, sharp corners, or undercuts that would act as stress raisers, then tempering would also be advisable. Recommended tempering temperatures for P/M parts range from 105 to 200 °C (220 to 390 °F). Above this temperature, entrained quench oil can ignite, creating a hazardous condition in the furnace. Tempering above 200 °C (390 °F) will result in improved toughness and fatigue properties of the heat-treated P/M steel. However, furnaces will need special adaptations to handle the high volume of smoke created by the ignition of the quench oil. Additional information is available in the article "Tempering of Steel" in this Volume.

Induction Hardening. Spur gears, bevel gears, splined hubs, and cams are ideal components to utilize P/M production techniques. These parts usually require hard wear-resistant surfaces in some areas, with the retention of the ductility of the sintered matrix in the remainder of the part. Induction hardening is commonly specified for these applications.

This process can be placed in an automated machining line that can reduce handling and be a cost-effective hardening treatment when high volumes of parts are being produced. Because the inductance of P/M materials is typically reduced due to porosity, a higher power setting is normally required to reach a given depth of hardening compared to that used for a wrought material of similar composition. Furthermore, because the heat is rapidly dissipated, a rapid transfer to the quench is mandatory.

As with wrought steels, the response to hardening by induction is dependent upon combined carbon content, alloy content, and surface decarburization. This latter variable can be a major concern with P/M parts. With today's conventional belt-type sintering furnaces using an Endogas atmosphere, decarburizing can occur as the parts leave the hot zone and cool slowly through the 1100 to 800 °C (2010 to 1470 °F) temperature range.

In most cases, P/M parts are quenched in a water-based solution containing some type of rust preventative to forestall internal corrosion. In those applications where induction hardening is considered, densities above 90% should be specified. With a decrease in density, the resistivity of the steel increases and permeability decreases. For this reason, integral quench coils using a high-velocity spray quench are generally used to attain maximum surface hardness in the P/M part. Additional information is available in the article "Induction Heat Treating of Steel" in this Volume.

Nitrocarburizing. This process is rapidly growing in popularity as a treatment for P/M parts. Here, nitrogen is diffused into the surfaces of the steel in sufficiently high concentration to form a thin layer of ε iron nitride on the surface of the part. This is done at temperatures ranging from 570 to 600 °C (1060 to 1110 °F). At these temperatures no austenite transformation occurs, thereby significantly reducing the dimensional changes and distortion.

The process uses conventional integral quench atmosphere furnaces. The atmosphere usually consists of a 50/50 mixture of endothermic gas and anhydrous ammonia. Control of the nitrided layer thickness, as with the other treatments, is dependent on density. If the nitrided layer is allowed to form on the internal pore surfaces to any significant extent, a volume expansion can occur. For this reason, density of the P/M part should be above 90% of theoretical. This nitrided layer, when properly applied, can reduce the coefficient of friction at the surface of the part and provide improved wear resistance compared to conventional hardening to martensite. This process is best applied to applications where sliding wear and fretting are involved.

Because the hard nitrided layer is relatively thin, this process should not be applied where high indentation or impact loading is involved. The ε nitride layer that is formed can attain a file hardness in excess of HRC 60, depending upon alloy content of the steel. Indentation hardness testing is not recommended when evaluating this process. Since no transformation occurs, the P/M parts can be air cooled without loss of surface hardness. Also, no oil absorption occurs, which leaves the porosity open for impregnation if desired.

Nitrocarburizing also provides improved strength and reduced notch sensitivity in P/M parts. Figure 9 shows the fatigue improvement of two low-carbon P/M steels after nitrocarburizing. A typical nitrocarburized microstructure of an iron-copper-carbon P/M steel is shown in Fig. 10. Additional information is available in the article "Gaseous and Plasma Nitrocarburizing" in this Volume.

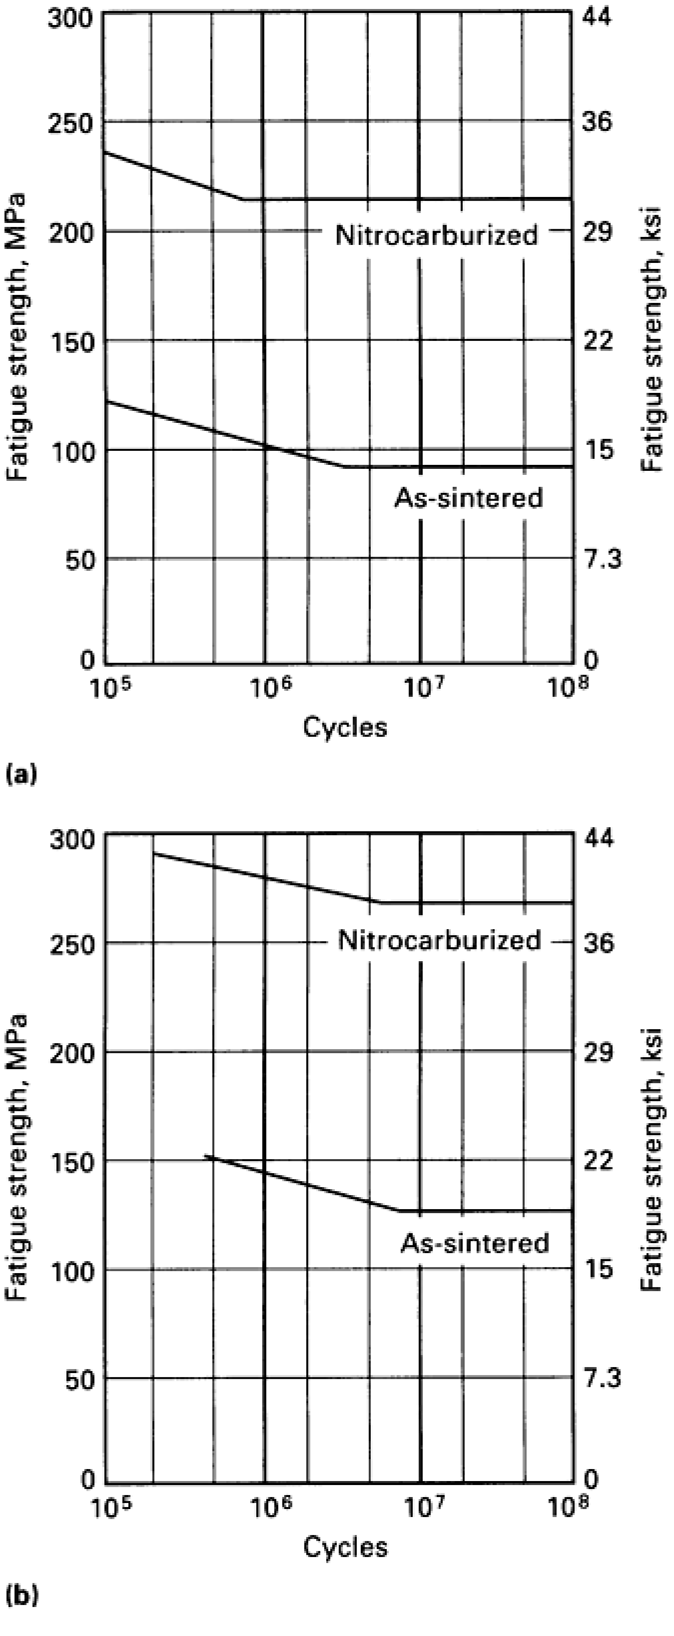

Fig. 9 Increase in the notched axial fatigue strength of sintered low-carbon P/M steels after nitro-carburizing for 2 h at 570 °C (1060 °F). (a) F-0000 carbon steel. (b) FC-0205 copper-carbon steel. Metal powder density was 7.1 g/cm^3 (0.256 lb/in.^{3}).

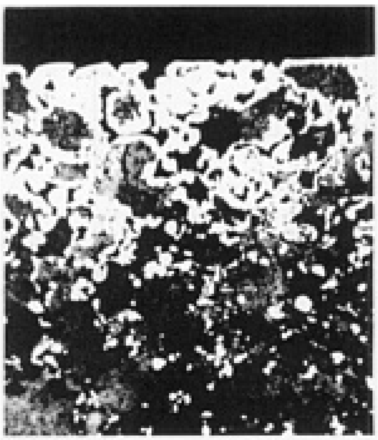

Fig. 10 Typical microstructure in a sintered ferritic nitrocarburized iron-copper-carbon P/M steel. 100×

Steam Treating. P/M parts have traditionally been steam treated for improved wear resistance, corrosion resistance, and sealing capacity. Here, P/M parts are heated in a specific manner under a steam atmosphere at temperatures between 510 to 595 °C (950 to 1100 °F) to form a layer of black iron oxide (magnetite, or ferrous-ferric oxide, $FeO \cdot Fe_2O_3$) in the surface porosity according to the chemical reactions:

$$3Fe + 4H_2O \text{ (steam) } Fe_3O_4 + 4H_2 \text{ (gas)} \qquad \textbf{(Eq 5)}$$

Steam treating cannot truly be described as a heat treatment because no structural changes occur in the matrix. In this process, magnetite (Fe_3O_4) is formed at the interconnecting surface porosity, filling the porosity with a second phase. Magnetite has a microhardness equivalent to HRC 50.

The process itself is straightforward, the primary variables being temperature, time, and steam pressure. Caution must be used to prevent the formation of hydroxides and lower oxides such as ferrous oxide (FeO) and ferric oxide (Fe_2O_3), which is red rust.

The recommended procedure for steam treating is:

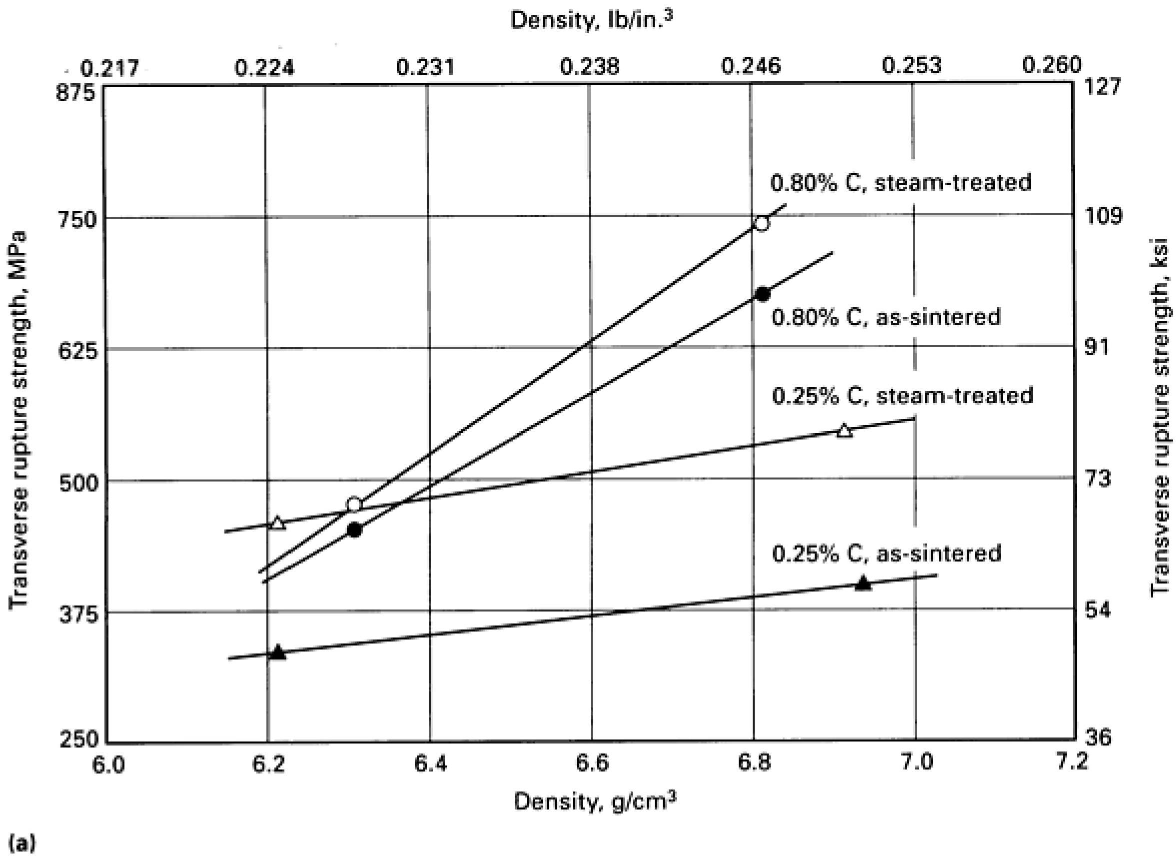
- Preclean parts to remove any oil or lubricants that may have been absorbed into the porosity from prior machining, sizing, or finishing operations
- Load clean sintered parts in loosely packed baskets and place fixture into a furnace preheated to 315 °C (600 °F)
- Heat parts in air until the center of the load has stabilized at the set temperature
- Introduce superheated steam at a line pressure of 35 to 105 kPa (5 to 15 psi) and allow furnace to purge for at least 15 min
- Increase furnace temperature to desired set point and hold for no longer than 4 h at heat
- Upon completion of cycle, reduce furnace temperature to 315 °C (600 °F). When parts reach this temperature, the steam can be shut off and the parts unloaded

Caution should be used when opening the furnace door after the steam cycle. As shown in Equation 5, hydrogen is produced during this process and can ignite. It is recommended that a nitrogen purge be applied prior to unloading. This process, when correctly applied, can impart improved surface properties, and, depending upon steel composition, increased compressive yield strength.

In all steam-treated P/M steels, the ductility is significantly reduced due to the internal stresses created by the formation of the iron oxide. Care must be taken when treating high-carbon P/M steels because these internal stresses can initiate microcracking and cause severe loss of ductility. Many cases have been reported in which parts were accidentally

dropped on the floor after being steam treated, and the parts subsequently shattered like glass. The best recommendation for preventing such an incident is to specify a 0.5% C (max) content on materials that are to be steam treated.

Figure 11(a) shows that transverse rupture strength increases proportionately with sintered density. Upon steam treating, low-carbon P/M steels exhibit a uniform increase in strength, whereas the higher-carbon P/M steels show only a small incremental increase in strength.



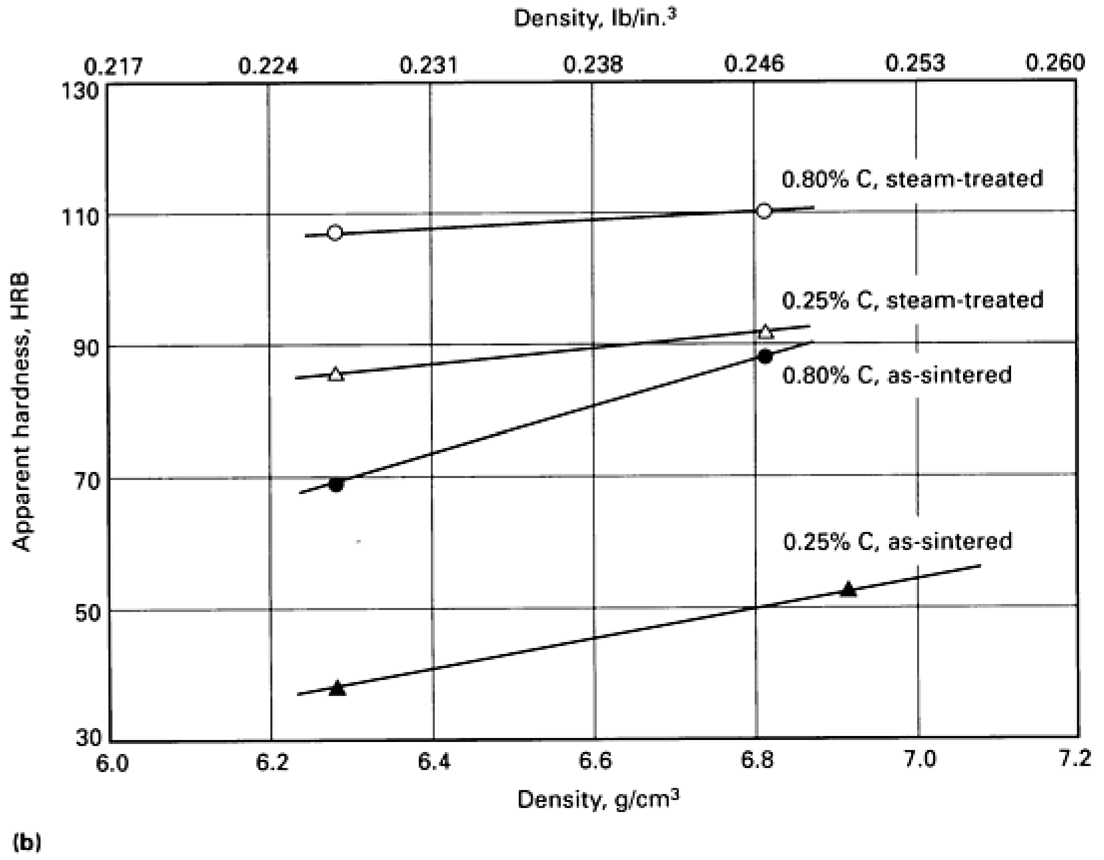


Fig. 11 Effect of steam treating on the mechanical properties of sintered carbon P/M steels as a function of density. (a) Transverse rupture strength. (b) Apparent hardness

Apparent hardness also is improved as shown in Fig. 11(b). By filling the porosity with a hard second phase, the P/M steel can offer better support to an indentation hardness test. As with rupture strength, the incremental increase in hardness of high-carbon steels is less than that of low-carbon steels.

Guidelines to Heat Treating P/M Parts

Whether this secondary operation is done in-house or sent out to a commercial heat treater, some guidelines need to be considered to ensure that parts get properly treated. In the past, a heat treatment was specified primarily to improve wear resistance. With the advent of high-compressibility powders and high-temperature sintering, heat treatments are added to provide improved dynamic properties as well. The following is a list of recommendations when heat treating porous P/M parts:

- Always degrease parts prior to heat treating. In many manufacturing plants, P/M parts are dipped in a rust preventative after sintering. Also, many P/M parts are machined prior to heat treatment and can retain some of the lubricant. These oils can contaminate the heat-treating atmosphere and cause discoloration
- Do not use dense loads. Overlapping parts can cause soft spots and distortion. For best results, parts should be single spaced in layers
- Use highly agitated quenching oil with a quench severity rating (*H*) of 0.7 to 1.5
- When tempering, hold at 205 °C (400 °F) for 2 h before proceeding to higher temperatures. This is to minimize the evolution of smoke and to prevent ignition

If it is planned to send parts outside to a commercial heat treater, a technical review of the part requirements and prior processing history is recommended. Many commercial shops have had bad experiences with P/M because they do not fully understand the implication of porosity and tend to treat parts as they would wrought steels. It is important that you establish a good communication network with your heat treater to alert him to any structural changes in your part caused by changes in powder lot, tooling, or sintering cycle.

A good procedure is to send sample lots to the heat treater for him to establish process capability. After he has met the print requirements, he should be requested to run the parts in the same furnace under the exact conditions as were established. As a parts fabricator, it would be wise to give as much consideration to the heat-treating process as would be given to the primary processes. Reworking because of improper heat treatment can not only add more cost but can also significantly affect the physical properties of the P/M part.

Thermomechanical Processing of Steels

A.J. DeArdo, C.I. Garcia, and E.J. Palmiere, Basic Metals Processing Research Institute, Department of Materials Science and Engineering, University of Pittsburgh

Introduction

ECONOMIC AND TECHNICAL DEMANDS of the last three decades have forced the global steel industry to undergo a series of important changes. These changes were made imperative by the need of the steel industry to maintain a competitive and leadership position in relation to other engineering materials. Significant advances have been made in both process metallurgy and product metallurgy. These advances have transferred the steel industry into a modern, cost-effective, and high-quality manufacturing force in the world marketplace. The improvements in steelmaking, ladle refining, and continuous casting practices have been matched with other advances in the science and technology of microstructural control in the final product. It is this ability to control microstructure during processing that has allowed significant and cost-effective improvements in the final properties of steel to be achieved. Central to the concept of controlled processing is thermomechanical processing (TMP).

It is now possible to produce as-rolled steels with final properties tailored to the requirements of the final application. The concept of tailored final properties is possible primarily through the ability of the heat treater to control the final microstructure in a predictable manner. This control of the final microstructure is based on an understanding of the way that steels respond to hot processing and how that response can be altered through alloying.

It is well known that the control (that is, refinement) of final microstructure begins during solidification and proceeds during reheating, hot rolling, and final transformation. Because the final transformed microstructure reflects the microstructure and composition of the austenite prior to transformation, it is obvious that the refinement of this final austenite is critical to obtaining the optimum final microstructure and properties. One of the key processing elements used to obtain the proper austenite microstructure is known as thermomechanical processing, which, as will be shown later, is a special type of hot deformation process (for example, rolling, forging, piercing, and so on). The most common form of thermomechanical processing in use today is called controlled rolling (Ref 1). During controlled rolling, it is the as-rolled austenite microstructure that is being controlled.

Because the goal of thermomechanical processing is the refinement of the austenite grain structure, the control of recrystallization and/or grain coarsening during processing are among the metallurgical techniques available. The presence of minute quantities of elements such as niobium, titanium, and vanadium have been shown to be particularly useful during thermomechanical processing because of the change in the solubilities of their carbides/carbonitrides/nitrides in austenite as a function of temperature. These elements are known as microalloying elements (MAE) because they are generally present at levels at or below 0.1 wt%. Hence, the use of these microalloying elements enables the goal of thermomechanical processing to be easily achieved because these elements permit forces retarding recrystallization and grain coarsening to be governed by controlled precipitation during processing. It is, therefore, normal to have microalloyed steels mentioned in discussions of thermomechanical processing. The discussion that follows is a review of various aspects of thermomechanical processing, including its justification, history, underlying physical metallurgy, methods of application, beneficial effects on properties, and current and future applications.

Effect of Microstructure on the Mechanical Properties of Ferrite-Pearlite Steels

Engineering steels require a range of properties in order to be technologically and economically successful. The principal properties of interest in these steels are strength, toughness, ductility, and weldability. Prior to the mid-1960s, structural steels were available in essentially two forms. The first were simple carbon-manganese-silicon steels which were available in either the as-rolled or as-normalized condition. These steels exhibited ferrite-pearlite (F-P) microstructures with yield strengths generally less than 350 MPa (51 ksi). Alternatively, higher-strength steels were available through the heat treatment of these and, more likely, the low-alloy steel grades. These steels exhibited tempered martensite structures with yield strengths generally in excess of 560 MPa (81 ksi). The technological demands of the 1970s in the transportation, energy, and construction industries required large quantities of higher strength, cost-effective steels. Because these demands could not be satisfied by either the existing hot-rolled steels or the existing heat-treated steels due to factors such as insufficient strength and excessive cost, respectively, new steels were clearly required. This demand was ultimately satisfied by the parallel development of microalloyed (MA) steels on the one hand and thermomechanical processing on the other. As discussed later in this section, the synergistic effect of microalloy additions to simple steels and thermomechanical processing together led to improvements in strength, toughness, and weldability. Hence, where it was once possible to have both high strength and toughness only in heat-treated steels, it is now possible to have similar properties in as-processed steels without the need of final heat treatment.

Effect of Microstructure on Yield Strength. Let us begin by discussing the yield strength of hot-rolled microalloyed low-carbon F-P steels. This strength is often expressed as an expanded Hall-Petch equation (Ref 2, 3):

$$\sigma = \sigma_o + \Delta\sigma_S + \Delta\sigma_T + \Delta\sigma_P + \Delta\sigma_D + \kappa_y d_F^{-\frac{1}{2}} \quad \textbf{(Eq 1)}$$

where σ is the observed yield strength, σ_o is the lattice friction stress, and $\Delta\sigma_S$, $\Delta\sigma_T$, $\Delta\sigma_P$, and $\Delta\sigma_D$ are strengthening increments caused by solid solution, texture, precipitation and dislocation effects, respectively. The last term, $\kappa_y d_F^{-\frac{1}{2}}$, is the contribution to strength by the ferrite grain size. More detailed information concerning the contribution of each term to the observed yield strength is given in Table 1.

Table 1 Contributions of microstructure to the yield strength of steel

Strength component	Description of strength variable	Definition or value	Ref
σ_o	Lattice friction	Constant	. . .
$\Delta\sigma_S$	Solid solution	$\approx k_1(C_S)^{\frac{1}{2}}$ (b) $\approx k_1 C_S$ (dilute)	Pickering (4)
$\Delta\sigma_T$	Texture	(hkl)<uvw>	Gladman (5) Backofen (6)
$\Delta\sigma_P$	Precipitation	$\approx f^{\frac{1}{2}}/r$ (c)	Gladman (5)
$\Delta\sigma_D$	Dislocation	$\approx k_2 d_D^{\frac{1}{2}}$ (d)	Dieter (7)
$\kappa_y d_F^{-\frac{1}{2}}$ (a)	Grain size	. . .	Pickering (6)

(a) κ_y, Hall-Petch constant; d_F, ferrite grain diameter.

(b) C_S, solute concentration; k_1, a constant.

(c) *f*, precipitate volume fraction; *r*, precipitate radius.

(d) d_D, dislocation density; k_2, a constant

As shown in Table 1, the lattice friction stress, for a given crystal structure, is a constant (Ref 8). Theoretically, the solid solution strengthening component should vary with the square root of the solute content, but $\Delta\sigma_S$ has been found to vary approximately linearly in dilute solutions (Ref 4). The texture component, $\Delta\sigma_T$, originates in the Schmid factor and, hence, would vary with the nature, sharpness, and intensity of the crystallographic texture exhibited by the ferrite grains (Ref 5, 6). The precipitation hardening increment, $\Delta\sigma_P$, varies with the square root of the volume fraction of precipitation, *f,* and inversely with precipitate size, *r,* while the dislocation strengthening increment, $\Delta\sigma_D$, increases with the square root of the excess dislocation density, d_D (Ref 5, 7). Finally, the strength also increases with the inverse square root of the ferrite grain size, d_F (Ref 4).

These contributions to yield strength are shown in Fig. 1. Superimposed on Fig. 1 are grain sizes typical of hot-rolled carbon steels and controlled-rolled MA steels. Note that these two steels differ in grain size and the presence of a precipitation hardening increment ($\Delta\sigma_P$ in Eq 1) in the MA steel. This combination of extra grain refinement and precipitation hardening renders the controlled-rolled MA steel approximately twice as strong as the hot-rolled carbon steel. A concrete example of these effects, shown in Fig. 2, compares the as-rolled behavior of a hot-rolled carbon steel

with a controlled-rolled MA steel. The presence of the niobium has led to finer grain sizes and higher-strength levels, all because of the synergism that exists between microalloying elements and thermomechanical processing.

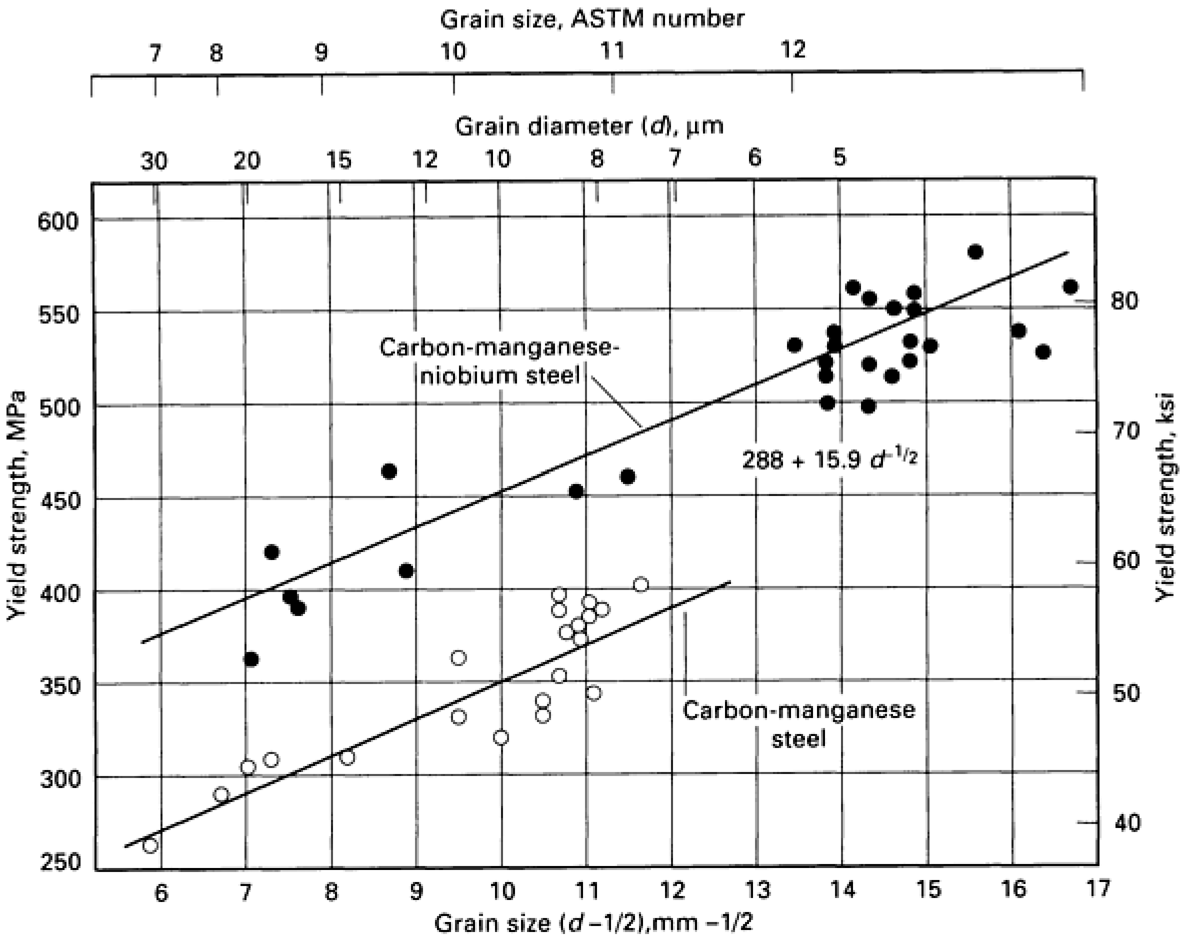

Fig. 2 Experimental Hall-Petch relationships as determined by quantitative metallography for carbon-manganese and carbon-manganese-niobium steels. Source: Ref 10

Of prime importance here is that, with the exception of the lattice friction term and solid solution strengthening by non-precipitating solutes, every component of the final strength of a given MA or high-strength low-alloy (HSLA) steel is affected, directly or indirectly, by not only the bulk microalloy composition but also by the hot-rolling process.

Resistance to Brittle Fracture. Another property of importance in hot-rolled material is the resistance to brittle fracture. This, of course, differs from the resistance to ductile fracture, which is controlled to a large extent by the cleanliness of the steel and its strength level. Clean steels typically have high Charpy shelf energies, high tensile ductilities, and excellent formabilities. The resistance to brittle fracture is usually measured in a Charpy V-notch impact test. This resistance is quoted either as a ductile-to-brittle transition temperature (DBTT) or as a test temperature corresponding to a given fracture energy (Ref 6, 8). In general, however, any index of the resistance to brittle fracture is improved with ferrite grain refinement and is deteriorated by increases in any of the other strengthening mechanisms. These relationships are shown in Fig. 3. Hence, the production of hot-rolled steels with good resistance to low-temperature brittle fracture is dependent on achieving a fine ferrite grain size in the final product. Furthermore, because grain refinement is the only strengthening mechanism that simultaneously improves both strength and toughness, it is the mechanism that assumes paramount importance in the design of strong and tough microstructures.

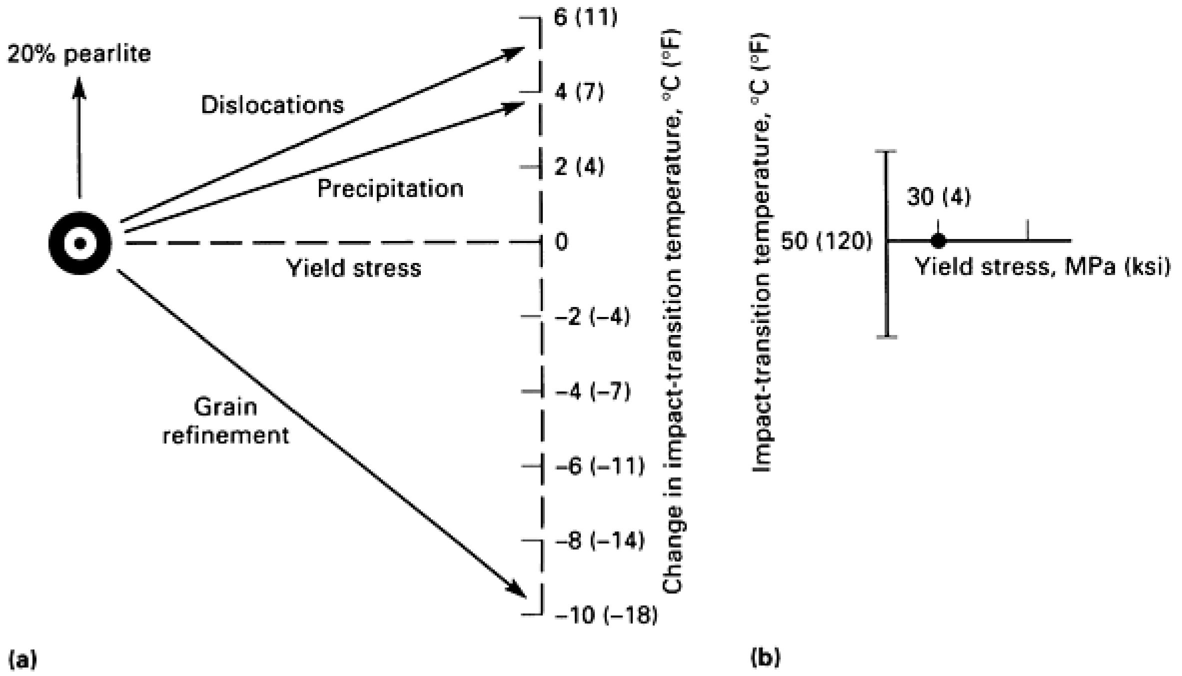

Fig. 3 Two methods of determining resistance to brittle fracture by Charpy V-notch impact testing. (a) Effect of ductile-to-brittle transition temperature on yield stress. (Ratios indicate the change in transition temperature per 15 MPa, or 2.2 ksi, increase in yield strength.) (b) Test temperature corresponding to given fracture energy. Source: Ref 3

The role of grain refinement in resisting brittle fracture extends beyond F-P steels to the acicular and bainitic steels as well. While the resistance to brittle fracture in F-P steels is controlled largely by the final ferrite grain size, the resistance to brittle fracture in fully acicular or bainitic steels is controlled by the prior-austenite grain size. In a recent study of the various contributions to the resistance to brittle fracture, several factors were found (Ref 11):

- Grain size ($D\gamma$) of the parent austenite
- Cleanliness of the steel (total projected inclusion length, $\sum b$)
- Strength level, YS

The influence of these factors is illustrated in Fig. 4. These data indicate that the effective grain size of the austenite is the most important factor, followed by the steel cleanliness, and the strength level in order of importance in increasing the resistance to brittle fracture.

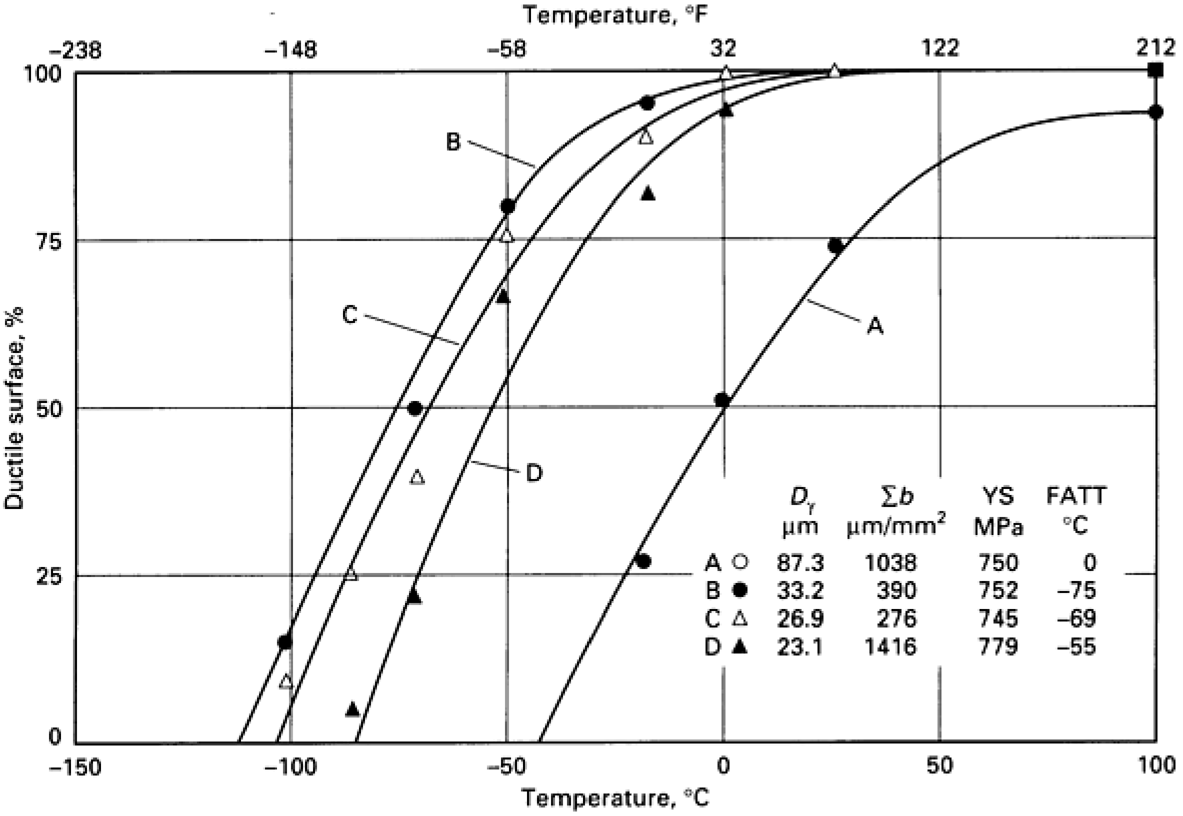

Fig. 4 Factors that affect the ductile-to-brittle transition in Charpy V-notch impact tests of ultralow carbon bainitic steels (ULCB). *Dγ*, average austenite grain size; $\sum b$, total projected length of inclusions per unit area; YS, yield strength; FATT, fracture-appearance transition temperature. Source: Ref 11

Whereas the texture contribution to strength in hot-rolled steels is rather small, on the order of a few percent (Ref 5), crystallographic texture can strongly influence other important properties such as through-thickness ductility in plate (that is, the phenomenon of splitting or separation) (Ref 12) and the deep drawability of cold-rolled and annealed steels (Ref 13). Finally, the weldability of the steel, taken here to mean the resistance to cold or underbead cracking, has been shown to be controlled chiefly by its composition (for example, its carbon content and its carbon equivalent value) (see Fig. 5).

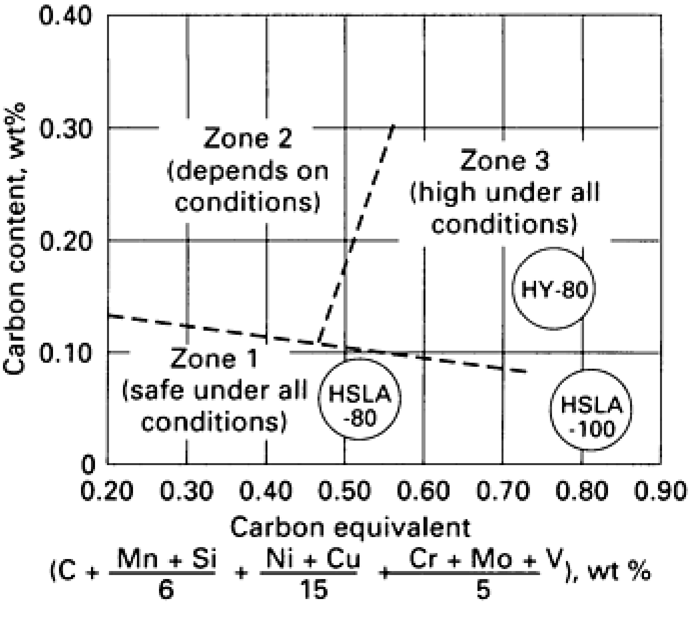

Fig. 5 Effect of steel composition on the susceptibility of the heat-affected zone (HAZ) to cold cracking for HY-80, HSLA-80, and HSLA-100 steels. Source: Ref 14

In summary, a properly designed and hot-rolled steel should exhibit the minimum required strength and the maximum resistance to brittle fracture. In the discussion that follows, an attempt will be made to explain how the proper microstructure and optimum properties can be obtained through the proper synergism of alloy design and thermomechanical processing.

Property Improvements Achieved through Thermomechanical Processing. As discussed above, the thermomechanical processing or controlled rolling of MA steel leads to enhanced grain refinement when compared with hot-rolled carbon steels. Furthermore, the presence of microalloying elements can lead to the precipitation hardening of ferrite. Together, these effects would be expected to lead to stronger and tougher steels. A good example of the benefits of thermomechanical processing regarding mechanical properties is illustrated in Fig. 6, which shows schematically the strength-toughness balance in linepipe steel. In Fig. 6, the strength is given by the American Petroleum Institute (API) grade which indicates the yield strength in ksi (for example, API X70 has a yield strength of 70 ksi). As shown in Fig. 6, X60 steel represented the technology from the mid-to-late 1960s and was represented by hot-rolled and normalized F-P steels. About ten years later, these steels were replaced by thermomechanically processed steels (labeled TM-treated in Fig. 6) that were able to attain both API X70 strength levels and higher levels of toughness. Further discussions including data are available in the literature (Ref 16, 17). A further example of the benefits of thermomechanical processing is given in Fig. 7 which shows the strength and toughness (that is, ductile-to-brittle transition temperature) of 30 mm ($1\frac{3}{16}$ in.) thick MA plate steel processed in several different ways. The processing variables examined in Fig. 7 include the type of rolling with or without subsequent normalizing. Normal hot-rolling and controlled-rolling schedules were used. An examination of the hot-rolled properties indicates very poor toughness. In order for these plates to be used, they would have to be normalized after rolling. However, while the normalizing treatment improves the toughness, it does so at the expense of strength. In comparison, the controlled as-rolled properties indicate that both high strength and high toughness are possible without the need of post-rolling normalizing. The data of Fig. 6 and 7 are intended as examples to show the improvement in mechanical properties attainable through the use of thermomechanical processing or controlled rolling.

Fundamentals of Thermomechanical Processing

In his 1981 review of controlled rolling, Tanaka (Ref 19) pointed out that by 1924 the advantages of grain refinement to the mechanical properties of steel were already appreciated. Later, the beneficial effects of low finish rolling temperatures to the mechanical properties of steels were first realized (Ref 20, 21). Simultaneously, the relationship between low-temperature rolling of the austenite and the effect of ferrite grain size was being discussed (Ref 22). It is interesting to note that this early work was conducted in Europe on non-microalloyed steels. Perhaps the first indication of the benefits of microalloying to the as-rolled structure and properties of carbon and low-alloy steels was presented in the early 1940s (Ref 23, 24). In this work, attention was focused on the increased strength and toughness obtained with decreased grain size that were associated with the presence of small amounts of niobium.

From the early 1960s through to the present, research on thermomechanical processing has been centered on the controlled rolling of plate. Since a large portion of this research has been presented in several international symposia (Ref 25, 26, 27, 28, 29, 30, 31, 32), only a few of the important highlights will be reviewed at this time. It should be mentioned that a majority of the research on controlled rolling was performed in Europe during this period (Ref 33, 34). This was in contrast to the research conducted in the United States at the same time (late 1950s through early 1970s) on high-strength quenched and tempered steels. The unusually high strengths in these steels were developed either by an ausforming process or by direct quenching followed by a tempering treatment (Ref 4, 35).

The results from early research on controlled rolling indicated the importance of the synergism which exists between thermomechanical processing and the microalloying elements. Two major results from these investigations were:

- It was very difficult to thermomechanically process steels that did not contain microalloying elements. Hence, it was difficult to achieve the benefits in mechanical properties of thermomechanical processing without the microalloying elements
- Steels with microalloying elements, but without thermomechanical processing, displayed a lower toughness than their plain-carbon steel counterparts

This second point is clearly observed in Table 2, which shows the lower yield stress and fibrous transition temperature for a plain-carbon and a MA steel that were both deformed at two different temperatures (Ref 34). Table 2 illustrates that with suitable thermomechanical processing (that is, deforming at 860 °C, or 1580 °F, and below the recrystallization stop temperature of austenite), the MA steel was able to lower its fibrous transition temperature by approximately 60 °C (110 °F), while simultaneously maintaining a similar yield stress. The key point to be made is that if the austenite is not grain-refined by thermomechanical processing, the large austenite grains will lead to the combination of large ferrite grains in addition to the potential for low-temperature transformation products (which contain high carbon concentrations) to be

present in the centers of the large, prior austenite grains. This, coupled with the higher strength imparted by the microalloying elements, all act to deteriorate the toughness of the steel.

Table 2 As-deformed mechanical properties of plain carbon steel and steel microalloyed with 0.03% Nb at 860 °C (1580 °F) and 950 °C (1740 °F)

Material	Deformation temperature		Mechanical properties			
			Lower yield stress		Fibrous transition temperature	
	°C	°F	MPa	ksi	°C	°F
Plain carbon steel (0% Nb)	860	1580	217.7	31.57	-21	-5.8
	950	1740	206.7	29.97	-20	-4.0
Microalloyed steel (0.03% Nb)	860	1580	364.5	52.85	-48	-54
	950	1740	349.3	50.65	13	55

Physical Metallurgy

Our understanding of the relationship between the microstructure and the properties in F-P steels has led us to very different views concerning the origins of strength and the origins of toughness. For example, it is apparent that high strengths can be obtained in a simple manner (for example, through the addition of solute strengthening or precipitation hardening elements). Resistance to brittle fracture, on the other hand, cannot be achieved through alloy additions but must be achieved through the control of the final microstructure. It is now known that tough microstructures exhibit fine ferrite grain sizes and a minimum amount of lower temperature transformation products that contain cementite (for example, upper bainite). Hence, obtaining large amounts of fine ferrite grains and small amounts of pearlite are among the principal goals of thermomechanical processing.

The key question then becomes how these two goals may be achieved. It is now clear that both of these goals can be achieved when the austenite itself, at the point of transformation, exhibits a fine grain size. The as-rolled austenite can show three types of microstructures:

- Fully recrystallized
- Partially recrystallized
- Fully unrecrystallized

While the grain size of fully recrystallized austenite is a simple matter to comprehend and determine, the determination of a fully unrecrystallized microstructure is not. In order to specify the grain size of fully recrystallized austenite, only an average grain diameter is required; this fully describes the grain boundary area per unit volume. In the case of fully unrecrystallized austenite, both the starting grain size and the aspect ratio of the deformed grains are required to determine the grain boundary surface per unit volume. In general, because the ferrite grain size is related to the number of sites for ferrite nucleation and since this number is related to the grain boundary area per unit volume, the ferrite grain size will decrease as this boundary area increases. Furthermore, finer austenite grains reduce the chances of forming upper bainite during transformation because the austenite grain volume can be completely consumed by the ferrite and pearlite reactions. Although both of the issues were qualitatively recognized in the 1960s (for example, ferrite grain size was

reduced by lowering the finish rolling temperature of austenite), it was not until the mid-1970s that effects such as these could be quantitatively assessed.

Significance of S_v in Ferrite Grain Refinement. The understanding of the hot deformation of austenite in general and its influence on final ferrite grain size was improved dramatically in the mid-1970s through the research of Kozasu *et al.* (Ref 36), Tanaka (Ref 37), Sekine and Maruyama (Ref 38), and Morrison and Chapman (Ref 39), and others. A summary of this work was presented in the review by Tanaka (Ref 19). Kozasu *et al.* (Ref 36) for example, showed that the key to understanding the process by which austenite links alloying and hot rolling with the final ferrite grain size was based on quantitatively assessing the number of preexisting or strain-induced heterogeneities introduced into the austenite during rolling that could act as sites for ferrite nucleation. Earlier research using quantitative metallography led Underwood (Ref 40) to define a parameter S_v that attempted to account for all the near planar crystalline defects which may exist in a polycrystalline aggregate. The parameter S_v has units of mm^{-1} or equivalently area (mm^2) per unit volume (mm^3). Kozasu *et al.* (Ref 36) applied the parameter S_v, which they defined as the total effective interfacial area per unit volume, to the problem of quantitatively assessing the number of sites in thermomechanically processed austenite for potential nucleation of ferrite and developed the correlation shown in Fig. 8.

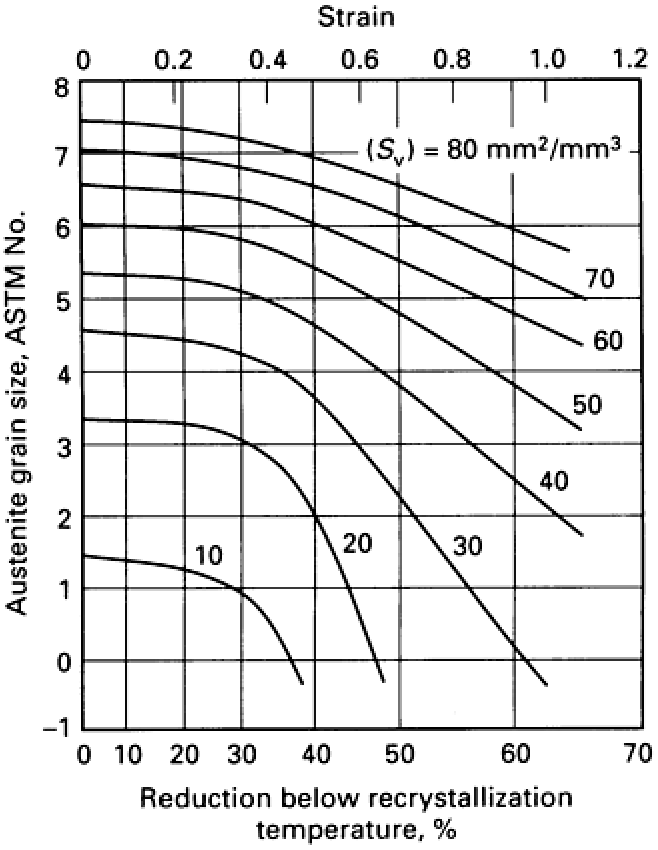

Fig. 8 Variation of effective austenite interfacial area (S_v) with initial grain size and amount of reduction below the recrystallization stop temperature for a 0.03 wt% Nb steel. Source: Ref 36

Attempts to quantify the influence of S_b on final ferrite grain size have been made by several groups. For example, Kozasu *et al.* (Ref 36) and later Roberts *et al.* (Ref 41) and Cuddy (Ref 42) have shown that the ferrite grain size decreases continuously with increases in S_v. There is still some disagreement over the exact relationship, but the general form has been well defined (see Fig. 9). Hence, from the standpoint of ferrite grain refinement, a well-conditioned austenite is one which exhibits a large S_v.

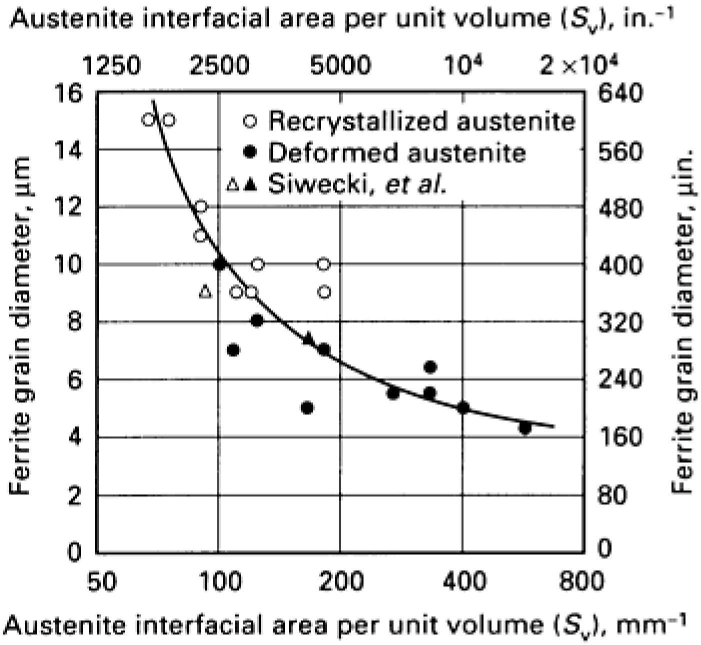

Fig. 9 Ferrite grain sizes produced from recrystallized and unrecrystallized austenite at various S_v values. Source: Ref 43

Methods of Obtaining Large S_v. As indicated in Fig. 9, ferrite grain refinement depends on obtaining a high S_v in the austenite prior to transformation. The discussion which follows suggests methods that achieve high S_v values through the proper combination of alloy design and thermomechanical processing.

In the extreme, a given as-reheated austenite grain structure can be hot rolled to two very different microstructures. If the rolling takes place above the recrystallization temperature of the austenite, then the original, equiaxed, recrystallized austenite grains are replaced with a different set of equiaxed grains that differ from the original chiefly in size. Because for equiaxed grains:

$$S_v = \frac{3}{D_g} \qquad \textbf{(Eq 2)}$$

where $D\gamma$ is the diameter of the austenite grains, a reduction in grain size by hot rolling will lead to an increase in grain boundary area and, hence, an increase in S_v (Ref 40).

The hot-rolling process, which leads directly to fine equiaxed grains, has been labelled recrystallization controlled rolling (RCR) (Ref 41, 44). This form of thermomechanical processing involves repeated recrystallization of austenite during deformation above the recrystallization temperature leading to a fine equiaxed austenite exhibiting a high S_v. The success of this technique depends on both achieving and maintaining a fine austenite grain size. While the origin of the grain refinement is based on repeated recrystallization, maintaining that grain size requires the use of grain coarsening inhibition mechanisms. Traditionally, successful mechanisms have involved the use of either stable precipitates or solute drag that can retard grain coarsening.

If the hot rolling takes place below the recrystallization temperature, the austenite grains become highly elongated and, at a sufficiently large strain, become filled with intragranular defects such as deformation bands and twins. This represents the wellknown and most popular variant of thermomechanical processing, controlled rolling (Ref 36, 37). Controlled rolling means rolling to control the microstructure of austenite (for example, pancaked grains containing intragranular crystalline defects). Obviously, not all hot-rolling practices which are under strict temperature and deformation control will lead to controlled-rolled microstructures and, hence, are not considered controlled-rolling practices. In controlled rolling, the final S_v is comprised of two terms, one describing the grain boundary surface area per unit volume and the other describing the surface area of the deformation bands and twins contained within the elongated grains. The S_v expression to be used in this case is (Ref 43):

$$S_v = S_v(\mathrm{GB}) + S_v(\mathrm{IPD}) \quad \textbf{(Eq 3)}$$

where S_v is the total effective area per unit volume, mm^2/mm^3; S_v(GB) is the grain boundary contribution to S_v; and S_v(IPD) is the intragranular planar defect contribution to S_v.

The quantity S_v can also be expressed as:

$$S_v = 0.429 N_{LR} + 2.571 N_{LZ} - N_{LT} + \frac{N_{DB}}{\sin q} \quad \textbf{(Eq 4)}$$

where N_{LR}, N_{LZ}, and N_{LT} are the grain boundary intercept number per unit length along the rolling, thickness, and transverse directions, respectively; N_{DB} is the number of intragranular planar defects (IPD) per unit area, mm/mm^2; and θ is the angle between the intergranular planar defect and the plate thickness direction.

Although the variation in S_v with alloying and processing has not been defined completely, the most important parameters have been shown to be the extent of deformation below the recrystallization temperature and the grain size of the austenite prior to pancaking (Ref 43, 44, 45). This work has been summarized by Speich *et al.* (Ref 43) and is illustrated in Fig. 10 and 11. Speich *et al.* calculated the variation of S_v for a hypothetical array of cube-shaped grains of variable initial size which were subjected to various plane strain deformations, all to simulate the behavior of grains during controlled rolling (Ref 43). A major contributor to S_v is the grain boundary area per unit volume. Under the assumptions of a cubical grain shape and plane strain deformation, the contribution of the grain boundary area to the total S_v will vary with reduction as follows (Ref 43):

$$S_v^{GB} = \frac{1}{D}\left(1 + \frac{1}{R} + R\right) \quad \textbf{(Eq 5)}$$

where D is the cube edge length and R is the rolling reduction ratio (original to final thickness). The variation of the contribution of the initial grain boundaries to S_v is shown in Fig. 11. Ouchi *et al.* (Ref 46) have shown that the intragranular defects, such as deformation bands and twin boundaries, contribute to the S_v as follows:

$$S_v^{GB} = 0.63\ (\%\ \mathrm{Reduction} - 30)\ \mathrm{mm}^{-1} \quad \textbf{(Eq 6)}$$

Equation 6 indicates that no deformation bands form during controlled rolling until a reduction of 30% has been reached, and then the band density increases linearly with additional strain. When S_v^{GB} and S_v^{DB} are plotted individually and added together, the sum, $S_v^{GB} + S_v^{DB}$, versus strain below the recrystallization temperature is as shown in Fig. 11. It is clear from Fig. 10 and 11 that both the grain size prior to pancaking and the amount of reduction below the recrystallization temperature play important roles in controlling the magnitude of S_v.

Forces that Activate Microstructural Restoration in Austenite. As shown in Fig. 9, the ferrite grain size was strongly influenced by the magnitude of S_v. Simultaneously, it was shown in the section "Methods of Obtaining Large S_v" that the magnitude of S_v is dependent upon the microstructural condition of the austenite at the point of transformation. The

metallurgical condition of the austenite at the transformation temperature is dependent on a complex interplay between the stored energy of deformation on one hand and retarding forces on the other hand. The stored energy of deformation is the driving force for any restoration process [that is, recovery (Ref 47) and recrystallization (Ref 48)) to occur. In this context, restoration means achieving a metallurgical condition that is energetically comparable to or lower than the condition existing before deformation. Hence, through the operation of the recovery and recrystallization processes, the predeformation condition is essentially restored. Clearly, when the driving force for a restoration process exceeds all retarding forces, the process will proceed. However, when the retarding forces exceed the driving force, the restoration processes will not occur, and the as-deformed condition will prevail.

Driving Forces for Restoration. The driving force for recovery and recrystallization has been shown to be equal to the difference in dislocation density that is present between strained and strain-free local volumes (Ref 49, 50, 51, 52). This driving force has been estimated and, based upon the area under the flow curve (Ref 53, 54), is expressed by the following equation:

$$\Delta\sigma = 0.2\mu\mathbf{b}\sqrt{\Delta r} \qquad \textbf{(Eq 7)}$$

where $\Delta\sigma$is the increment in flow stress due to work hardening, $\mu$is the shear modulus, **b** is the Burgers vector, and $\Delta\rho$is the excess dislocation density.

In addition to recovery and recrystallization, other types of restoration processes can exist. One familiar process is grain coarsening. The driving force for grain coarsening is the minimization of grain boundary energy (or area) per unit volume (Ref 47).

Retarding Forces for Restoration. Up until this point, only driving forces for restoration have been considered. Attention will now be turned towards the forces that resist the progress of restoration. The two major retarding forces are solute drag and particle pinning. The influence of solutes (Ref 55) and particles (Ref 56) on the mobility of grain boundaries were recognized as early as 1949. The effectiveness of solute drag has been shown to be related to differences in size and valence between the solute and solvent atoms (Ref 57, 58, 59). Hence, the level of solute drag depends on the nature of the solute and its concentration in solid solution. While solute drag has been discussed extensively in the literature (Ref 60, 61, 62, 63, 64), there is no acceptable quantitative expression of this effect currently available.

Particle pinning, on the other hand, has been subjected to a more quantitative treatment. The first attempt to treat the retarding effects of second-phase particles on a migrating grain boundary was made by Zener (Ref 56). He indicated that when particles were present in the vicinity of a grain boundary, the effective energy of the grain boundary would be lowered. The reduction in grain boundary energy occurs because the surface area of second-phase particles would replace part of the grain boundary. Therefore, the movement of a grain boundary away from particles would require work as the effective grain boundary area is increased (Ref 65). Zener's original theory was later quantified by Gladman (Ref 66) who assumed the rigid motion of grain boundaries through a regular array of spherical particles. It was shown that the pinning force for each particle (F) and the particle radius (r) were related by:

$$F = 4r\sigma \qquad \textbf{(Eq 8)}$$

where σ is the interfacial energy per unit area of boundary. Gladman (Ref 66) subsequently derived an expression for the critical particle size, r_c, below which grain boundaries are pinned:

$$r_c = \frac{6R_0 f_v}{p} \cdot \left(\frac{3}{2} - \frac{2}{z}\right)^{-1} \qquad \textbf{(Eq 9)}$$

The relationship shown by Eq 9 was obtained by equating the rates of the grain boundary energy increase during grain growth and the particle pinning force. In this expression, R_o is the mean radius of the matrix grain and f_v is the volume fraction of second-phase particles. The term z represents the ratio of the radii of growing and matrix grains. Hillert (Ref 67) has deduced that z can range in value between $\sqrt{2}$ to 2 throughout the grain growth process. The important point to be realized from Eq 9 is that a high volume fraction of small particles will inhibit boundary migration.

Equation 8 can be expanded to account for the total pinning force, F_{PIN}, that a number of particles per unit area (N_s) exert on a migrating boundary. This total pinning force is expressed as:

$$F_{PIN} = 4r\sigma N_s \qquad \textbf{(Eq 10)}$$

Three models have been postulated to explain how microalloy precipitates suppress austenite recrystallization (Ref 60, 65, 68, 69, 70, 71). All of these models are based upon the general form of Eq 10. Their differences arise from the method by which N_s is calculated. The first of these models was an extension of Gladman's (Ref 66) work. This model is often referred to as the rigid boundary model because it assumes the motion of a rigid grain boundary which is capable of interacting with those particles lying within $\pm r$ of the boundary plane (Ref 56, 60, 65, 66, 68). Under this set of conditions, N_s is defined by:

$$N_s = 2rN_v \qquad \textbf{(Eq 11)}$$

where N_v is the number of particles per unit volume. Again, assuming spherical particles having radius r and volume fraction f_v, N_v is defined by the following expression (Ref 66, 68):

$$Nv = \frac{3f_v}{4p\,r^3} \qquad \textbf{(Eq 12)}$$

Combining Eq 11 and 12 yields the number of particles per unit area assuming a rigid boundary model, N_s^R:

$$N_s^R = \frac{3f_v}{2p\,r^2} \qquad \textbf{(Eq 13)}$$

The rigid boundary model, however, was rather simple and unrealistic since it did not account for any flexibility of the austenite grain boundaries (Ref 65).

Cuddy (Ref 53, 72) proposed a model that was at the opposite extreme of the rigid boundary model. This model was termed the flexible boundary model. It assumed that an infinitely flexible boundary was capable of interacting with every particle in the three dimensional array until it is fully pinned (Ref 53). This led to the relationship:

$$N_s = rf_v^{-1/3}N_v \qquad \textbf{(Eq 14)}$$

which, when combined with Eq 12, yields the number of particles per unit area assuming a flexible boundary model, N_s^F:

$$N_s^F = \frac{3f_v^{2/3}}{4p\,r^2} \qquad \textbf{(Eq 15)}$$

The most realistic of these models was the one proposed by Hansen *et al.* (Ref 68). This model considered the effect of a precipitate distribution that could exist on austenite subgrain boundaries prior to the start of recrystallization (Ref 53, 69). Assuming that the average subgrain intercept is l, the surface area per unit volume for such subgrain boundaries would be $2/l$, and the number of particles per unit subgrain boundary area would be given by (Ref 68):

$$N_s = \frac{lN_v}{2} \qquad \textbf{(Eq 16)}$$

As before, combining Eq 12 and 16 gives the number of particles per unit area assuming a subgrain boundary model, N_s^S:

$$N_s^S = \frac{3 f_v l}{8 p r^3} \quad \textbf{(Eq 17)}$$

Substitution of the expressions for N_s^R, N_s^F, and N_s^S into Eq 10 gives the respective pinning force for each model:

$$F_{PIN}^{R} = \frac{6\sigma f_v}{\pi r} \quad \textbf{(Eq 18)}$$

$$F_{PIN}^{F} = \frac{3\sigma f_v^{2/3}}{\pi r} \quad \textbf{(Eq 19)}$$

$$F_{PIN}^{S} = \frac{3\sigma f_v l}{2\pi r^2} \quad \textbf{(Eq 20)}$$

where F_{PIN}^R, F_{PIN}^F, and F_{PIN}^S are pinning forces for rigid boundary model, flexible boundary model, and subgrain boundary model, respectively.

Microalloying, Solubility, and Precipitation in Austenite

The achievement of high levels of S_v depends on the ability to control the restoration processes that could otherwise occur during thermomechanical processing. Obviously, for a given deformation process, this means that the level of retarding force must be controlled during the process. In the ideal system, the partitioning of solutes between solid solution and precipitate could be controlled (that is, when low retarding forces are required), the solutes could be kept in solid solution and when high retarding forces are required, the solutes could form precipitates. The ability of a solute to be partitioned in this way is directly controlled by its solubility product. Elements such as niobium, titanium, and vanadium have been shown to have solubility products that vary with temperature in such a way as to make them particularly useful in generating retarding forces under controlled and predictable conditions during thermomechanical processing. These elements are known as the microalloying elements and are central to thermomechanical processing. The microalloying elements perform three major roles in thermomechanically processed steels:

- Help maximize S_v through their ability to generate retarding forces
- Contribute to hardenability when they are in solid solution at the transformation temperature
- Can cause precipitation hardening of the transformation product

Solubility Product. The extent to which elements can be maintained in solid solution in austenite is governed by the appropriate solubility product. If, for example, we are interested in the extent of solid solubility of niobium and carbon in austenite ($[NB]\gamma$ and $[C]\gamma$) that is in equilibrium with pure, stoichiometric niobium carbide, NbC, then we must consider the following reaction:

$$[Nb]\gamma + [C]\gamma = NbC \quad \textbf{(Eq 21)}$$

This reaction will have an associated equilibrium constant K_1 (that is, solubility product):

$$\log K_1 = \log[Nb][C] = A_1 - \frac{B_1}{T} \quad \textbf{(Eq 22)}$$

where A_1 and B_1 are constants normally specified such that [NB] and [C] can be expressed by their weight percent and T is the absolute temperature. If, however, we wanted to consider the extent of solubility of the austenite in equilibrium with $NbC_{0.85}$, then the appropriate solubility product would be:

$$\log K_2 = \log[Nb][C]^{0.85} = A_2 - \frac{B_2}{T} \qquad \textbf{(Eq 23)}$$

Similarly, the solubility product for austenite in equilibrium with NbC_xN_y would be:

$$\log K_3 = \log[Nb][C]^x[N]^y = A_3 - \frac{B_3}{T} \qquad \textbf{(Eq 24)}$$

The solubility of NbC in austenite has been studied in numerous investigations, and this work has been carefully Summarized and reviewed by Nordberg and Aronsson (Ref 73). The 13 independent investigations reviewed by Nordberg and Aronsson examined the solubility products associated with NbC, NbC_x, NbC_xN_y, and NbN. Several solubility products are illustrated in Fig. 12, and the equations for these products are listed in Table 3.

Table 3 Solubility product of niobium carbonitride precipitates in austenite at 1000 °C (1830 °F)

Precipitate	**Solubility product equation**	**Solubility product at *T* of 1000 °C (1830 °F) K × 10^6 × $(wt\%)^2$**
$NbC_{0.87}$	log $[Nb][C]^{0.87}$ = 3.43 - 7170/*T*	1510
NbC	log [Nb][C] = 2.96 - 7510/*T*	1070
$NbC_{0.83}N_{0.14}$	log $[Nb][C]^{0.83}[N]^{0.14}$ = 4.46 - 9800/*T*	525
$NbC_{0.24}N_{0.65}$	log $[Nb][C]^{0.24}[N]^{0.65}$ = 4.09 - 10400/*T*	77.6
NbN	log [Nb][N] = 2.80 - 8500/*T*	8.0

Source: Ref 74

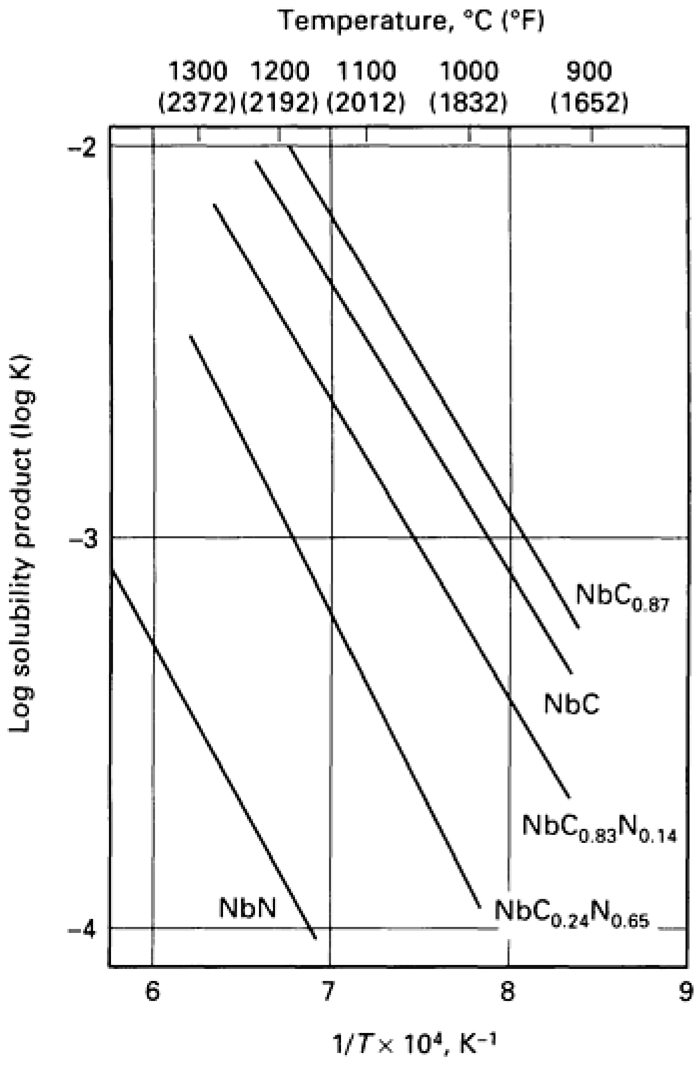

Fig. 12 Solubility products for various niobium precipitates in austenite. Source: Ref 74

Effect of Solubility Product on Niobium Precipitation. The relationship between the solubility product and the nature or composition of the niobium precipitate is evident in Fig. 12. If the solubility product line for pure stoichiometric NbC is used as a reference, two interesting trends are observed:

- There is a substantial lowering of the solubility product as the precipitate becomes more enriched with nitrogen
- There is an apparent increase in solubility product with a reduction in *x* (that is, with an increase in vacancy concentration)

These two trends are demonstrated in Table 3 with a comparison of selected solubility products for several precipitates in austenite at 1000 °C (1830 °F).

Solubility products play a vital role in understanding the physical metallurgy of microalloyed steel, especially those aspects that are concerned with precipitation-related phenomena. Solubility products can be plotted in either one of two ways. Consider the case for the solubility product of NbC in austenite at some given temperature. If the abscissa [C] and ordinate [NB] axes have a linear scale, then any given solubility isotherm will have the shape of a hyperbole. If, however, the axes have a logarithmic scale, then the solubility isotherm will be a straight line. Both approaches have been widely used in the literature.

A hypothetical solubility isotherm for NbC in equilibrium with austenite at 1000 °C (1830 °F) is shown in Fig. 13(a). The solubility isotherm gives the locus of niobium and carbon products that represent the limit of solid solubility of NbC in austenite at 1000 °C (1830 °F), that is, any combination of products located above the line will be in the (γ + NbC) phase field at 1000 °C (1830 °F). The straight line with a positive slope on the diagram represents the stoichiometric ratio. The precipitation of NbC can be followed by considering the slightly curved line that is nearly equidistant from the stoichiometric line and passes through the point with the niobium and carbon coordinates which describe the composition of the steel. A schematic illustration is presented in Fig. 13(b). Consider a steel of composition given by point B that is reheated to 1300 °C (2370 °F) and is very slowly cooled to 900 °C (1650 °F). Because 1300 °C (2370 °F) is the solution temperature for the NbC under consideration here, the NbC can be assumed to be completely dissolved after reheating. If it is further assumed that precipitation occurs during the cooling, then the composition of the austenite in equilibrium with NbC would move along the curve passing through point B that is equidistant from the stoichiometric line. The distance moved along the curved line through point B is proportional to the volume fraction of precipitate formed as a result of the cooling, assuming that equilibrium is established at all temperatures. In other words, the distance moved along the curved line through point B during cooling is proportional to the solute supersaturation and would also be proportional to the volume fraction of precipitate formed if equilibrium prevailed. Therefore, if steel B is reheated to 1300 °C (2370 °F) and then cooled to and rolled at 900 °C (1650 °F), the distance $\overline{BC}$ in Fig. 13(b) will be proportional to the volume fraction of NbC formed in austenite. This precipitation would be of two types: that formed during cooling and that formed during or after rolling. The first type is not likely to be significant because precipitation in recrystallized austenite is normally very sluggish, as will be discussed in the section "Effect of Microalloying Elements on the Critical Temperatures of Austenite" of this article. The second type is referred to as strain-induced precipitation (labelled ε -induced in Fig. 13b). A second interesting case would occur if steel of composition A in Fig. 13(b) is considered. If this steel is reheated at 1300 °C (2370 °F) and hot rolled at 900 °C (1650 °F), then two arrays of NbC particles would be expected. The first would be the precipitates that survived the reheating treatment (having a volume fraction proportional to $\overline{AB}$) and the second would be a strain-induced precipitate (having a volume fraction proportional to $\overline{BC}$).

Finally, solubility products appear to be influenced by the presence of elements that do not directly precipitate in the precipitation sequence. Koyama *et al.* (Ref 75, 76, 77) have examined the influence of several elements on the solubility of NbC in austenite. These elements can affect the solubility of NbC in austenite by altering the activity coefficients of both niobium and carbon. By way of an example, the solubility product for NbC in otherwise unalloyed austenite at 1150 °C (2100 °F) is approximately 5×10^{-3}. An addition of manganese increased log K by about 5%/wt% Mn added while an addition of silicon reduced log K by about 45% per wt% Si added. The solubility product at 1150 °C (2100 °F) for a steel containing 1.5 wt% Mn and 0.4 wt% Si was $\approx 4 \times 10^{-3}$. Hence, the addition of both manganese and silicon acted to reduce the solubility product by approximately 20%.

Effect of Microalloying Elements on the Critical Temperatures of Austenite

The influence of microalloying elements on the response of austenite to thermomechanical processing can be understood by the way in which the microalloying elements influence the three critical temperatures of austenite:

- Grain coarsening temperature, T_{GC}
- Recrystallization stop temperature, T_{RXN}

- Transformation temperature, Ar_3 or B_s

Grain Coarsening Temperature. The grain coarsening temperature T_{GC} is defined to be that temperature above which grain coarsening by secondary recrystallization commences and refers to the temperature above which the undissolved precipitates can no longer suppress grain growth. The influence of various microalloying elements on grain growth during reheating is shown in Fig. 14. While it does not appear that the final average austenite grain size is very dependent on the reheated grain size prior to multipass deformation (Ref 78), it does appear likely that the distribution of grain sizes about the average is much smaller when the reheating temperature is kept below the grain coarsening temperature (Ref 79).

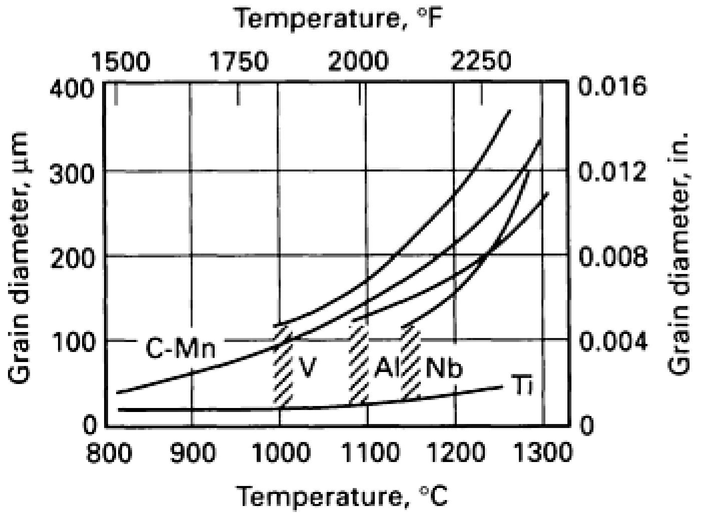

Fig. 14 Austenite grain coarsening characteristics in steels containing various microalloying additions. Source: Ref 43

During reheating, a slab is slowly heated from room temperature to the reheating temperature, where it is soaked for an appropriate period of time and after which it is available for hot rolling. During this heating and soaking period, events occur which ultimately control the grain size and composition of austenite prior to hot rolling. The ultimate response of a given steel to subsequent processing will, to a large extent, be strongly influenced by the reheating stage. The major events which may occur during reheating include:

- Nucleation, growth, and possible coarsening of austenite grains
- Elimination of inhomogeneities in solute distribution
- Dissolution of microalloy precipitates that were inherited from the original microstructure

Austenite first forms at ferrite-carbide (cementite) interfaces (Ref 80) and the increase in amount of austenite is accompanied by a decrease in the amount of cementite, at least in the early stages of austenite formation (Ref 80). Also, although the kinetics of austenite formation are very rapid at normal reheating temperatures, the elimination of heterogeneities in solute distribution is very sluggish (Ref 80).

Once the austenite grains have formed from the F-P starting structure, they will coarsen with time and temperature. This coarsening behavior has been reviewed in some detail (Ref 74).

Reheating controls not only the grain size, but also the initial composition of the austenite (Ref 74, 78). Cuddy has shown that niobium is not fully taken into solution until a steel is heated to approximately 100 °C (180 °F) above its grain coarsening temperature (Ref 78). Similar results have been found in a separate work (Ref 81). The factors that control the composition of the austenite at various stages of processing have recently been reviewed by Gray and DeArdo (Ref 82).

Recrystallization Stop Temperature. Perhaps the most important effect of microalloying elements is in controlling the recrystallization stop temperature of austenite (Ref 53, 81). The influence of several microalloying elements on the

recrystallization stop temperature is shown in Fig. 15 (Ref 53). As shown in Fig. 15, niobium has the most profound effect in increasing the T_{RXN} value and this accounts for its selection as the primary microalloying element in modern HSLA steels. Some early steels used vanadium in conjunction with nitrogen additions to produce a moderate effect in retarding austenite recrystallization but such practices are not compatible with current ideas for limiting free nitrogen concentrations, nor were they particularly effective. Consequently, the predominant use of vanadium is for precipitating vanadium carbide in the low-temperature transformation product. Similarly, titanium is not considered useful for retarding austenite recrystallization but is highly effective in preventing grain growth (Fig. 14). Titanium's grain refining benefits have another primary use in welding that are unrelated to their benefit during austenite processing, and this has led to widespread use of approximately 0.015 wt% Ti in plate and pipeline steels. This approach is not readily accessible when nitrogen concentrations are above 0.008 wt% N or when the ingot casting route is involved.

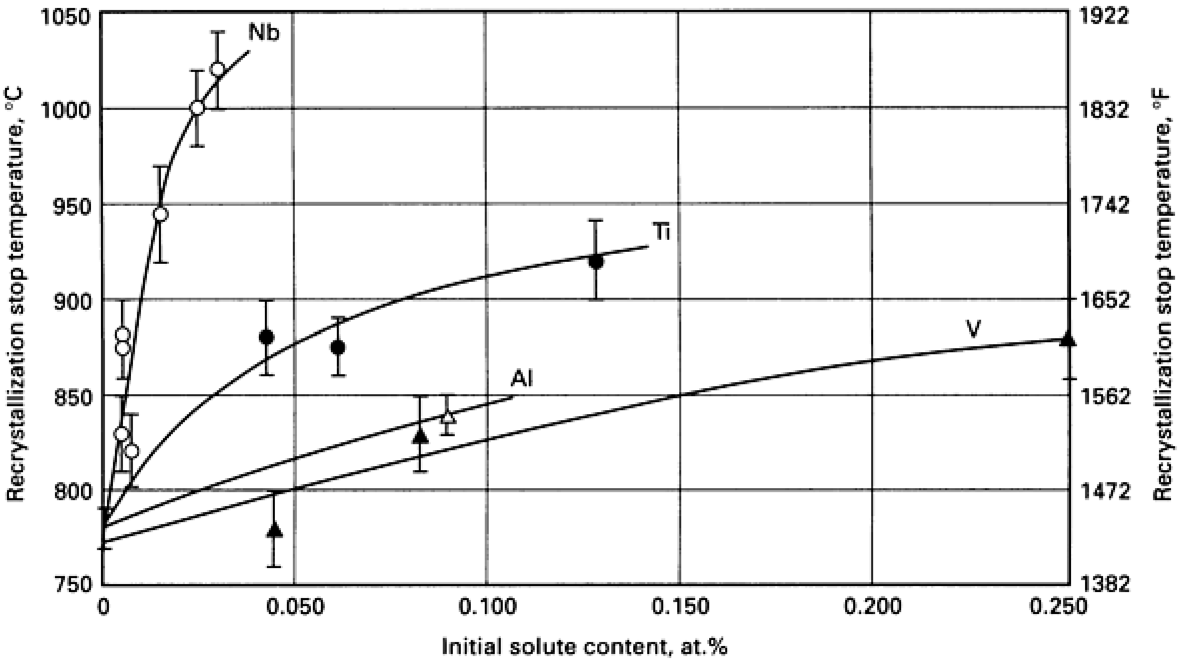

Fig. 15 Effect of microalloying additions on the recrystallization stop temperature of austenite. Source: Ref 53

The data shown in Fig. 14 and 15 reveal that the various microalloying elements all show the same general behavior. The differences between them are predominantly the temperature range over which they exert their influence and the level of intensity of that influence. This difference in behavior is chiefly due to differences in the solubility of the various precipitates in austenite. The difference in the temperature range of precipitation in austenite is clearly shown in Fig. 16 for vanadium and niobium carbonitrides (Ref 83, 84). In Fig. 16, the deformation temperature is plotted against the deformation time required to initiate dynamic recrystallization (that is, time-to-peak stress, t^p), which is one form of austenite restoration. When no strain-induced precipitation forms, the curves are only slightly offset from the base steel. This is indicative of the weak retarding effect of solute drag as a retarding force. However, when precipitation accompanies the early stages of deformation as it does in the vanadium plus nitrogen steel at low temperatures and the two niobium steels at higher temperatures, there is a drastic retardation of dynamic recrystallization, and the curves display a plateau. Notice that when precipitation occurs, the curves are virtually identical. They are only displaced on the temperature scale.

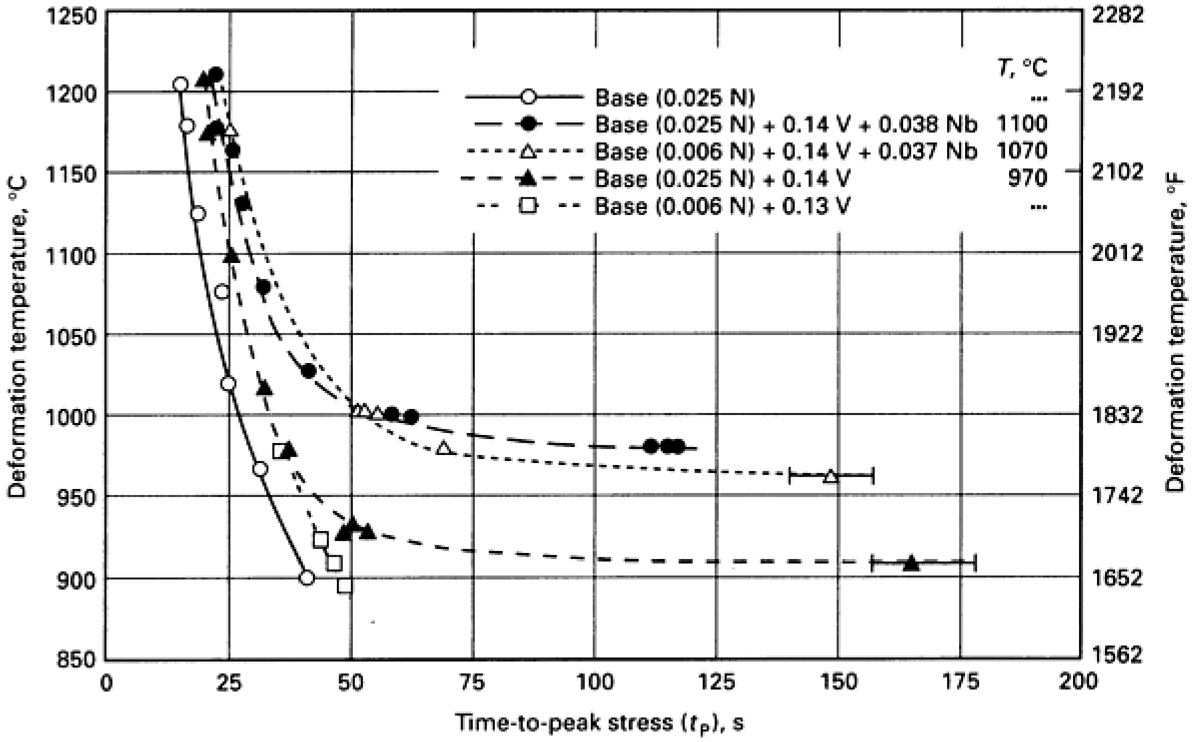

Fig. 16 Dependence of the time-to-peak stress (t_p) on deformation temperature at a low strain rate ($\dot{\epsilon}$ is 0.006 s^{-1}) for selected microalloyed steels containing two levels of nitrogen (0.006 and 0.025% N). The 0.025% N steel is a reference steel. Source: Ref 83

A good comparison of the various precipitation systems can be made through the use of the appropriate solubility relations. For example, the driving force for precipitation at a given temperature is directly related to the solute supersaturation at that temperature (Ref 81). A comparison of the variation of supersaturation with temperature is shown in Fig. 17 for several important systems. Figure 17 reveals that the titanium-base system shows a large supersaturation at temperatures well above those associated with hot rolling. The VC and VN systems, on the other hand, display a large supersaturation at the very lowest range of hot-rolling temperatures. Finally, the niobium-base system shows a large supersaturation at temperatures that are well situated within the hot-rolling range. Hence, titanium precipitates are very effective for high-temperature control (for example, during reheating), niobium precipitates are very effective for intermediate temperature exploitation (for example, control of recrystallization stop temperature) and the vanadium can easily be retained in solid solution in the austenite for the eventual precipitation hardening of the transformation product.

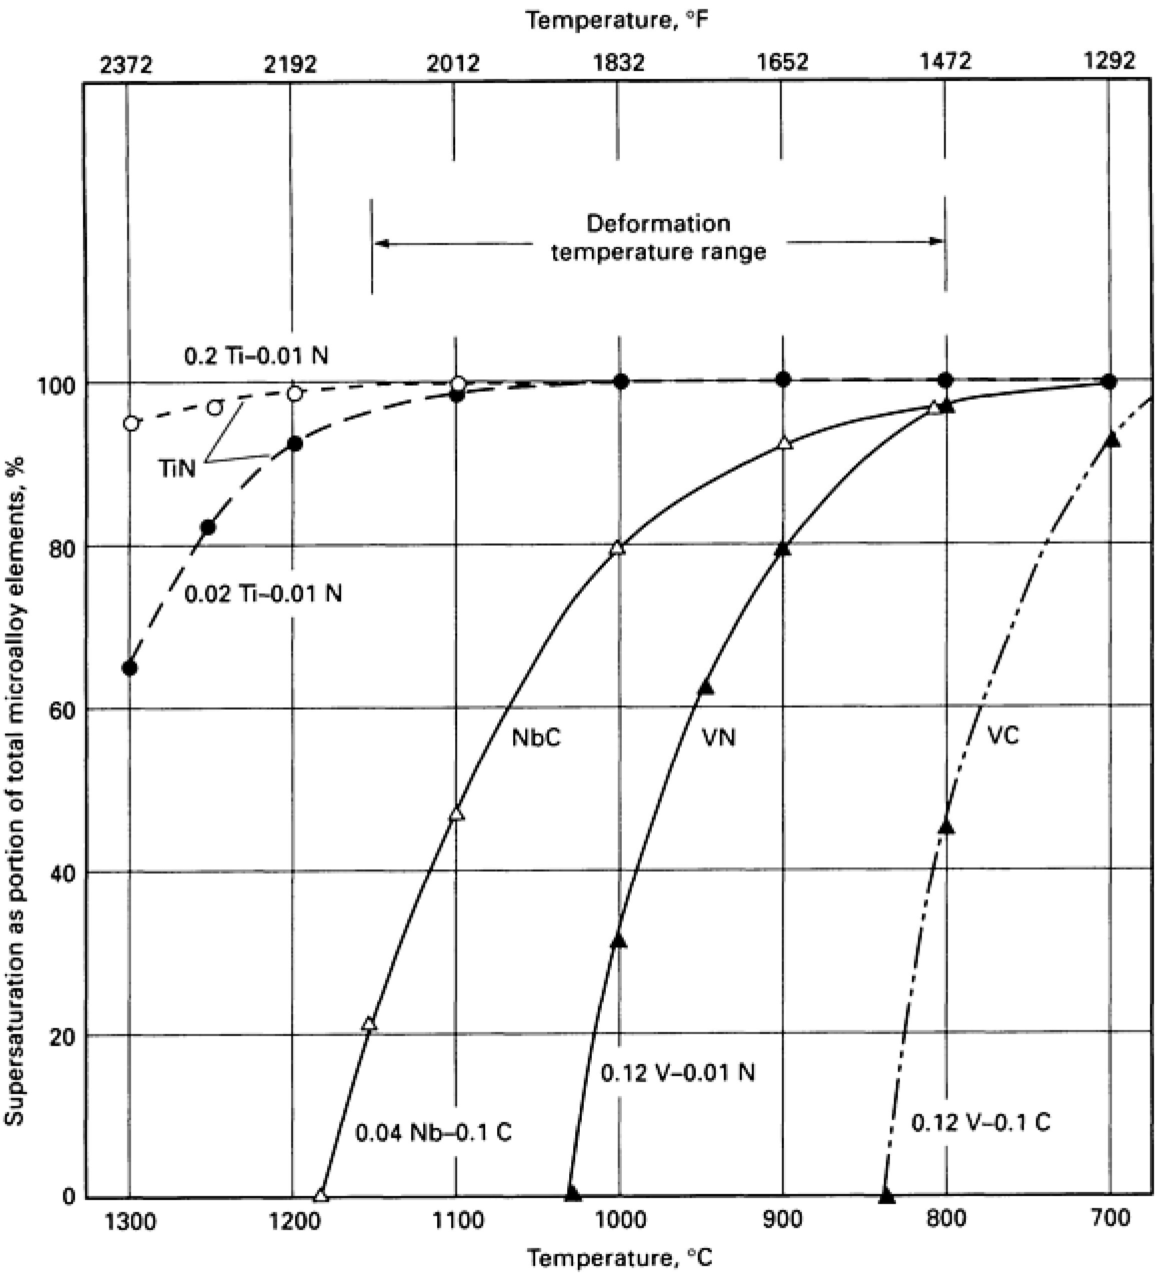

Fig. 17 Precipitation potential of various microalloying element systems. Source: Ref 85

Transformation Temperature. The third critical temperature that can be strongly influenced by microalloying elements is the transformation temperature, either the Ar_3 or B_s temperature. In either case, the effect of the microalloying elements is based on hardenability concepts. The transformation temperature is important because it has a direct influence on the scale of the resulting microstructure (for example, ferrite grain size or bainitic lath size). This effect occurs because the thermodynamic driving force for nucleation is inversely related to the square of the difference between the equilibrium transformation temperature, Ae_3, and the actual transformation temperature, Ar_3. Hence, lower Ar_3 temperatures result in lower transformation temperatures that result in higher nucleation rates and lower rates of growth and coarsening (Ref 86). There are, therefore, two major contributors to the ferrite grain size in F-P steels: S_v and Ar_3. The Ar_3 in F-P steels is defined as the temperature where the cooling rate intersects the start of the polygonal ferrite transformation. Hence, both the cooling rate and the hardenability of the steel will contribute to the Ar_3 temperature. An example of the influence of the composition of austenite on the transformation temperature is shown in Fig. 18 for the air cooling of niobium bearing steels (Ref 87). In Fig. 18, the cooling time for transformation is inversely related to the transformation temperature. When the steels were reheated at 900 °C (1650 °F), the addition of 0.04 wt% Nb had little effect on the transformation temperature. This is because virtually none of the niobium had been dissolved into the austenite during reheating at that low temperature. The transformation temperature in this case was about the same as for the niobium-free steels. The

behavior at 1100 °C (2190 °F) reheating in Fig. 18 was very different. Here, the addition 0.04 wt% Nb had a very large effect on depressing the transformation temperature. In this case, virtually all of the niobium had been taken into solution during reheating and had a large effect on the hardenability.

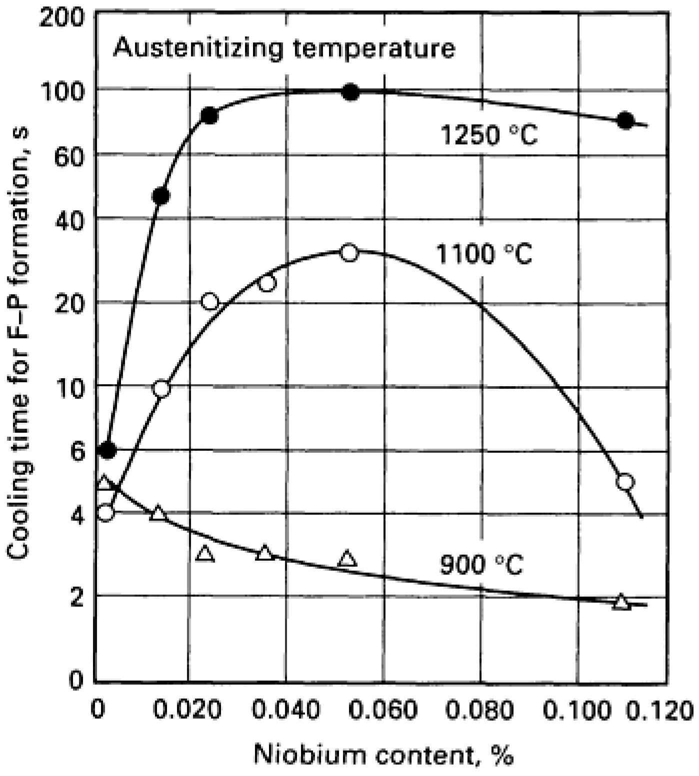

Fig. 18 Cooling time between 800 and 500 °C (1470 and 930 °F) for the start of F-P formation in niobium-alloy steels after austenitizing at different temperatures. The steel also contained 0.2% C and 1.2% Mn. Source: Ref 87

The effects of nickel in solution and of accelerated cooling on the Ar_3 temperature and the resulting ferrite grain size are shown in Fig. 19 (Ref 88). A comparison of Fig. 18 and 19 reveals the differences in effectiveness between niobium in solution and nickel in solution. The niobium in solution is a much stronger contributor to hardenability than is nickel. Accelerated cooling from the finish rolling temperature also has a dramatic effect on both the Ar_3 temperature and the resulting ferrite grain size (see Fig. 19). The beneficial effects of accelerated cooling have been so pronounced that two major international symposia have been dedicated to this technology (Ref 88, 89) and have been the subject of recent reviews (Ref 90, 91). The effects of alloying on the Ar_3 temperature (Ref 46) for proeutectoid ferrite and the B_s temperature (Ref 92) for bainite have been quantified and are shown below:

$$Ar_3(°C) = 910 - 310(C) - 80(Mn) - 20(Cu) - 15(Cr) - 55(Ni) + 0.35(t - 8) \quad \textbf{(Eq 25)}$$

$$B_s(°C) = 830 - 270(C) - 90(Mn) - 37(Ni) - 70(Cr) - 83(Mo) \quad \textbf{(Eq 26)}$$

In Eq 26 *t* refers to the plate thickness in millimeters and all elements are represented by their weight percent.

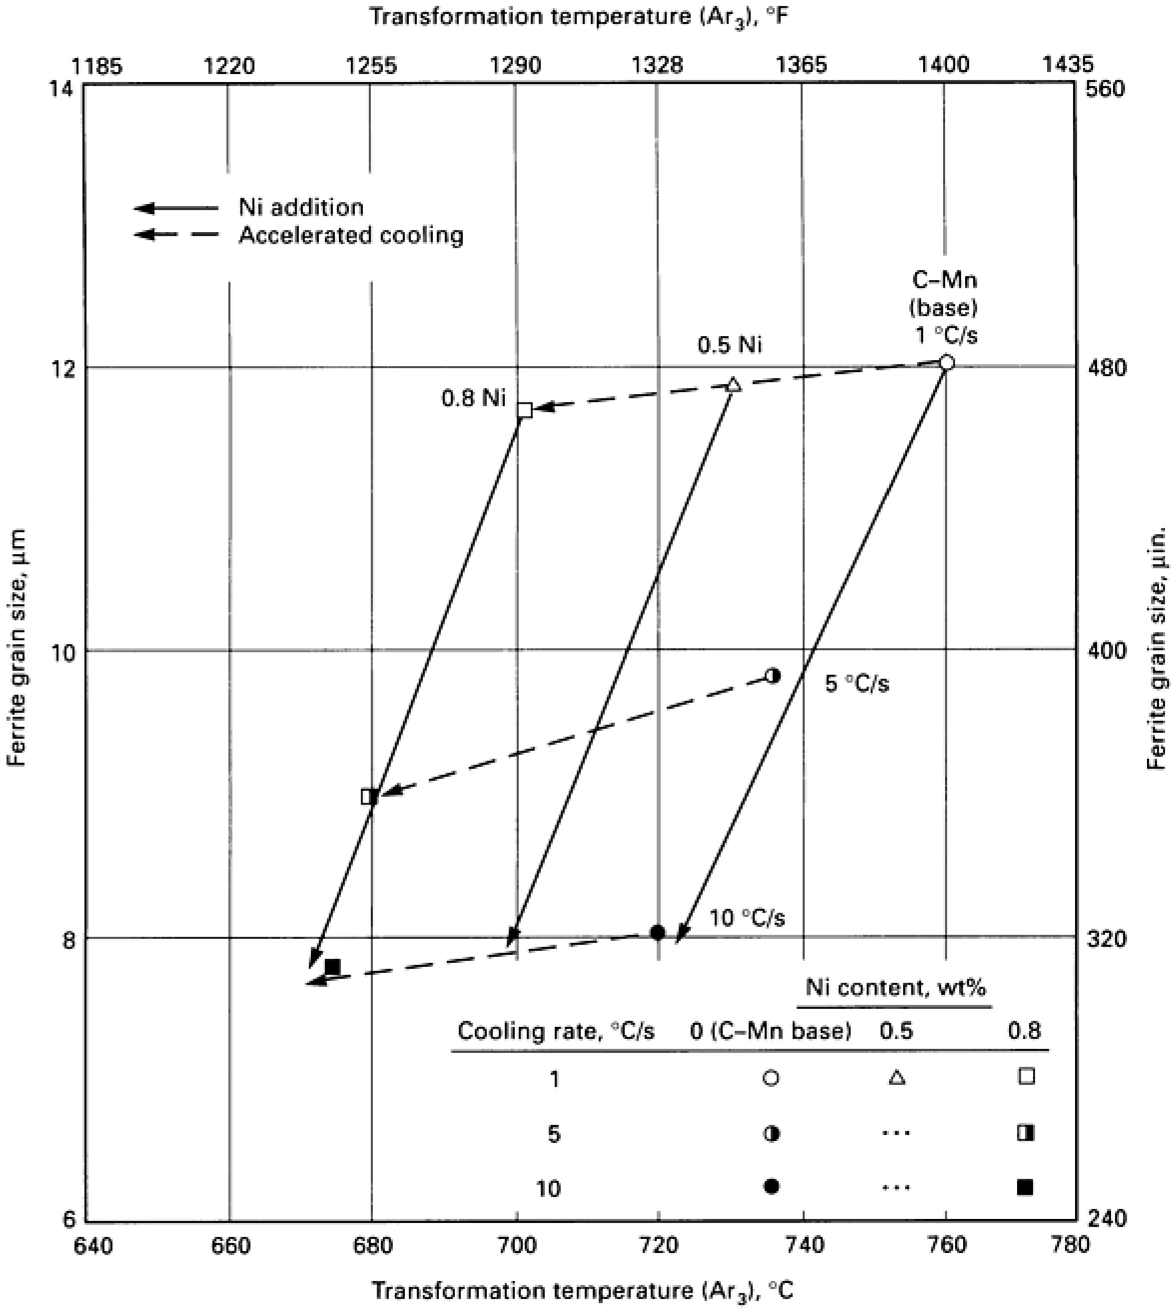

Fig. 19 Effect of accelerated cooling and nickel content on ferrite grain size transformed from deformed and unrecrystallized austenite. Source: Ref 88

When microalloyed austenite undergoes multipass hot rolling at temperatures where large supersaturations exist, various amounts of strain-induced precipitation may occur depending on factors such as the finishing temperature and the interpass holding time. The effect on the amount of precipitation caused by variations in deformation temperature, extent of recrystallization, and interpass holding time is shown in Fig. 20. Figure 20 shows that the amount of strain-induced precipitation, which attends hot rolling, is a variable and hence, the amount of niobium in solution can also vary. Because it is known that the Ar_3 temperature varies with the amount of niobium in solution, it should be expected that the Ar_3 temperature may also vary with the details of the rolling practice. This is, in fact, the case. Figure 21 shows the dependence of the Ar_3 temperature on the amount of deformation that takes place below the recrystallization stop temperature (Ref 46). In Fig. 21, the amount of strain-induced precipitation increases with the amount of deformation below the T_{RXN}. The resulting amount of niobium in solution becomes lower with increasing reduction, leading to an increase in the Ar_3 temperature. Hence, when most of the niobium is in solution in austenite (that is, with little or no deformation below the T_{RXN}), the Ar_3 temperature is relatively low. On the other hand, when most of the niobium is in the

form of precipitate (that is, at large strains below the T_{RXN}), the Ar_3 temperature is relatively high (Ref 46). The correspondence between the behavior of the Ar_3 value with niobium in solution in Fig. 18 and 21 is quite striking.

Applications of Thermomechanical Processing to Heat Treat As-Rolled Microalloyed Steels

In the most general sense, thermomechanical processing is comprised of reheating, hot rolling, and cooling. The difference between thermomechanical processing and conventional hot rolling (CHR) and the differences among various forms of thermomechanical processing can perhaps most simply be described using Fig. 22. The first method presented in Fig. 22 is conventional hot rolling, which shows that the reheating, rough rolling, and finish rolling all occur at the highest possible temperatures. The goal of conventional hot rolling has traditionally been to optimize productivity while neglecting the as-rolled mechanical properties. The second method shown in Fig. 22 is conventional controlled rolling (CCR) (Ref 93). The goal of conventional cold rolling is to produce very fine ferrite grain sizes by conditioning the austenite through extensive rolling in the non-recrystallization region of austenite. Another rolling technique shown in Fig. 22 is recrystallization controlled rolling (RCR). This technique differs from the previous two methods in that both rough rolling and finish rolling take place above the recrystallization stop temperature (Ref 21, 93, 94, 95, 96). The goal of the RCR method is to produce a fine ferrite grain size by transforming a fine, fully recrystallized austenite.

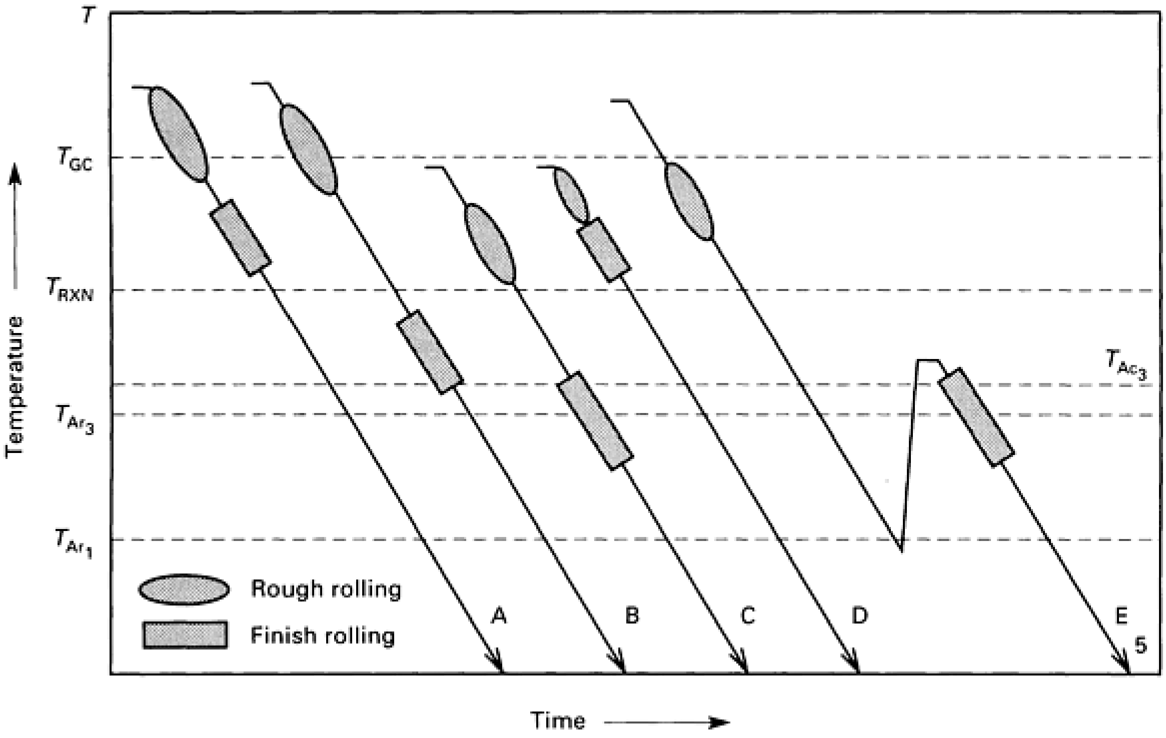

Fig. 22 Comparison of selected thermomechanical treatments based on critical austenite temperatures, transformation temperatures, and rough and finish rolling operations: A, conventional hot rolling; B, conventional controlled rolling; C, intensified controlled rolling; D, recrystallization controlled rolling; E, Sumitomo high toughness rolling

Conventional Controlled Rolling

As mentioned above, one of the principal goals of thermomechanical processing is to have well-conditioned austenite (that is, austenite having the proper composition, texture, and S_v) prior to transformation. Because S_v comprises near-planar crystalline defects such as grain boundaries, deformation bands, and twin boundaries, the control of recrystallization during thermomechanical processing is critical: it dictates the size and shape of grains as well as the presence or absence of the intragranular defects. We now turn to a discussion of multistage hot deformation with

particular emphasis on the principal factors that control the recrystallization stop temperature, or the suppression of recrystallization. The question arises, however, as to which form of recrystallization is, in fact, to be suppressed.

During multipass hot rolling, there are three possible forms of recrystallization that may take place (Ref 97, 98):

- Dynamic recrystallization that might occur during deformation in the roll gap
- Static recrystallization that might occur in the time period between deformations
- Metadynamic recrystallization that, if it occurred, would begin in the roll gap and go to completion in the time period between deformations

Hence, any discussion of recrystallization must begin with some understanding of the form(s) of recrystallization that is most likely to actually control the austenite microstructure.

Dynamic Recrystallization and Metadynamic Recrystallization. In the opinion of the authors, it is extremely unlikely that either dynamic recrystallization or metadynamic recrystallization could occur during industrial processing. This position can be summarized by stating that the time required for substantial amounts of dynamic recrystallization to occur is orders of magnitude longer than the times actually available in the roll gap (Ref 99, 100, 101, 102).

Static Recrystallization. The elimination of dynamic and metadynamic recrystallization leaves static recrystallization as the most likely candidate for the recrystallization process, which must be suppressed in defining the recrystallization stop temperature observed in multipass hot rolling. Fortunately, static recrystallization has been rather extensively studied over the last two decades; hence, our understanding of this phenomenon is fairly well advanced (Ref 97, 98, 103, 104, 105, 106, 107). Two major techniques have been used to study high-temperature static recrystallization. One, based on optical metallography, relies on changes in grain structure with holding time after deformation. The second is based on changes in flow strength with isothermal holding, the so-called double hit test (Ref 69). The overall static softening behavior of the austenite is monitored by a fractional softening parameter that is based on either yield or offset flow stresses.

Static Softening Behavior of Austenite. When the static softening behavior of single-phase austenite is studied, curves of the type shown in Fig. 23 are obtained (Ref 69, 101). The curves shown in Fig. 23 are for a plain carbon steel (K-0). Note that the softening begins with a short, but finite, incubation period that is followed by a monotonic increase in softening to saturation. The change in recrystallization with softening and holding time is also apparent. This behavior is, of course, exactly that which is expected: an initial period of static recovery, which causes no appreciable change in strength, followed by static recrystallization, which leads to appreciable softening.

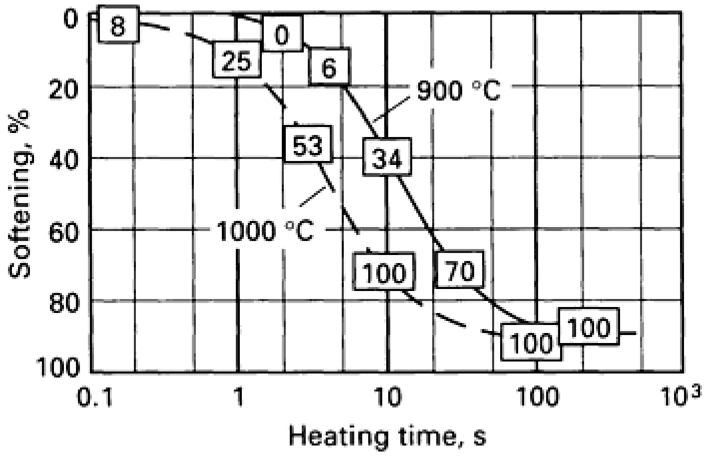

Fig. 23 Relationship between softening and fractional recrystallization in a plain carbon steel (K-0 with composition 0.1C-0.008N-Fe) deformed at 0.1 s^{-1} with an applied prestrain of 0.3. The peak strains were 0.48 at 900 °C (1650 °F) and 0.35 at 1000 °C (1830 °F) Numbers in boxes represent the percentage of recrystallization measured by the point-count method. Source: Ref 69

The static softening behavior becomes much more complicated if the experiment is performed on a supersaturated solid solution (for example, VCN or NbCN in austenite at temperatures where the appropriate solubility product has been exceeded). The static softening behavior of a niobium-bearing austenite that contains high and low levels of nitrogen is illustrated in Fig. 24 (Ref 69, 101). Superimposed on the softening curves are the amounts of static recrystallization determined by quantitative optical metallography. The curves shown in Fig. 24 can be divided into two classes: those with shapes resembling the shapes of single-phase austenite and those with shapes differing from single-phase austenite. It is fairly clear that the change in shape is related to both the suppression of static recrystallization and to precipitation hardening in certain cases. A comparison of the conditions that lead to suppressed versus unsuppressed static recrystallization kinetics reveals that the suppressed kinetics are associated with relatively large potentials for precipitation (that is, large supersaturations at the test temperature). The results of a study of precipitation revealed that precipitation-start times correlated closely with deviations in static softening curves (see Fig. 24). Curves of the type shown in Fig. 24 lead to two important questions:

- Is the precipitation observed capable of suppressing static recrystallization?
- How does niobium in solution compare to niobium in precipitate in terms of suppressing recrystallization?

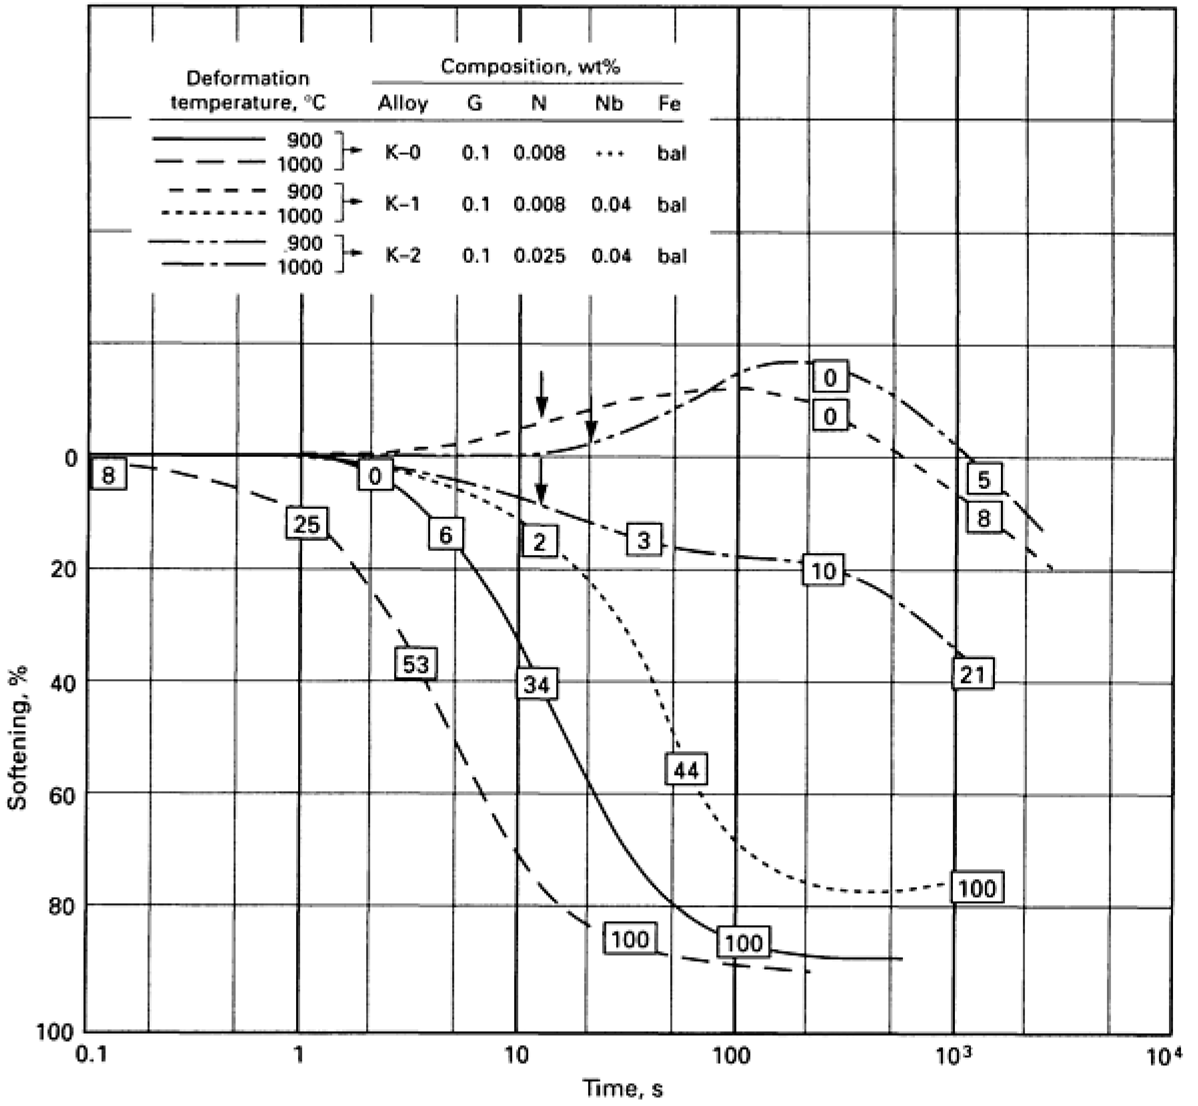

Fig. 24 Static restoration behavior of three steels (K-0, K-1, and K-2) isothermally deformed at 900 °C (1650 °F) and 1000 °C (1830 °F) and then held at temperature for various times. Arrows denote first observable precipitation. Strain rate is 0.1 s^{-1}; prestrain, 0.3. Numbers in boxes represent the fractional recrystallization. Source: Ref 69, 101

Local Pinning Force Generated by Precipitates. Recently, precipitation dispersion parameters were used to calculate the pinning force that the precipitates could exert on various boundaries (Ref 53, 68, 69, 81, 101, 107). For the experiments described in Fig. 24, this pinning force was found to be sufficiently large to suppress recrystallization. The driving force for static recrystallization was estimated to be approximately 9.0 MPa (1.3 ksi) whereas the local pinning forces for different conditions are shown in Table 4 (Ref 101). Clearly, there are conditions under which the pinning force can equal or exceed the driving force.

Table 4 Results of local pinning force calculations based on the rigid boundary model (RB), flexible boundary model (FB), and subgrain boundary model (SB). Specimens were deformed at 900 °C (1650 °F) using a strain rate of 10 s^{-1}

Time, s	Alloy	Precipitation distribution data		Number of particles per unit area (N_S), 10^{-14} m^{-2}	Local pinning force, MN · m^{-2}					
		Particle diameter (*d*), nm	Standard deviation, nm		RB		FB		SB	
					MPa	ksi	MPa	ksi	MPa	ksi
10	K-1	4.7	3.5	2.98	3.48	0.505	9.95	1.44	2.24	0.325
	K-2	4.1	2.7	1.02	0.96	0.14	4.41	0.639	0.67	0.097
100	K-1	6.3	3.7	4.32	5.86	0.850	12.76	1.85	4.35	0.631
	K-2	6.5	3.4	2.76	3.66	0.531	16.32	2.37	2.86	0.415
1000	K-1	9.2	3.5	2.08	3.50	0.508	7.99	1.16	3.06	0.444
	K-2	9.8	3.8	1.52	2.74	0.397	6.64	0.963	2.38	0.345

Additional information regarding the nature of the pinning force is evident from transmission electron microscopy (TEM) observations of the actual precipitation dispersions. Excellent evidence of these dispersions of strain-induced microalloy precipitates has been published (Ref 68, 69, 74, 81, 108, 109). A good example of this is shown in Fig. 25 for the precipitation of NbCN in austenite after low-temperature rolling and holding. The similarity between the precipitate dispersion shown in Fig. 25 and that shown for strain-induced precipitates of VCN formed in austenite in a vanadium-bearing steel after rolling at 870 °C (1600 °F) is striking (Ref 96). It has been suggested for some time that the strain-induced precipitation that forms in conjunction with hot rolling appears to decorate the subgrain boundaries of the statically (or dynamically) recovered austenite grains (Ref 96, 104). Recent work has revealed that the volume fraction of precipitates found on the subgrain boundaries is appreciably larger than that which would have been predicted by equilibrium solubility products (Ref 69, 81, 101). It appears that niobium has segregated to the subgrain boundaries causing an abnormally large volume fraction of NbCN to subsequently form. Because the pinning force varies with the volume fraction, this unexpectedly high localized volume fraction of NbCN would be expected to lead to larger than expected pinning forces. Alternatively, the niobium supersaturation eventually available to drive the precipitation reaction is larger than normally thought for a given bulk niobium concentration.

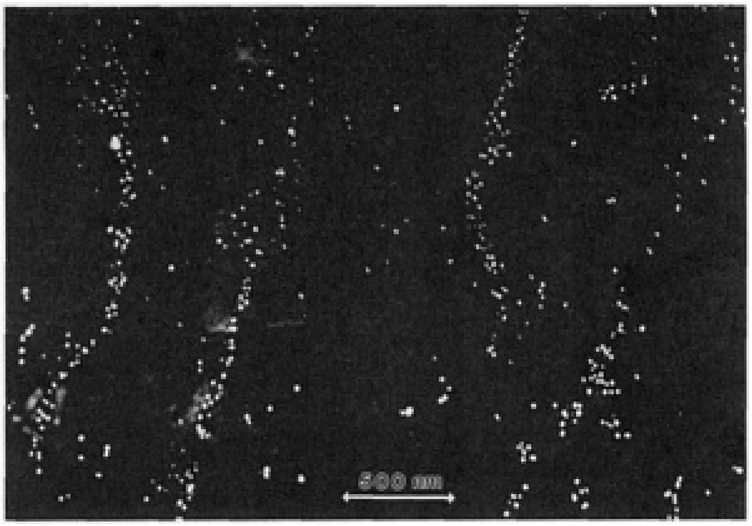

Fig. 25 Strain-induced precipitation of NbCN in austenite in a steel containing 0.9 wt% C and 0.07 wt% Nb. Specimen was reheated at 1250 °C (2280 °F), rolled 25%, and held at 950 °C (1740 °F), and then air cooled to room temperature. Centered dark field electron micrograph was obtained using a (111) NbC zone axis. Source: Ref 74

Effect of Niobium in Suppressing Recrystallization. The second question comparing the suppression of recrystallization by solute and precipitate is addressed in Table 5. In this case, the time to 20% static softening was measured for a variety of conditions, including those where niobium was largely in solution and those where niobium was present as a precipitate. The data for the strain rate of 10 s^{-1} are perhaps the more interesting because they have been generated under conditions approximating industrial plate rolling. When the niobium is in solution, the measured delay was less than 1.5 s at 1000 °C (1830 °F), whereas the delay caused by precipitates was on the order of several minutes. Furthermore, a comparison of the curves presented in Fig. 23 and 24 indicates that the precipitation-start time at 900 °C (1650 °F) corresponds to about 34% recrystallization in the niobium-free reference steel. A close examination of Fig. 24 reveals that this means the niobium in solution has retarded recrystallization for about 8 s at 900 °C (1650 °F) in the niobium steel.

Table 5 Times required for 20% softening in three selected steels at strain rates of 0.1 and 10 s^{-1}

Strain rate (ε), s^{-1}	Temperature		Time to 20% static softening ($t_{20\%}$), s		
	°C	°F	Alloy K-0	Alloy K-1	Alloy K-2
0.1	900	1650	5	2000[(a)]	3000[(a)]
	1000	1830	2	15	200[(a)]
	1100	2010	0.6	3	3.5
10	900	1650	0.2	300[(a)]	1000[(a)]
	1000	1830	0.1	1	1.5

(a) Condition where extensive precipitation occurs.

Recrystallization Controlled Rolling

An alternate form of thermomechanical processing exists in addition to controlled rolling. This new process is called recrystallization controlled rolling. The metallurgical basis of the RCR process and how it is distinguished from the CCR or CHR processes and intensified controlled rolling (ICR) can be understood with the help of Fig. 22.

Whereas there is a clear distinction in processing (that is, finish rolling temperatures) between recrystallization controlled rolling and conventional controlled rolling, the difference between recrystallization controlled rolling and conventional hot rolling is not initially obvious because they both rely on high-temperature deformation. There are in fact two major differences between recrystallization controlled rolling and conventional hot rolling. First, all of the deformation in recrystallization controlled rolling is completed in the region of full recrystallization. This is in contrast to the CHR method, where a portion of the deformation takes place in the region of partial recrystallization. Second, only certain steels are amenable to the RCR method since a mechanism to inhibit grain coarsening must be present in the steel. Alloys not configured for recrystallization controlled rolling undergo static recrystallization following each high-temperature deformation. This is followed by rapid grain coarsening in the remaining interpass time. Hence, this leads to coarse, as-rolled austenite grain sizes. This austenite structure is characterized by a small S_v and is therefore indicative of poor thermomechanical processing. The central feature of steels exhibiting RCR behavior is the presence of a grain coarsening inhibition system. Recent research has indicated that this inhibition system can take one of two forms (Ref 44, 94, 96). The first relies on the presence of stable particles whose distribution provides an adequate pinning force to suppress coarsening following post-deformation static recrystallization. These particles must have sufficient stability to resist Ostwald ripening (solution-crystallizer phenomenon in which small crystals, more soluble than large ones, dissolve and reprecipitate onto larger particles) themselves and must be present in a sufficiently fine dispersion. As was shown above, the pinning force exerted by an array of particles on a boundary is given by Equation 18 assuming a rigid boundary model. As was shown by Ashby (Ref 65), the driving force for normal grain coarsening is nearly three orders of magnitude smaller than that for recrystallization. Hence, the particle pinning force required to suppress coarsening is much smaller than that required to suppress recrystallization. Because the particle pinning force varies with f_v/r, even particle distributions with rather small f_v and large r can still be effective barriers to grain coarsening. This, of course, would not be true in the suppression of recrystallization, where only large, local volume fractions of fine particles are effective. Particles such as titanium nitride have been shown to be particularly well suited for the suppression of grain coarsening (Ref 44, 96). In this regard, the titanium nitride particles are formed via solid state precipitation immediately following solidification and, hence, exist prior to deformation.

An alternate grain coarsening inhibition mechanism has recently been discovered (Ref 110). This mechanism involves intense solute drag as the critical element. It has been found that high levels of soluble molybdenum and niobium can be very effective in retarding boundary motion at high reheating temperatures (see Fig. 26). Hence, these solute effects act to retard grain coarsening both during reheating and after post-deformation static recrystallization. In summary, recrystallization controlled rolling offers an attractive alternative to conventional controlled rolling in several applications where low-temperature rolling is impractical (for example, older underpowered plate mills and hot forgings) (Ref 112, 113). That recrystallization controlled rolling can lead to excellent austenite conditioning is evidenced by values of S_v well in excess of 100 mm^{-1} which can be easily realized (Ref 11).

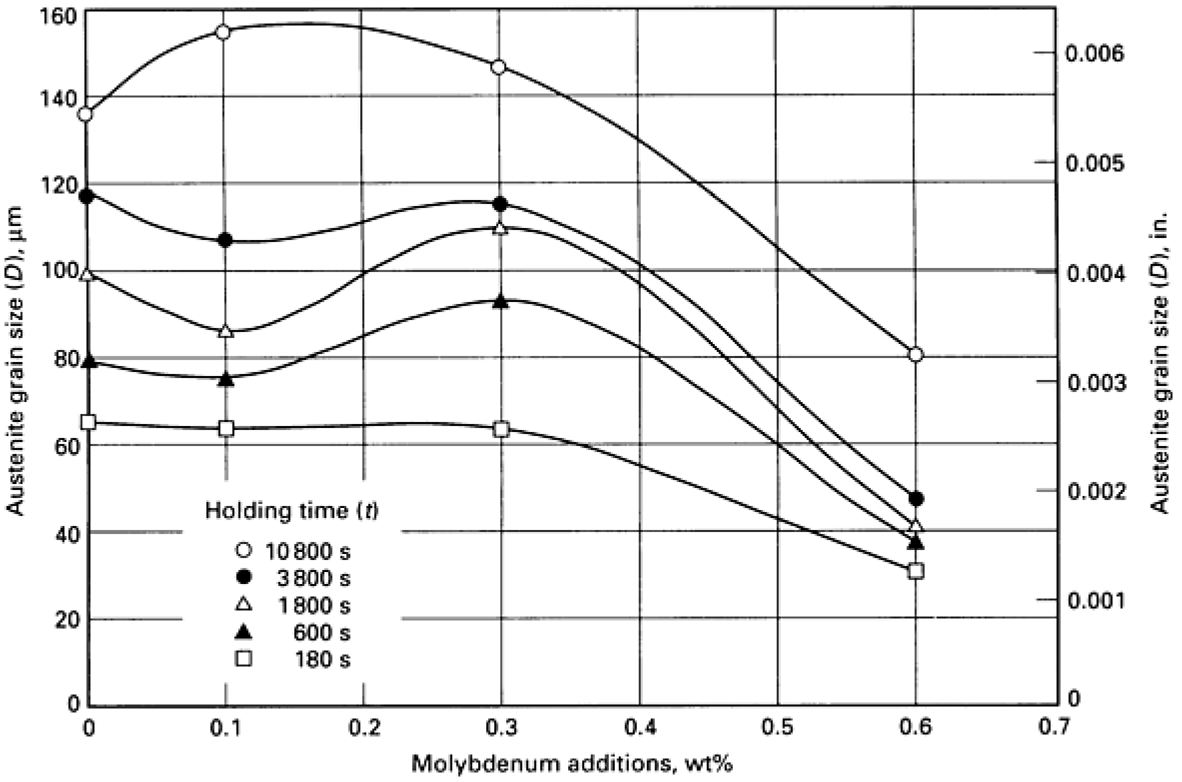

Fig. 26 Effect of molybdenum addition on austenite grain size after reheating at 1150 °C (2100 °F) and holding at this temperature for various times. Source: Ref 111

Intensified Controlled Rolling

A variation in conventional controlled rolling, known as intensified controlled rolling, is shown in Fig. 22. Note that intensified controlled rolling differs from conventional controlled rolling in that finish rolling not only occurs below the T_{RXN}, but also extends to temperatures below the Ar_3. The goal of intensified controlled rolling is to increase the strength and toughness of the as-rolled MA steel over what could be achieved through conventional controlled rolling. The combination of the lower reheat and lower rolling temperatures leads to finer as-rolled austenite. Furthermore, because a portion of the rolling occurs in the intercritical or two-phase ($\alpha + \gamma$) region, a certain amount of proeutectoid ferrite would be deformed during this rolling. This deformed ferrite is partially responsible for the higher strengths observed with intensified controlled rolling (Ref 93, 114).

High Toughness Rolling Processes

Heat treatment processes incorporating high toughness rolling have been developed by Sumitomo and Broken Hill Proprietary.

Sumitomo High Toughness Rolling. An additional rolling practice shown in Fig. 22 is known as the Sumitomo high toughness (SHT) process (Ref 93, 115, 116). The goal of the SHT process is to produce steels with very high resistance to brittle fracture at the expense of strength when compared to a steel processed by the CCR process. In the SHT process, extra grain refinement of the austenite is achieved by the introduction of a cooling and low-temperature reheating cycle positioned between rough and finish rolling. The finish rolling is performed in the intercritical region as with intensified controlled rolling.

Broken Hill Proprietary High Toughness Rolling. There are some conditions where neither the CCR process nor the ICR process will achieve a resistance to brittle fracture in plate steels. Such conditions exist when the plate thickness exceeds $\approx$ 18 mm ($\approx \frac{23}{32}$ in.) or when the plate width causes the mill loads to exceed acceptable levels. These shortcomings have been overcome by Broken Hill Proprietary (BHP) through a variation of both the alloy design and controlled rolling practice of their plate steels intended for line pipe and offshore applications (Ref 117, 118, 119). During conventional

controlled rolling, the total reduction is fairly evenly distributed between the roughing and finishing passes. In the BHP process, a larger portion of the deformation takes place in the roughing passes and, consequently, a smaller portion in the finishing passes. Hence, while the low-temperature deformation in conventional controlled rolling and intensified controlled rolling is used to generate high values of S_v through extensive pancaking, the high-temperature passes and the associated recrystallization and grain refinement are responsible for the high S_v found in the BHP process. This emphasis on high-temperature rolling is beneficial for the rolling of both heavy sections and large widths. Because the BHP process involves high-temperature rolling, the phenomenon of grain coarsening must be avoided. This is accomplished by a microtitanium addition to a niobium MA steel. The titanium nitride that forms is effective in suppressing grain coarseing.

Applications of Thermomechanical Processing to Heat Treat Low-Alloy Steels

Up until this point, the benefits of thermomechanical processing have been examined for as-hot rolled strip and plate microalloyed steels. By definition, these steels contain less than about 2 wt% in total alloying and usually exhibit F-P microstructures. Recently, the benefits of thermomechanical processing have been extended to the low-alloy steels, including the HY steels, the HSLA steels, the ultralow carbon bainitic steels, and the multiphase steels. These steels differ from the as-rolled microalloyed steels in two ways:

- Steels contain >3 wt% in total alloying
- Steels may be heat treated after rolling

These steels are often bainitic, martensitic, or multiphase in microstructure.

HSLA Steels. Thermomechanical processing has been shown to greatly improve the resistance to brittle fracture in the new HSLA-80 and HSLA-100 steels (Ref 120). Figure 27 compares the notch toughness of quenched and aged steels that had been either hot rolled or controlled rolled prior to heat treatment. The benefit of the controlled rolling is obvious. Note that the benefits derived from the controlled rolling existed even after the post-rolling reheating treatment.

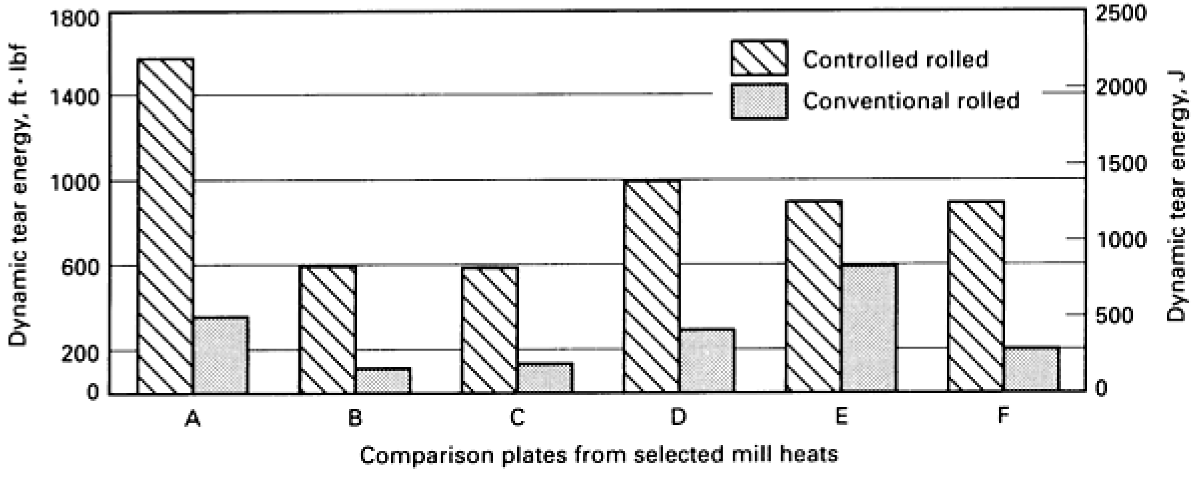

Fig. 27 Comparison of dynamic tear toughness at -40 °C (-40 °F) of 25 mm (1 in.) thick HSLA-80 plates produced either by controlled rolling or conventional rolling prior to reheating, water quenching, and aging. Source: Ref 120

ULCB Steels. Austenite conditioning has also been shown to be critical in achieving low-temperature toughness in as-hot rolled ULCB steels (Ref 11, 121). A study of the factors that control the resistance to brittle fracture in these steels indicated the importance of the prior austenite grain size (see Fig. 4). In a similar study (Ref 121), an important relationship was found between low-temperature toughness and the S_v of the controlled rolled austenite that existed prior to transformation. While S_v improves the toughness of F-P steels through the refinement of the ferrite grain size, the role of S_v in ULCB steels is somewhat different. As was shown in a later study (Ref 11), the only significant barrier to a growing cleavage crack in a high-strength bainitic matrix is the prior austenite grain boundary. Hence, the higher the S_v, the smaller the growth phase of the cleavage cracking event. It was shown that when these cleavage cracks could be kept relatively small, their existence did not preclude an otherwise high-toughness value at low temperatures.

Multiphase steels intended for long product applications have also benefitted from thermomechanical processing. Low-carbon steels based on the manganese-molybdenum-niobium system have been shown to exhibit ferrite-lower bainite microstructures after controlled rolling. These steels display excellent ductility and work hardening characteristics and, hence, are ideal steels for cold forging applications. In this case, the controlled rolling not only leads to grain refinement but also to establishing the proper balance between the phases in the final microstructure (Ref 11, 122, 123). This same steel exhibits austenite conditioning via recrystallization controlled rolling during high-temperature forging processing. In the as-direct quenched condition, these forgings display unusually high levels of strength, toughness, and fatigue resistance (Ref 124).

Future Outlook

The thermomechanical processing of austenite is often associated with significant improvements in final properties and offers a degree of flexibility in achieving various packages of properties that are quite impressive. While the elements of thermomechanical processing (reheating, hot rolling, and cooling) are easily distinguishable and individually amenable to thorough investigation, the response of a given MA steel to a given processing step will, to a large measure, depend on what had occurred in previous stages. It is this interdependence that makes the rationalization of commercial hot rolling so very complex and challenging. This is specially true in the MA steels, where the dissipation or retention of microalloy solute supersaturation in a given process step might have drastically different effects on microstructural evolution in subsequent steps. There is little doubt that thermomechanical processing offers a very cost-effective route to good properties in steel. It is interesting to consider where the concepts of thermomechanical processing and microalloying technology may lead us in the future.

Introduction to Surface Hardening of Steels

S. Lampman, ASM International

Introduction

SURFACE HARDENING, a process which includes a wide variety of techniques (Table 1), is used to improve the wear resistance of parts without affecting the more soft, tough interior of the part. This combination of hard surface and resistance to breakage upon impact is useful in parts such as a cam or ring gear that must have a very hard surface to resist wear, along with a tough interior to resist the impact that occurs during operation. Further, the surface hardening of steel has an advantage over through hardening because less expensive low-carbon and medium-carbon steels can be surface hardened without the problems of distortion and cracking associated with the through hardening of thick sections.

Table 1 Engineering methods for surface hardening of steels

Layer Additions
Hardfacing
Fusion hardfacing (welded overlay)
Thermal spray (nonfusion bonded overlay)
Coatings:
Electrochemical plating
Chemical vapor deposition (electroless plating)
Thin films (physical vapor deposition, sputtering, ion plating)
Ion mixing
Substrate treatment
Diffusion methods:
Carburizing
Nitriding
Carbonitriding
Nitrocarburizing
Boriding
Titanium-carbon diffusion
Toyota diffusion process
Selective hardening methods:
Flame hardening
Induction hardening
Laser hardening
Electron beam hardening
Ion implantation
Selective carburizing and nitriding
Use of arc lamps

There are two distinctly different approaches to the various methods for surface hardening (Table 1):

- Methods that involve an intentional buildup or addition of a new layer
- Methods that involve surface and subsurface modification without any intentional buildup or increase in part dimensions

The first group of surface hardening methods includes the use of thin films, coatings, or weld overlays (hardfacings). Films, coatings, and overlays generally become less cost effective as production quantities increase, especially when the entire surface of workpieces must be hardened. The fatigue performance of films, coatings, and overlays may also be a limiting factor, depending on the bond strength between the substrate and the added layer. Fusion-welded overlays have strong bonds, but the primary surface-hardened steels used in wear applications with fatigue loads include heavy case-hardened steels and flame- or induction-hardened steels. Nonetheless, coatings and overlays can be effective in some applications. With tool steels, for example, TiN and Al_2O_3 coatings are effective not only because of their hardness but also because their chemical inertness reduces crater wear and the welding of chips to the tool. Overlays can be effective when the selective hardening of large areas is required.

This introductory article on surface hardening focuses exclusively on the second group of methods, which is further divided into diffusion methods and selective hardening methods (Table 1). Diffusion methods modify the chemical composition of the surface with hardening species such as carbon, nitrogen, or boron. Diffusion methods allow effective hardening of the entire surface of a part and are generally used when a large number of parts are to be surface hardened. In contrast, selective surface hardening methods allow localized hardening. Selective hardening generally involves transformation hardening (from heating and quenching), but some selective hardening methods (selective nitriding, ion implantation and ion beam mixing) are based solely on compositional modification. Factors affecting the choice of these surface hardening methods are discussed in the section "Process Selection" in this article.

Diffusion Methods of Surface Hardening

As previously mentioned, surface hardening by diffusion involves the chemical modification of a surface. The basic process used is thermochemical because some heat is needed to enhance the diffusion of hardening species into the surface and subsurface regions of a part. The depth of diffusion exhibits a time-temperature dependence such that:

$$\text{Case depth} \propto K\sqrt{time} \qquad \textbf{(Eq 1)}$$

where the diffusivity constant, *K*, depends on temperature, the chemical composition of the steel, and the concentration gradient of a given hardening species. In terms of temperature, the diffusivity constant increases exponentially as a function of absolute temperature. Concentration gradients depend on the surface kinetics and reactions of a particular process.

Methods of hardening by diffusion include several variations of hardening species (such as carbon, nitrogen, or boron) and of the process method used to handle and transport the hardening species to the surface of the part. Process methods for exposure involve the handling of hardening species in forms such as gas, liquid, or ions. These process variations naturally produce differences in typical case depth and hardness (Table 2). Factors influencing the suitability of a particular diffusion method include the type of steel (Fig. 1), the desired case hardness (Fig. 2), and the case depth (Fig. 3).

Table 2 Typical characteristics of diffusion treatments

Process	Nature of case	Process temperature,	Typical case	Case hardness,	Typical base	Process characteristics

		°C (°F)	depth	HRC	metals	
Carburizing						
Pack	Diffused carbon	815-1090 (1500-2000)	125 µm-1.5 mm (5-60 mils)	50-63[(a)]	Low-carbon steels, low-carbon alloy steel	Low equipment costs, difficult to control case depth accurately
Gas	Diffused carbon	815-980 (1500-1800)	75 µm-1.5 mm (3-60 mils)	50-63[(a)]	Low-carbon steels, low-carbon alloy steels	Good control of case depth, suitable for continuous operation, good gas controls required, can be dangerous
Liquid	Diffused carbon and possibly nitrogen	815-980 (1500-1800)	50 µm-1.5 mm (2-60 mils)	50-65[(a)]	Low-carbon steels, low-carbon alloy steels	Faster than pack and gas processes, can pose salt disposal problem, salt baths require frequent maintenance
Vacuum	Diffused carbon	815-1090 (1500-2000)	75 µm-1.5 mm (3-60 mils)	50-63[(a)]	Low-carbon steels, low-carbon alloy steels	Excellent process control, bright parts, faster than gas carburizing, high equipment costs
Nitriding						
Gas	Diffused nitrogen, nitrogen compounds	480-590 (900-1100)	125 µm-0.75 mm (5-30 mils)	50-70	Alloy steels, nitriding steels, stainless steels	Hardest cases from nitriding steels, quenching not required, low distortion, process is slow, is usually a batch process
Salt	Diffused nitrogen, nitrogen compounds	510-565 (950-1050)	2.5 µm-0.75 mm (0.1-30 mils)	50-70	Most ferrous metals including cast irons	Usually used for thin hard cases <25 µm (1 mil), no white layer, most are proprietary processes
Ion	Diffused nitrogen, nitrogen compounds	340-565 (650-1050)	75 µm-0.75 mm (3-30 mils)	50-70	Alloy steels, nitriding, stainless steels	Faster than gas nitriding no white layer, high equipment costs, close case control
Carbonitriding						
Gas	Diffused carbon and nitrogen	760-870 (1400-1600)	75 µm-0.75 mm (3-30 mils)	50-65[(a)]	Low-carbon steels, low-carbon alloy steels, stainless steel	Lower temperature than carburizing (less distortion), slightly harder case than carburizing gas control critical

Liquid (cyaniding)	Diffused carbon and nitrogen	760-870 (1400-1600)	2.5-125 µm (0.1-5 mils)	50-65[(a)]	Low-carbon steels	Good for thin cases on noncritical parts, batch process, salt disposal problems
Ferritic nitrocarburizing	Diffused carbon and nitrogen	565-675 (1050-1250)	2.5-25 µm (0.1-1 mil)	40-60[(a)]	Low-carbon steels	Low-distortion process for thin case on low-carbon steel, most processes are proprietary
Other						
Aluminizing (pack)	Diffused aluminum	870-980 (1600-1800)	25 µm-1 mm (1-40 mils)	<20	Low-carbon steels	Diffused coating used for oxidation resistance at elevated temperatures
Siliconizing by chemical vapor deposition	Diffused silicon	925-1040 (1700-1900)	25 µm-1 mm (1-40 mils)	30-50	Low-carbon steels	For corrosion and wear resistance, atmosphere control is critical
Chromizing by chemical vapor deposition	Diffused chromium	980-1090 (1800-2000)	25-50 µm (1-2 mils)	Low-carbon steel, <30; high-carbon steel, 50-60	High- and low-carbon steels	Chromized low-carbon steels yield a low-cost stainless steel, high-carbon steels develop a hard corrosion-resistant case
Titanium carbide	Diffused carbon and titanium, TiC compound	900-1010 (1650-1850)	2.5-12.5 µm (0.1-0.5 mil)	>70[(a)]	Alloy steels, tool steels	Produces a thin carbide (TiC) case for resistance to wear, high temperature may cause distortion
Boriding	Diffused boron, boron, compound	400-1150 (750-2100)	12.5-50 µm (0.5-2 mils)	40->70	Alloy steels, tool steels, cobalt and nickel alloys	Produces a hard compound layer, mostly applied over hardened tool steels, high process temperature can cause distortion

(a) Requires quench from austenitizing temperature.

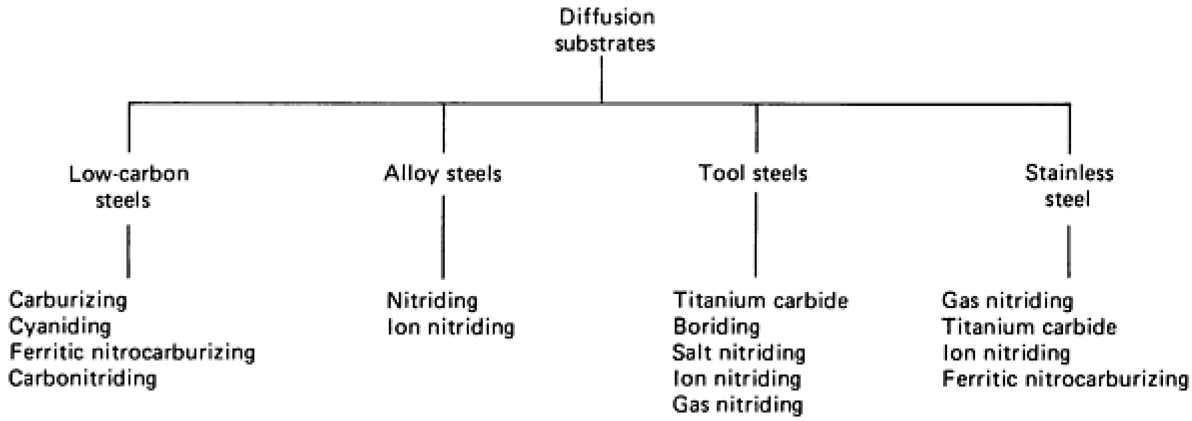

Fig. 1 Types of steels used for various diffusion processes

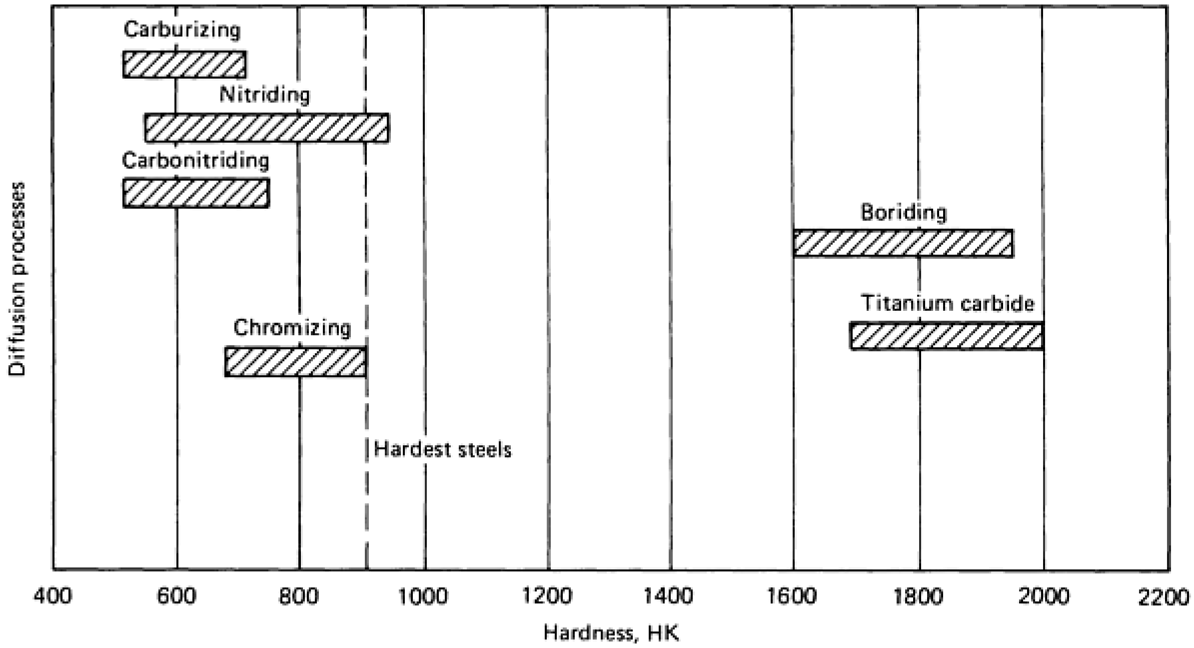

Fig. 2 Spectrum of hardness obtainable with selected diffusion processes of steel

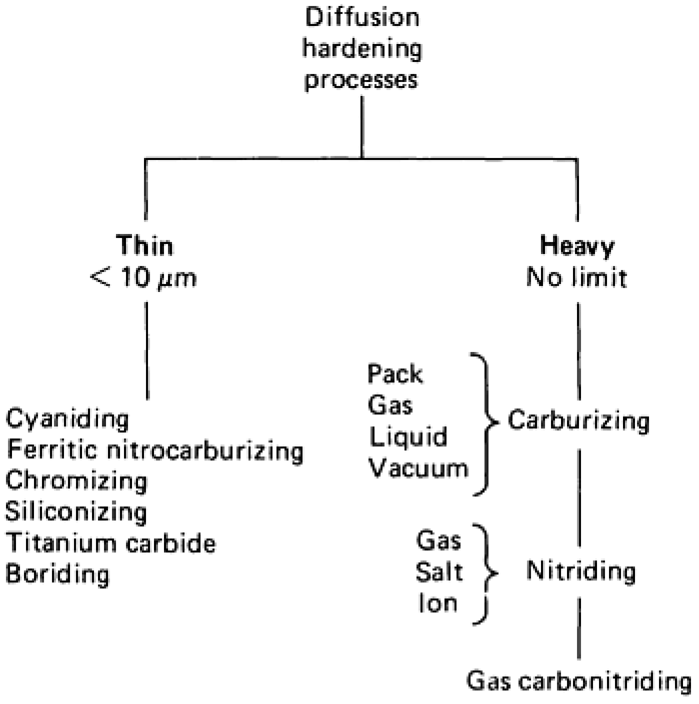

Fig. 3 Categorization of diffusion processes by typical case depth

It is also important to distinguish between total case depth and effective case depth. The effective case depth is typically about two-thirds to three-fourths the total case depth. The required effective depth must be specified so that the heat treater can process the parts for the correct time at the proper temperature.

Carburizing

Carburizing is the addition of carbon to the surface of low-carbon steels at temperatures (generally between 850 and 950 °C, or 1560 and 1740 °F) at which austenite, with its high solubility for carbon, is the stable crystal structure. Hardening is accomplished when the high-carbon surface layer is quenched to form martensite so that a high-carbon martensitic case with good wear and fatigue resistance is superimposed on a tough, low-carbon steel core. Of the various diffusion methods (Table 2), gas carburization is the most widely used, followed by gas nitriding and carbonitriding.

Case hardness of carburized steels is primarily a function of carbon content. When the carbon content of the steel exceeds about 0.50%, additional carbon has no effect on hardness but does enhance hardenability. Carbon in excess of 0.50% may not be dissolved, which would thus require temperatures high enough to ensure carbon-austenite solid solution.

Case depth of carburized steel is a function of carburizing time and the available carbon (carbon potential) at the surface. When prolonged carburizing times are used for deep case depths, a high carbon potential produces a high surface-carbon content, which may thus result in excessive retained austenite or free carbides. These two microstructural elements both have adverse effects on the distribution of residual stress in the case-hardened part. Consequently, a high carbon potential may be suitable for short carburizing times but not for prolonged carburizing. Selection of carbon potential also depends on the carburizing response of a particular steel. Further information on the characteristics of carburized steels is covered in the article "Microstructures and Properties of Carburized Steels" in this Volume.

Carburizing steels for case hardening usually have base-carbon contents of about 0.2%, with the carbon content of the carburized layer generally being controlled at between 0.8 and 1% C (Ref 2). However, surface carbon is often limited to 0.9% (Ref 3) because too high a carbon content can result in retained austenite and brittle martensite (due to the formation of proeutectoid carbides on the grain boundaries).

Most steels that are carburized are killed steels (deoxidized by the addition of aluminum), which maintain fine grain sizes to temperatures of about 1040 °C (1900 °F). Steels made to coarse grain practices can be carburized if a double quench

provides grain refinement. Double quenching usually consists of a direct quench and then a requench from a lower temperature. In most instances, however, carbonitriding of coarse-grained steels is more appropriate because of the lower temperatures and shorter cycle times.

Many alloy steels for case hardening are now specified on the basis of core hardenability. Although the same considerations generally apply as apply to the selection of uncarburized grades, there are some peculiarities in carburizing applications.

First, in a case-hardened steel, the hardenability of both case and core must be considered. Because of the difference in carbon content, case and core have quite different hardenabilities, and this difference is much greater for some steels than for others. Moreover, the two regions have different in-service functions to perform. Until the introduction of lean alloy steels such as the 86*xx* series, with and without boron, there was little need to be concerned about case hardenability because the alloy content combined with the high carbon content always provided adequate hardenability. This is still generally true when the steels are direct quenched from carburizing, so that the carbon and alloying elements are in solution in the case austenite. In parts that are reheated for hardening and in heavy-sectioned parts, however, both case and core hardenability requirements should be carefully evaluated.

The hardenability of the steels as purchased is the core hardenability. Because these low-carbon steels, as a class, are shallow hardening and because of the wide variation in the section sizes of case-hardened parts, the hardenability of the steel must be related to some critical section of the part, for example, the pitch line or the root of a gear tooth. This is best accomplished by making a part of a steel of known hardenability, heat treating it, and then, by means of equivalence of hardness, relating the hardenability in the critical section or sections to the proper positions on the endquench hardenability specimens, both base carbon and carburized.

Finally, the relationship between the thermal gradient and the carbon (hardenability) gradient during quenching of a carburized part can make a measurable difference in the case depth as measured by hardness. That is, an increase in base hardenability can produce a higher proportion of martensite for a given carbon level, yielding an increased measured case depth. Therefore, a shallower carbon profile and shorter carburizing time could be used to attain the desired result in a properly chosen steel.

Core Hardness. A common mistake is to specify too narrow a range of core hardness. When the final quench is from a temperature high enough to allow the development of full core hardness, the hardness variation at any location will be that of the hardenability band of the steel at the corresponding position on the end-quenched hardenability specimen. One way to alter this state of affairs is to use higher-alloy steels. In the commonly used alloy steels having a maximum of 2% total alloy content, the range for the core hardness of sections such as gear teeth is 12 to 15 points HRC. Higher-alloy steels exhibit a narrower range; for example, in 4815 the range is 10 points, while in 3310 it is 8 points. Such steels are justified only for severe service or special applications.

In standard steels purchased to chemical composition requirements rather than to hardenability, the range can be 20 or more HRC points; for example, 8620 may vary from 20 to 45 HRC at the $\frac{4}{16}$ in. position. The 25 point range emphasizes the advantage of purchasing to hardenability specifications to avoid the intolerable variation possible within the ranges for standard-chemistry steels. Another way to control core hardness within narrow limits without resorting to the use of high-alloy steels is to use a final quench from a lower temperature so that full hardness in the case will be developed without the disadvantage of excessive core hardness.

Gears and Low-Distortion Applications. Gears are almost always oil quenched because distortion must be held to the lowest possible level. Therefore, alloy steels are usually selected, with much debate about which particular alloy. The lower-alloy steels such as 4023, 5120, 4118, 8620, and 4620, with a carbon range between 0.15 and 0.25%, are widely used and generally satisfactory. Usually, the first choice is one of the last two steels mentioned, either of which should be safe for all ordinary applications. The final choice, based on service experience or dynamometer testing, should be the least expensive steel that will do the job. To this list should be added 1524, which, although not classified commercially as an alloy steel, has sufficient manganese to make it oil hardening up to an end-quench correlation point of $\frac{3}{16}$.

For heavy-duty applications, higher-alloy grades such as 4320, 4817, and 9310 are justifiable if based on actual performance tests. The life testing of gears in the same mountings used in service to prove both the design and the steel selection is particularly important.

The carbonitriding process extends the use of carbon steels such as 1016, 1018, 1019, and 1022 into the field of light-duty gearing by permitting the use of oil quenching in teeth of eight diametral pitch and finer. Steels selected for such applications should be specified silicon killed fine grained in order to ensure uniform case hardness and dimensional control. The core of such gears will, of course, have the properties of low-carbon steel, oil quenched. In the thin sections of fine-pitch teeth, this may be up to 25 HRC. The carbonitriding process is usually limited, for economic reasons, to maximum case depths of approximately 0.6 mm (0.025 in.).

Nongear Applications. In other applications, when distortion is not a major factor, the carbon steels described above, water quenched, can be used up to a 50 mm (2 in.) diameter. In larger sizes, low-alloy steels, water quenched, such as 5120, 4023, and 6120, can be used, but possible distortion and quench cracking must be avoided.

Carburizing Methods. While the basic principle of carburizing has remained unchanged since carburizing was first employed, the method used to introduce the carbon into the steel has been a matter of continuous evolution. In its earliest application, parts were simply placed in a suitable container and covered with a thick layer of carbon powder (pack carburizing). Although effective in introducing carbon, this method was exceedingly slow, and as the demand for greater production grew, a new process using a gaseous atmosphere was developed. In gas carburizing, the parts are surrounded by a carbon-bearing atmosphere that can be continuously replenished so that a high carbon potential can be maintained. While the rate of carburizing is substantially increased in the gaseous atmosphere, the method requires the use of a multicomponent atmosphere whose composition must be very closely controlled to avoid deleterious side effects, for example, surface and grain-boundary oxides. In addition, a separate piece of equipment is required to generate the atmosphere and control its composition. Despite this increased complexity, gas carburizing has become the most effective and widely used method for carburizing steel parts in large quantities.

In efforts required to simplify the atmosphere, carburizing in an oxygen-free environment at very low pressure (vacuum carburizing) has been explored and developed into a viable and important alternative. Although the furnace enclosure in some respects becomes more complex, the atmosphere is greatly simplified. A single-component atmosphere consisting solely of a simple gaseous hydrocarbon, for example, methane, may be used. Furthermore, because the parts are heated in an oxygen-free environment, the carburizing temperature may be increased substantially without the risk of surface or grain-boundary oxidation. The higher temperature permitted increases not only the solid solubility of carbon in the austenite but also its rate of diffusion, so that the time required to achieve the case depth desired is reduced.

Although vacuum carburizing overcomes some of the complexities of gas carburizing, it introduces a serious new problem that must be addressed. Because vacuum carburizing is conducted at very low pressures, and the rate of flow of the carburizing gas into the furnace is very low, the carbon potential of the gas in deep recesses and blind holes is quickly depleted. Unless this gas is replenished, a great nonuniformity in case depth over the surface of the part is likely to occur. If, in an effort to overcome this problem, the gas pressure is increased significantly, another problem arises, that of free-carbon formation, or sooting. Thus, in order to obtain cases of reasonably uniform depth over a part of complex shape, the gas pressure must be increased periodically to replenish the depleted atmosphere in recesses and then reduced again to the operating pressure. Clearly, a delicate balance exists in vacuum carburizing: The process conditions must be adjusted to obtain the best compromise between case uniformity, risk of sooting, and carburizing rate. A method that overcomes both of these major problems, yet retains the desirable features of a simple atmosphere and a higher permissible operating temperature is plasma or ion carburizing.

To summarize, carburizing methods include:

- Gas carburizing
- Vacuum carburizing
- Plasma carburizing
- Salt bath carburizing
- Pack carburizing

These methods introduce carbon by the use of gas (atmospheric-gas, plasma, and vacuum carburizing), liquids (salt bath carburizing), or solid compounds (pack carburizing). All of these methods have limitations and advantages, but gas carburizing is used most often for large-scale production because it can be accurately controlled and involves a minimum of special handling.

Vacuum carburizing and plasma carburizing have found applications because of the absence of oxygen in the furnace atmosphere. Salt bath and pack carburizing are still done occasionally, but have little commercial importance today.

In a survey of 800 commercial shops in the United States and Canada (Ref 4), 70% offered carburizing services, of which:

- 48% offered gas atmosphere carburizing
- 19% offered pack carburizing
- 12% offered salt carburizing
- 5% offered carburizing in fluid beds
- 2% offered vacuum carburizing
- 1% offered ion carburizing

Each of these methods is described in separate articles in this Volume.

Process characteristics of the above-mentioned carburizing methods fall into two general groups:

- Conventional methods, which introduce carbon by gas atmospheres, salt baths, or charcoal packs
- Plasma methods, which impinge positive carbon ions on the surface of a steel part (the cathode)

The main difference between conventional and glow-discharge (or plasma) methods is the reduced carburizing times achieved in plasma-assisted methods. The quickly attained surface saturation also results in faster diffusion kinetics. Furthermore, plasma carburizing produces very uniform case depths, even in parts with irregular surfaces (Ref 5, 6). This uniformity is caused by the glow-discharge plasma, which closely envelops the specimen surface, provided that recesses or holes are not too small (Ref 6).

With the conventional methods, carburization always takes place by means of a gaseous phase of carbon monoxide; however, each method also involves different reaction and surface kinetics, producing different case-hardening results. In general, with conventional methods, carbon monoxide breaks down at the steel surface:

$$2CO \rightleftharpoons CO_2 + C \qquad \textbf{(Eq 2)}$$

The liberated carbon is readily dissolved by the austenite phase and diffuses into the body of the steel. For some process methods (gas and pack carburizing), the carbon dioxide produced may react with the carbon atmosphere or pack charcoal to produce new carbon monoxide by the reverse reaction of Eq 2. Because the reaction can proceed in both directions, an equilibrium relationship exists between the constituents (Fig. 4). If the temperature is increased at constant pressure, more carbon monoxide is produced (Fig. 4). In turn, the equilibrium percentages of carbon monoxide and carbon dioxide influence the carbon concentrations in steel (Fig. 5). Carburizing is most frequently performed between 850 and 950 °C (1550 and 1750 °F), but sometimes higher temperatures are used to reduce cycle times and/or produce deeper depths of the high-carbon surface layer.

Quantitative algorithms for estimating case depth from carburization often focus on making the proportional relation of Eq 1 explicit (Case depth = $K\sqrt{time}$) for gas carburization only (Ref 2, 3). Even with gas carburization, however, heat treaters have long recognized that considering only the kinetics of carbon diffusion gives an incomplete picture of carburizing. A comprehensive model of gas carburization must include algorithms that describe:

- Carbon diffusion
- Kinetics of the surface reaction
- Kinetics of the reaction between endogas and enriching gas
- Purging (for batch processes)
- The atmosphere control system

Reference 9 discusses possible modeling of each of these factors for gas carburization. The effects of process variables are also covered in the article "Gas Carburizing" in this Volume.

Nitriding

Nitriding is a surface-hardening heat treatment that introduces nitrogen into the surface of steel at a temperature range (500 to 550 °C, or 930 to 1020 °F), while it is in the ferritic condition. Thus, nitriding is similar to carburizing in that surface composition is altered but different in that nitrogen is added into ferrite instead of austenite. Because nitriding does not involve heating into the austenite phase field and a subsequent quench to form martensite, nitriding can be accomplished with a minimum of distortion and with excellent dimensional control.

The mechanism of nitriding is generally known, but the specific reactions that occur in different steels and with different nitriding media are not always known. Nitrogen has partial solubility in iron. It can form a solid solution with ferrite at nitrogen contents up to about 6%. At about 6% N, a compound called gamma prime (γ'), with a composition of Fe_4N, is formed. At nitrogen contents greater than 8%, the equilibrium reaction product is ε compound, Fe_3N. Nitrided cases are stratified. The outermost surface can be all γ' and, if this is the case, it is referred to as the white layer (it etches white in metallographic preparation). Such a surface layer is undesirable: It is very hard but is so brittle that it may spall in use. Usually it is removed; special nitriding processes are used to reduce this layer or make it less brittle. The ϵ zone of the case is hardened by the formation of the Fe_3N compound, and below this layer there is some solid solution strengthening from the nitrogen in solid solution (Fig. 6).

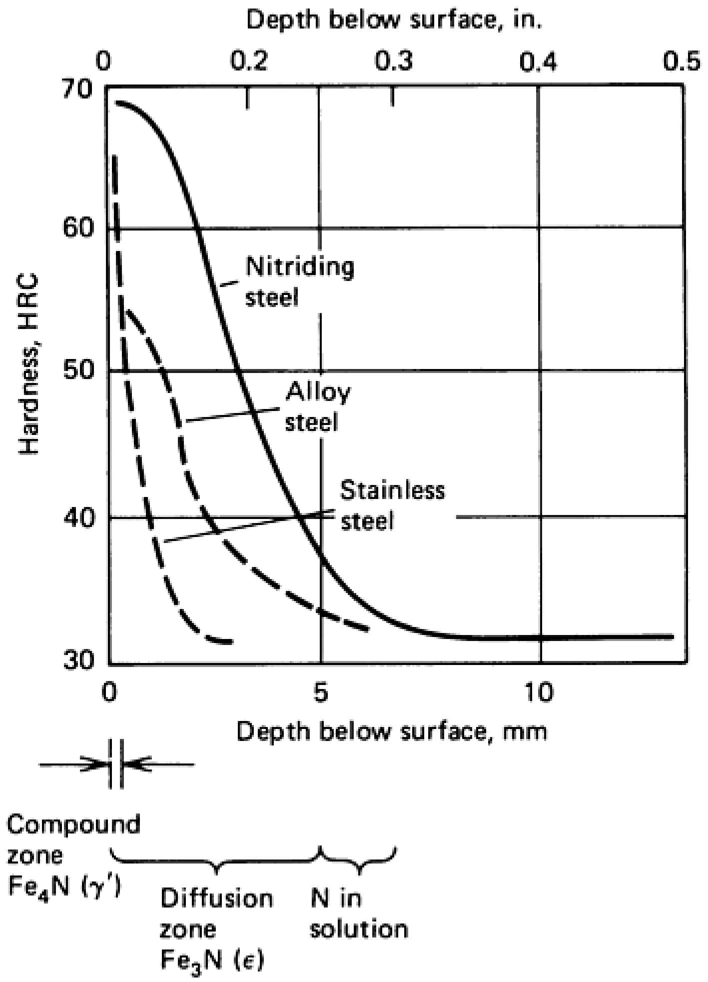

Fig. 6 Nitride case profiles for various steels. Source: Ref 1

Nitrided steels are generally medium-carbon (quenched and tempered) steels that contain strong nitride-forming elements such as aluminum, chromium, vanadium, and molybdenum. The most significant hardening is achieved with a class of alloy steels (nitralloy type) that contain about 1% Al (Fig. 6). When these steels are nitrided, the aluminum forms AIN particles, which strain the ferrite lattice and create strengthening dislocations. Titanium and chromium are also used to enhance case hardness (Fig. 7a), although case depth decreases as alloy content increases (Fig. 7b). The microstructure also influences nitridability because ferrite favors the diffusion of nitrogen and because a low carbide content favors both diffusion and case hardness. Usually alloy steels in the heat-treated (quenched and tempered) state are used for nitriding (Ref 7).

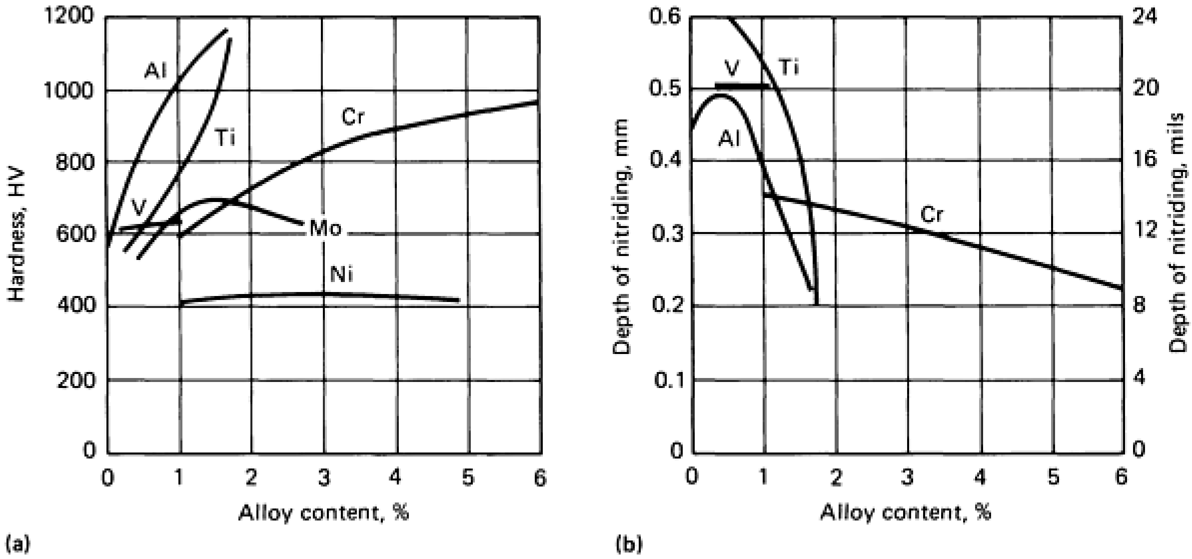

Fig. 7 Influence of alloying elements on (a) hardness after nitriding (base alloy, 0.35% C, 0.30% Si, 0.70% Mn) and (b) depth of nitriding measured at 400 HV (nitriding for 8 h at 520 °C, or 970 °F). Source: Ref 7

Process methods for nitriding include gas (box furnace or fluidized bed), liquid (salt bath), and plasma (ion) nitriding. In a survey of 800 commercial shops in the United States and Canada, 30% offered nitriding services, of which (Ref 4):

- 21% offered gas nitriding
- 7% offered salt bath nitriding
- 6% offered fluidized-bed nitriding
- 5% offered plasma nitriding

The advantages and disadvantages of these techniques are similar to those of carburizing. However, times for gas nitriding can be quite long, that is, from 10 to 130 h depending on the application, and the case depths are relatively shallow, usually less than 0.5 mm (0.020 in.). Plasma nitriding allows faster nitriding times, and the quickly attained surface saturation of the plasma process results in faster diffusion. Plasma nitriding can also clean the surface by sputtering.

Other Diffusion Methods

Surface hardening with carbon and nitrogen offers processing temperatures between those of carburizing and nitriding. In general, there are three techniques that use carbon and nitrogen for surface hardening:

- Carbonitriding
- Austenitic nitrocarburizing
- Ferritic nitrocarburizing

The latter two methods rely on the formation of a thin white layer of ε carbonitride while the first method, carbonitriding, uses nitrogen as a hardening agent in carburized austenite. Although all three methods have higher processing temperatures than does nitriding (Table 2), they have the advantage of being suitable for plain carbon steels.

Carbonitriding is a surface-hardening heat treatment that introduces carbon and nitrogen in the austenite of steel. This treatment is similar to carburizing in that the austenite composition is changed and high surface hardness is produced by quenching to form martensite. However, because nitrogen enhances hardenability, carbonitriding makes possible the use of low-carbon steel to achieve surface hardness equivalent to that of high-alloy carburized steel without the need for

drastic quenching, resulting in less distortion and reducing the danger of cracking the work. To some extent, hardening is also dependent on nitride formation.

Although the process of carbonitriding can be performed with gas atmospheres or salt baths, the term carbonitriding often refers solely to treatment in a gas atmosphere (see the article "Carbonitriding" in this Volume). Basically, carbonitriding in a salt bath is the same as cyanide bath hardening. In both processes, nitrogen enhances hardenability and case hardness but inhibits the diffusion of carbon.

Like carbon, nitrogen is an austenite stabilizer. Therefore, considerable austenite may be retained after quenching a carburized part. If the retained austenite content is so high that it reduces hardness and wear resistance, it may be controlled by reducing the ammonia content of the carbonitriding gas either throughout the cycle or during the latter portion of the cycle. Another consequence of excessive nitrogen content in the carbonitrided case is porosity (Ref 10).

Austenitic Nitrocarburizing. Although the lower carbonitriding temperatures (700 to 760 °C, or 1300 to 1400 °F) are not used because of the explosion hazard and the brittle structures formed, a lower-temperature variant of carbonitriding has been developed. This technique, which is sometimes referred to as austenitic nitrocarburizing, is optimally applied in the temperature range of 675 to 775 °C (1250 to 1425 °F). Unlike carbonitriding, the hardening effect in nitrocarburizing relies primarily on the formation of ε carbonitrides. This may eliminate the need for quenching.

Ferritic nitrocarburizing involves the diffusion of carbon and nitrogen into the ferrite phase and the formation of a thin white layer of ε carbonitrides. The diffusion of nitrogen into the substrate is necessary for fatigue resistance. The case depths are thin (Table 2), but the ε carbonitrides formed in nitrocarburizing have a reduced tendency to spall, compared to the white layer formed during conventional nitriding. Further information on this process is given in the article "Gaseous and Plasma Nitrocarburizing" in this Volume.

Specialized Diffusion Methods. In addition to carburizing, nitriding, and carbonitriding, there are a number of specialized diffusion methods that induce chemical modification with elements such as aluminum, boron, chromium, silicon, titanium, and vanadium. Of these, boron and titanium treatments offer high levels of hardness (Fig. 2), while aluminum, chromium, and silicon treatments are primarily used for corrosion resistance. Another specialized diffusion method is the Toyota diffusion process (see the article "Thermoreactive Deposition/Diffusion Process" in this Volume). Specialized methods such as chromizing and vanadizing are discussed in the Selected References section at the end of this article.

Boriding involves the diffusion of boron into metal surfaces for the enhancement of hardness and wear resistance. Boriding is most often applied to tool steels that have already been hardened by heat treatment. Boriding techniques include metallizing, chemical vapor deposition, and pack cementation. For additional information, see the article "Boriding (Boronizing)" in this Volume.

Titanium Carbide. With process temperatures in the range of 900 to 1010 °C (1650 to 1850 °F), titanium and carbon will diffuse to form a diffused case of titanium carbide during chemical vapor deposition. This treatment is most commonly applied to tool steels and hardenable stainless steels. Because the treatment is performed above the austenitizing temperatures of these steels, the core must be hardened by quenching.

Selective Surface Hardening

The selective hardening of steel surfaces is typically achieved by localized heating and quenching, without any chemical modification of the surface. However, selective surface hardening can also include chemical modification by such techniques as ion implantation and selective carburization.

The more common methods currently used to harden the surface of steels include flame and induction hardening. However, each of these methods has shortcomings that can prevent its use in some applications. For example, the disadvantages of flame hardening include the possibility of part distortion, while induction hardening requires very small part-to-coil distances (especially when using high frequencies), which must be precisely maintained.

Flame hardening consists of austenitizing the surface of a steel by heating with an oxyacetylene or oxyhydrogen torch and immediately quenching with water. The result is a hard surface layer of martensite over a softer interior core with a ferrite-pearlite structure. There is no change in composition, and therefore the flame-hardened steel must have adequate carbon content for the desired surface hardness. The rate of heating and the conduction of heat into the interior appear to be more important in establishing case depth than the use of a steel of high hardenability.

Flame-heating equipment may be a single torch with a specially designed head or an elaborate apparatus that automatically indexes, heats, and quenches parts. Large parts such as gears and machine tool ways, with sizes or shapes that would make furnace heat treatment impractical, are easily flame hardened. With improvements in gas-mixing equipment, infrared temperature measurement and control, and burner design, flame hardening has been accepted as a reliable heat-treating process that is adaptable to general or localized surface hardening for small and medium-to-high production requirements. Further information on this process is given in the article "Flame Hardening" in this Volume.

Induction heating is an extremely versatile heating method that can perform uniform surface hardening, localized surface hardening, through hardening, and tempering of hardened pieces. Heating is accomplished by placing a steel part in the magnetic field generated by high-frequency alternating current passing through an inductor, usually a water-cooled copper coil. The depth of heating produced by induction is related to the frequency of the alternating current: The higher the frequency, the thinner or more shallow the heating. Therefore, deeper case depths and even through hardening are produced by using lower frequencies. The electrical considerations involve the phenomena of hysteresis and eddy currents. Because secondary and radiant heat are eliminated, the process is suited for production line areas. Further information on this technique is given in the article "Induction Heat Treating of Steel" in this Volume.

Laser surface heat treatment is widely used to harden localized areas of steel and cast iron machine components. The heat generated by the absorption of the laser light is controlled to prevent melting and is therefore used in the selective austenitization of local surface regions, which transform to martensite as a result of rapid cooling (self-quenching) by the conduction of heat into the bulk of the workpiece. This process is sometimes referred to as laser transformation hardening to differentiate it from laser surface melting phenomena (Fig. 8). There is no chemistry change produced by laser transformation hardening, and the process, like induction and flame hardening, provides an effective technique to harden ferrous materials selectively. Other methods of laser surface treatments include surface melting and surface alloying. Laser surface melting results in a refinement of the structure due to the rapid quenching from the melt. In surface alloying, alloying elements are added to the melt pool to change the composition of the surface. The novel structures produced by laser surface melting and alloying can exhibit improved electrochemical behavior.

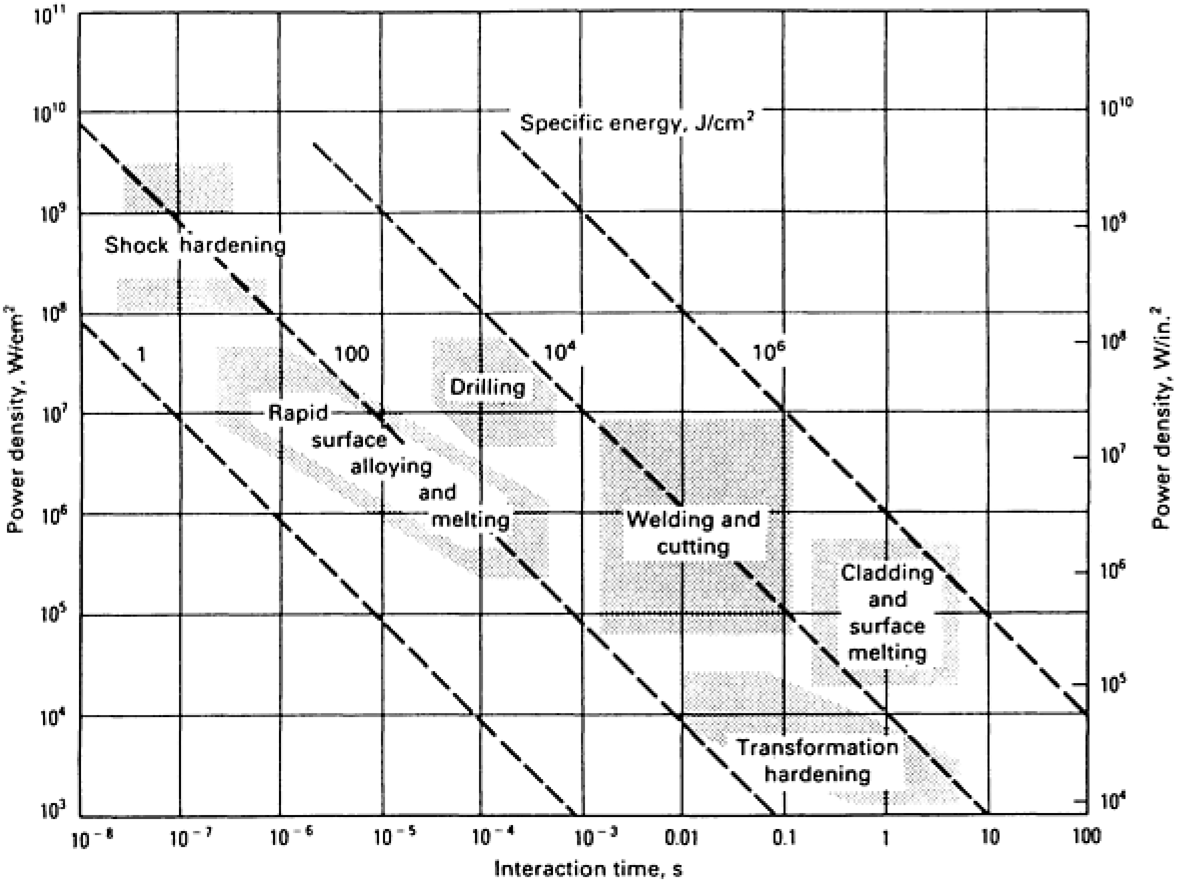

Fig. 8 Interaction times and power densities necessary for various laser surface modification processes

Laser transformation hardening produces thin surface zones that are heated and cooled very rapidly, resulting in very fine martensitic microstructures, even in steels with relatively low hardenability. High hardness and good wear resistance with less distortion result from this process. The laser method differs from induction and flame heating in that the laser can be located at some distance from the workpieces. Also, the laser light is reflected by mirrors to the focusing lens, which control the width of the heated spot or track.

Molian (Reference 11) has tabulated the characteristics of 50 applications of laser transformation hardening. The materials hardened include plain carbon steels (1040, 1050, 1070), alloy steels (4340, 52100), tool steels, and cast irons (gray, malleable, ductile). Because the absorption of laser radiation in cold metals is low, laser surface hardening often requires energy-absorbing coatings on surfaces. Reference 11 lists some energy-absorbing coatings.

Typical case depths for steels are 250 to 750 μm (0.01 to 0.03 in.) and for cast irons are about 1000 μm (0.04 in.). The flexibility of laser delivery systems and the low distortion and high surface hardness obtained have made lasers very effective in the selective hardening of wear and fatigue-prone areas on irregularly shaped machine components such as camshafts and crankshafts. Further information is contained in the article "Laser Surface Hardening" in this Volume.

Electron beam (EB) hardening, like laser treatment, is used to harden the surfaces of steels. The EB heat-treating process uses a concentrated beam of high-velocity electrons as an energy source to heat selected surface areas of ferrous parts. Electrons are accelerated and are formed into a directed beam by an electron beam gun. After exiting the gun, the beam passes through a focus coil, which precisely controls beam density levels (spot size) at the workpiece surface and then passes through a deflection coil. To produce an electron beam, a high vacuum of 10^{-5} torr (1.3×10^{-3} Pa) is needed in the region where the electrons are emitted and accelerated. This vacuum environment protects the emitter from oxidizing and avoids scattering of the electrons while they are still traveling at a relatively low velocity.

Like laser beam hardening, the EB process eliminates the need for quenchants but requires a sufficient workpiece mass to permit self-quenching. A mass of up to eight times that of the volume to be EB hardened is required around and beneath

the heated surfaces. Electron beam hardening does not require energy-absorbing coatings, as does laser beam hardening. Processing considerations and property changes associated with EB hardening are covered in Ref 12 and in the article "Electron Beam Surface Hardening" in this Volume.

Ion implantation is a surface modification process in which ions with very high energy are driven into a substrate. Ions of almost any atom species can be implanted, but nitrogen is widely used to improve corrosion resistance and the tribological properties of steels and other alloys. Although the nitrogen content of alloy surfaces is increased by both nitrogen ion implantation and plasma nitriding, major differences exist between the two processes and the surface modifications they create. The major difference is that ion implantation can be performed at room temperature.

Ion implantation machines accelerate ions, generated by specially designed sources, at very high energies (from 10 to 500 keV). In contrast, the energy of ions and atoms in plasma nitriding is much lower (<1 keV). Ion implantation is carried out with the substrate at about room temperature, thereby minimizing the diffusion-controlled formation of precipitates and coarsening of the subsurface microstructure. Because the temperature of application is low and the process is carried out in accelerators with very good vacuums ($\geq 10^{-5}$ torr, or 1.3×10^{-3} Pa), clean surfaces are ensured and undesirable surface chemical reactions such as oxidation are lessened. Ion implantation is a line-of-sight process; that is, only relatively small areas directly exposed to the ion beam are implanted. For the coverage of areas larger than the beam, either the specimen must be translated or the ion beam must be rastered over the specimen surface.

Because of the virtual absence of diffusion-controlled case formation during ion implantation, case depths are shallow (generally <0.25 μm). Very high strengths or hardnesses of the nitrogen-implanted surface layers compensate for the shallow case depths of ion implantation. Ion implantation is a complex, nonequilibrium process that creates significant lattice damage in the form of vacancies and interstitial point defects. Concentrations of implanted species much higher than equilibrium solubility limits may be introduced. In fact, the incorporation of high densities of atoms of significantly different size than those of the substrate lattice may produce amorphous structures or metastable phases (Ref 13).

The properties of ion-implanted surfaces and shallow case depths make ion implantation suitable for very special applications. Because the surface of the part itself is modified, the adhesion problems sometimes encountered with coated layers of high hardness do not arise. Also, because ion implantation is usually accomplished with very little heating, dimensional stability is excellent. Examples of applications of ion implantation include the surface hardening of razor blades (Ref 5) and knives (Ref 13), a variety of tool steel applications (Ref 14), and the implantation of 52100 and 440C bearings with titanium and/or nitrogen to improve rolling-contact fatigue resistance (Ref 15, 16, 17). In the latter applications, titanium was found to reduce the coefficient of friction, and nitrogen was found to raise hardness by intermetallic compound formation. Additional information on ion implantation is given in Ref 18 and Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Selective Carburizing. If it is necessary to prevent carburization on certain areas of a part, stopoff compounds or copper plating may be used. Preventing carburization requires attention to cleanliness and handling to achieve the desired stopoff. Copper plate thicknesses of a minimum of 0.03 mm (0.001 in.) are required. Stopoff compounds are proprietary, and instructions should be closely followed because it is difficult to achieve 100% stopoff. Carburization prevention may be necessary on areas to be machined further after heat treating or to prevent a thin area from being carburized all the way through its section, thereby becoming brittle (Ref 3).

Surface hardening with arc lamps is used in applications that involve surface remelting or surface hardening by solid-phase recrystallization. Examples include the surface remelting of cast iron and the large-area remelting of titanium in the presence of nitrogen or methane to produce titanium carbides in the surface layer. In the surface remelting of cast irons, lasers are also used (see the article "Heat Treating of Ductile Irons" in this Volume). Another area in which arc lamps are finding application is in the selective hardening of the edges on agricultural sweeps and tilling equipment blades.

Surface treating using white light from a high-power arc lamp offers several advantages over traditional methods and the beam techniques. For example, arc lamp treatment can achieve higher surface radiation intensities than can flame heating, making the procedure faster and less likely to cause distortion. Compared with induction hardening, arc lamp treatment allows much larger distances between the part and heat source, providing more flexibility in treating irregularly shaped surfaces. Unlike the EB treatment, this method does not require the use of a vacuum chamber, and an arc lamp can deliver greater power to the part surface than can a laser beam.

However, with the arc lamp method, significant power loss is encountered if arc radiation is concentrated onto surface areas smaller than the arc itself. Therefore, the illuminated spot on the sample surface should always be larger than the arc. This necessitates extremely high arc power to achieve the surface intensities needed for thermal treatment. Such high power is achieved in a very small space with specially designed arc lamps.

Process Selection

The benefits of the most common methods of surface hardening are compared in Table 3. Flame and induction hardening are generally limited to certain families of steels such as medium-carbon steels, medium-carbon alloy steels, some cast irons, and the lower-alloy tool steels. There is no size limit to parts that can be flame hardened because only the portion of the part to be hardened need be heated. With induction hardening, the part or area to be hardened usually must fit within an inductor coil. Flame hardening is generally used for very heavy cases (in the range of about ~1.2 to 6 mm, or 0.6 to 0.25 in.); thin case depths are difficult to control because of the nature of the heating process. Diffusion methods are compared in Table 2.

Table 3 Relative benefits of five common surface-hardening processes

Process	Benefits
Carburizing	Hard, highly wear-resistant surface (medium case depths); excellent capacity for contact load; good bending fatigue strength; good resistance to seizure; excellent freedom from quench cracking; low-to-medium-cost steels required; high capital investment required
Carbonitriding	Hard, highly wear-resistant surface (shallow case depths); fair capacity for contact load; good bending fatigue strength; good resistance to seizure; good dimensional control possible; excellent freedom from quench cracking; low-

	cost steels usually satisfactory; medium capital investment required
Nitriding	Hard, highly wear-resistant surface (shallow case depths); fair capacity for contact load; good bending fatigue strength; excellent resistance to seizure; excellent dimensional control possible; good freedom from quench cracking (during pretreatment); medium-to-high-cost steels required; medium capital investment required
Induction hardening	Hard, highly wear-resistant surface (deep case depths); good capacity for contact load; good bending fatigue strength; fair resistance to seizure; fair dimensional control possible; fair freedom from quench cracking; low-cost steels usually satisfactory; medium capital investment required
Flame hardening	Hard, highly wear-resistant surface (deep case depths); good capacity for contact load; good bending fatigue strength; fair resistance to seizure; fair dimensional control possible; fair freedom from quench cracking; low-cost steels usually satisfactory; low capital investment required

Transformation hardening introduces compressive residual stresses, which are beneficial for fatigue strength. In selective hardening, however, some residual tensile stress will exist in the region where the hardened zone meets the unhardened zone. Consequently, selective hardening by methods such as flame or induction heating should be applied away from geometric stress concentrations. Both nitriding and carburizing provide good resistance to surface fatigue and are widely used for gears and cams. In terms of bending fatigue resistance, the ideal case depth appears to be reached where the failure initiation point is transferred from the core to the surface (Ref 19). However, specification of required case depth is a complex subject, which is briefly discussed in Ref 19 for carburized steels.

Flame Hardening of Steels

Revised by Thomas Ruglic, Hinderliter Heat Treating, Inc.

Introduction

FLAME HARDENING is a heat-treating process in which a thin surface shell of a steel part is heated rapidly to a temperature above the critical point of the steel. After the grain structure of the shell has become austenitic (austenitized), the part is quickly quenched, transforming the austenite to martensite while leaving the core of the part in its original state. In contrast, slow cooling causes transformation, as the temperature passes through the corresponding ranges, to pearlite, bainite, and martensite, with the final structure being a combination of the three. The result is a relatively soft and ductile steel. To achieve hardness, therefore, the steel must be cooled rapidly so that it bypasses the first two transformation phases and transforms directly from austenite to martensite.

Flame hardening employs direct impingement of a high-temperature flame or high-velocity combustion product gases. The part is then cooled at a rate that will produce the desired levels of hardness and other properties. The high-temperature flame is obtained by combustion of a mixture of fuel gas with oxygen or air; flame heads are used for burning the mixture. Depths of hardening from about 0.8 to 6.4 mm ($\frac{1}{32}$ to $\frac{1}{4}$ in.) or more can be obtained, depending on the fuels used, the design of the flame head, the duration of heating, the hardenability of the work material, and the quenching medium and method of quenching used. The process can be used for the through hardening of work 75 mm (3 in.) or less in cross section, depending on the hardenability of the steel.

Hardening by flame differs from true case hardening because the hardenability necessary to attain high levels of hardness is already contained in the steel, and hardening is obtained by localized heating. Although flame hardening is mainly used to develop high levels of hardness for wear resistance, the process also improves bending and torsional strength and fatigue life. One of the major advantages of flame hardening is the ability to satisfy stringent engineering requirements with carbon steels.

Scope and Application

Flame hardening is applied to a wide diversity of workpieces and ferrous materials for one or more reasons. This process is used because:

- Parts are so large that conventional furnace heating and quenching are impracticable or uneconomical. Typical examples include large gears, machineways, dies, and rolls
- Only a small segment, section, or area of a part requires heat treatment, or because heat treating all over would be detrimental to the function of the part. Typical examples include the ends of valve stems and pushrods and the wearing surfaces of cams and levers
- The dimensional accuracy of a part is impracticable or difficult to attain or control by furnace heating and quenching. A typical example is a large gear of complex design for which flame hardening of the teeth would not disturb the dimensions of the gear
- The use of flame hardening permits a part to be made from a less costly material, thereby effecting an overall cost saving in comparison with other technically acceptable methods. The process gives inexpensive steels the wear properties of alloyed steels, and parts can be hardened without scaling or decarburization, thereby eliminating costly cleaning operations. For example, a large steel part might be made at a lower cost if produced from a flame-hardened plain carbon steel rather than from a carburized low-carbon alloy steel

For a detailed discussion of materials suitable for flame hardening and for a comparison of flame hardening with other methods used to attain similar results, see the sections "Selection of Process" and "Selection of Material" near the end of this article.

Methods of Flame Hardening

The versatility of flame-hardening equipment and the wide range of heating conditions obtainable with gas burners often permit flame hardening to be done by a variety of methods, of which the principal ones are:

- Spot, or stationary
- Progressive
- Spinning
- Combination progressive-spinning

The selection of the appropriate method depends on the shape, size, and composition of the workpiece; the area to be hardened; the depth of case required; and the number of pieces to be hardened. In many instances, more than one method will provide the desired result; the choice will then depend on comparative costs.

The spot (stationary) method, shown in Fig. 1(a), consists of locally heating selected areas with a suitable flame head and subsequently quenching. The heating head may be of either single-orifice or multiple-orifice design, depending on the extent of the area to be hardened. The heat input must be balanced to obtain a uniform temperature over the entire selected area. After being heated, the parts are usually immersion quenched; however, in some mechanized operations, a spray quench may be used.

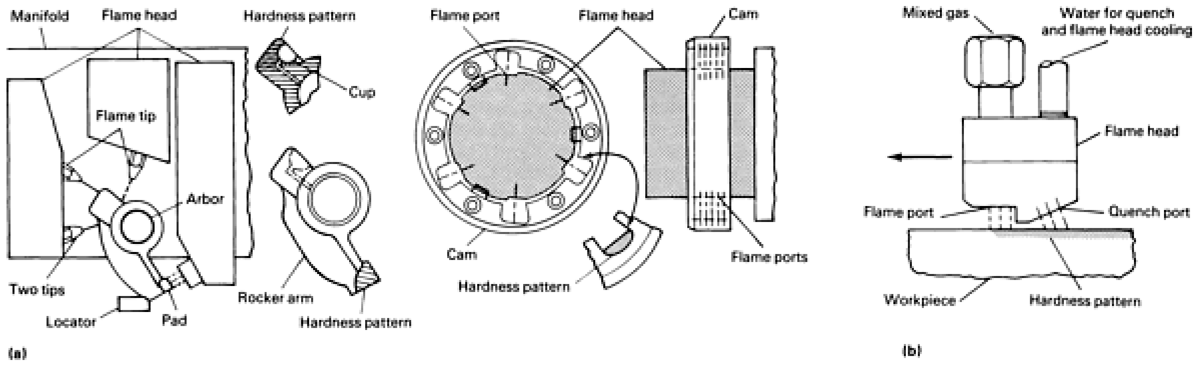

Fig. 1 Spot (stationary) and progressive methods of flame hardening. (a) Spot (stationary) method of flame hardening a rocker arm and the internal lobes of a cam; quench not shown. (b) Progressive hardening method

Basically, the spot method requires no elaborate equipment, except, perhaps, fixtures and timing devices to ensure the uniform processing of each piece. However, the operation may be automated by indexing the heated parts into either a spray quench or a suitable quench bath.

The progressive method, shown in Fig. 1(b), is used to harden large areas that are beyond the scope of the spot method. The size and shape of the workpiece, as well as the volume of oxygen and fuel gas required to heat the specified area, are factors in the selection of this method. In progressive hardening, the flame head is usually of the multiple-orifice type, and quenching facilities may be either integrated with the flame head or separate from it. The flame head progressively heats a narrow band that is subsequently quenched as the head and quench traverse the workpiece.

The equipment needed for flame hardening by the progressive method consists of one or more flame heads and a quenching means mounted on a movable carriage that runs on a track at a regulated speed (flame-cutting machines are adaptable to this type of flame hardening). Workpieces mounted on a turntable or in a lathe can be hardened readily by the progressive method; either the flame head or the workpiece may move. There is no practical limit on the length of parts that can be hardened by this method, because it is easy to lengthen the track over which the flame head travels. Single passes as wide as 1.5 m (60 in.) can be made; wider areas must be hardened in more than one pass.

When more than one pass is required to cover a flat surface, or when cylindrical surfaces are hardened progressively, such surfaces will exhibit soft bands because of overlapping or underlapping of the heated zones. These soft bands can be minimized, however, by closely controlling the extent of the overlapping. Wherever overlapping occurs, the possibility of severe thermal upset and cracking should be anticipated. Tests should be conducted to determine whether overlapping will cause cracking or other harmful effects. Simple curved surfaces may be hardened progressively by means of contoured flame heads, and some irregular surfaces may be traversed by the use of tracer template methods.

The rate of travel of the flame head over the surface is mainly governed by the heating capacity of the head, the depth of case required, the composition and shape of the work, and the type of quench used. Speeds ranging from 0.8 to 5 mm/s (2 to 12 in./min) are typical with oxyacetylene heating heads. Ordinarily, water at ambient temperatures is used as a quenchant, although air is sometimes used when a less-severe quench is indicated; under special conditions (particularly for quenching alloy steels), warm or hot water or a polymer-base synthetic quenchant may be employed.

The spinning method (Fig. 2) is applied to round or semiround parts such as wheels, cams, or gears. In its simplest form, the method uses a mechanism for rotating or spinning the workpiece, in either a horizontal or a vertical plane, while the surface is being heated by the flame head. One or more water-cooled heating heads equal in width to the surface to be heated are employed. The speed of rotation is relatively unimportant, provided uniform heating is obtained. After the surface has been heated to the desired temperature, the flame is extinguished or withdrawn and the work is quenched by immersion or spray or a combination of both.

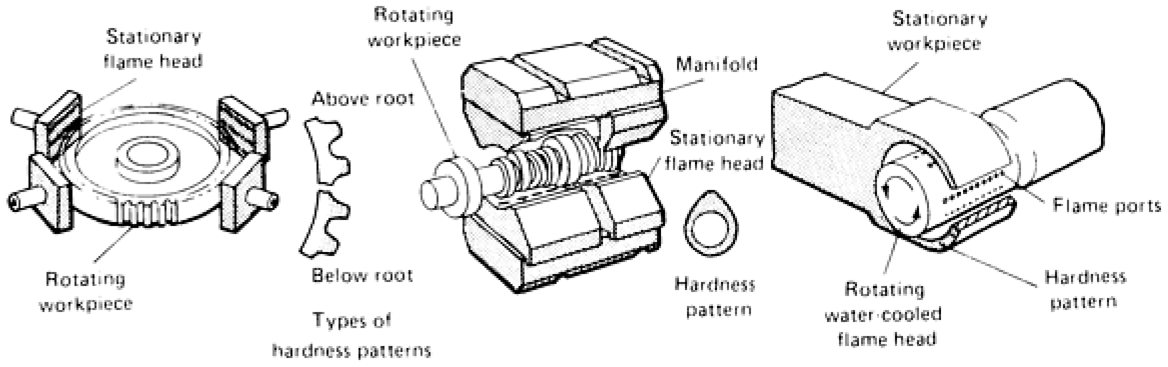

Fig. 2 Spinning methods of flame hardening. In methods shown at left and at center, the part rotates. In method at right, the flame head rotates. Quench not shown

The spinning method is particularly adaptable to extensive mechanization and automation. This makes it possible, for example, for all the cams on a camshaft to be hardened at the same time.

Today, fully automatic flame-heating equipment is available that can treat round components up to 1.5 m (60 in.) in diameter and up to 2 Mg (2.2 tons) in weight. Much of it has been designed to treat gear wheels of all types.

Commercial machines have been built that can provide automatic control of timing, temperature, and quenching, as well as accurate control of gas flow, so that close metallurgical specifications can be met consistently. Frequently, when production is sufficient, the spinning method can be set up so that either parts are loaded manually and unloaded automatically or they are loaded and unloaded automatically.

This method has been extended to components of irregular cross section and mass distribution. Typical are large drive wheels for tracked vehicles, cams and camshafts for marine diesel engines, and crane traveling wheels. Speed, deep hardness penetration, localized hardness zone, and uniformity of hardness pattern are the main advantages.

In one technique, a rotating flame head is used for internal spin hardening of odd-shape parts that would present handling problems if the parts themselves were rotated. Each part is positioned by a simple handling device, and the flame head rotates inside the part.

In contrast to the progressive method, in which acetylene is usually used (because of its high flame temperature and rapid heating rates), satisfactory results can be obtained in spin hardening with natural gas, propane, or manufactured gas. The choice of gas depends on the shape, size, and composition of the workpiece and on the depth of case required, as well as on the relative cost and availability of each gas.

A wide choice of quenchants also is possible in the spin hardening method. Because the flame is extinguished or withdrawn before the part is quenched, any appropriate quenchant may be used for immersion quenching. In spray quenching, the quenchant is usually water, a water-based liquid such as soluble oil, or a simulated oil in the form of a polymer-base quenchant; air also has been used.

The combination progressive-spinning method (Fig. 3), as the name implies, combines the progressive and spinning methods for hardening long parts such as shafts and rolls. The workpiece is rotated as in the spinning method; but, in addition, the heating heads traverse the roll or shaft from one end to the other. Only a narrow circumferential band is heated progressively as the flame head moves from one end of the work to the other. The quench follows immediately behind the heating head, either as an integral part of the head or as a separate quench ring.

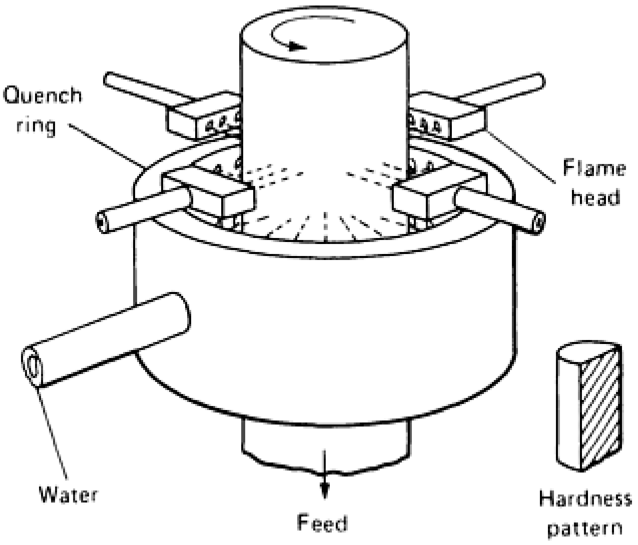

Fig. 3 Combination progressive-spinning flame hardening

This method provides a means of hardening large surface areas with relatively low gas flows. Progressive-spinning units designed to handle a broad range of diameters and lengths are available commercially.

Fuel Gases

Several different fuel gases are used in flame hardening. In selecting a fuel gas for a given application, the required rate of heating and the cost of the gas must be considered, along with the initial cost of equipment and maintenance costs.

Flame hardening does not alter the composition of the base metal if done properly. Carburizing, neutral, and oxidizing flames can be used. Oxidizing flames have high oxygen ratios and can be detrimental because they produce extremely hot temperatures that can cause decarburization and overheating. A carburizing flame can prevent some decarburization but can also introduce unwanted carbon into the surface. For best results, neutral or slightly carburizing flames should be used (Ref 1).

A comparison of the heating rates of fuel gases can be made when certain fundamental properties of usable mixtures with oxygen are known. A parameter that correlates well with actual heating speed is combustion intensity, or specific flame output. This is the product of the normal velocity of burning multiplied by the net heating value of the mixture of oxygen and fuel gas. A knowledge of these two properties often permits the selection of the most suitable fuel gas for a specific hardening speed and depth of case. The fuels of greatest commercial interest are ranked by combustion intensity (at metallurgically suitable ratios of mixture with oxygen) in the following order: acetylene, MAPP (methylacetylene propadiene), propane, methane. Values of normal burning velocity and the heating values of metallurgically suitable mixtures are listed in Table 1.

Table 1 Fuel gases used for flame hardening

Gas	Heating value		Flame temperature				Usual ratio of oxygen to fuel gas	Heating value of oxy-fuel gas mixture		Normal velocity of burning		Combustion intensity[a]		Usual ratio of air to fuel gas
			With oxygen		With air									
	MJ/m^3	Btu/ft^3	°C	°F	°C	°F		MJ/m^3	Btu/ft^3	mm/s	in./s	mm/s × MJ/m^3	in./s × Btu/ft^3	

Acetylene	53.4	1433	3105	5620	2325	4215	1.0	26.7	716	535	21	14,284	15,036	12
City gas	11.2-33.5	300-900	2540	4600	1985	3605	(b)	(b)	(b)	(b)	(b)	(b)	(b)	(b)
Natural gas (methane)	37.3	1000	2705	4900	1875	3405	1.75	13.6	364	280	11	3,808	4,004	9.0
Propane	93.9	2520	2635	4775	1925	3495	4.0	18.8	504	305	12	5,734	6,048	25.0
MAPP	90	2406	2927	5301	1760	3200	3.5	20.0	535	381	15	7,620	8,025	22

(a) Product of normal velocity of burning multiplied by heating value of oxy-fuel gas mixture.

(b) Varies with heating value and composition

The time required for heat penetration is another good criterion for judging the heating qualities of a fuel provided that all other variables remain constant. Figure 4 shows comparative heating times for stabilized MAPP, acetylene, and propane, using an efficient coupling distance for each fuel. These curves show that a greater depth of hardness can be obtained with MAPP in a shorter length of time (Ref 2).

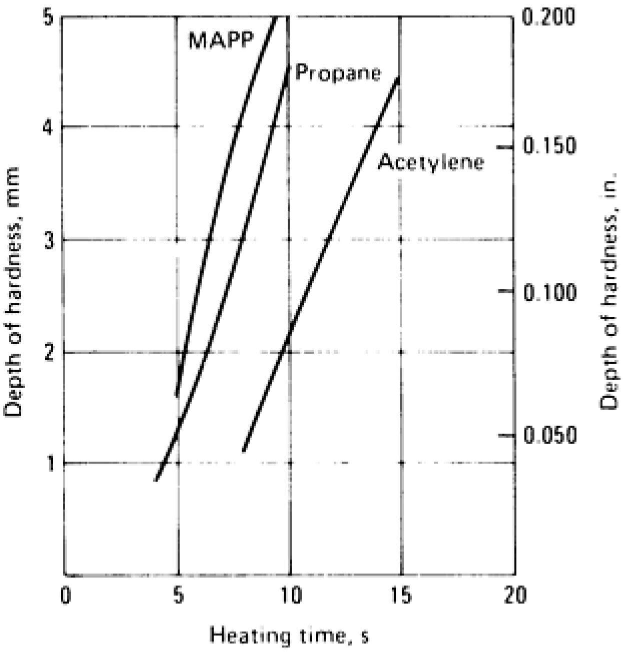

Fig. 4 Comparison of heating times for MAPP, acetylene, and propane. Flame velocity, 170 m/s (550 ft/s); port size, No. 69 drill (0.74 mm, or 0.0292 in.); coupling distance, 9.5 mm ($\frac{3}{8}$ in.); material, 1036 steel. Oxygen-to-fuel ratios: MAPP, 5.0; acetylene, 1.33; propane, 4.5

The ratio of oxygen to fuel is very important in obtaining maximum heating efficiency from the fuel. However, oxygen-to-fuel ratios should not be confused with oxygen and fuel consumption rates, which vary with flame velocity, port size, and heating time. Stoichiometrically, acetylene requires $2\frac{1}{2}$ mols of oxygen per mol of gas for complete combustion, MAPP requires 4 mols, and propane requires 5 mols. With acetylene, however, a range of only 1 to 1.5 volumes of oxygen is provided directly, with the remainder being drawn from the surrounding atmosphere. Neither MAPP nor propane has sufficient heat for flame hardening unless more oxygen is supplied, normally at a rate of four parts of oxygen per part of fuel. MAPP burns over a rather wide range of oxygen-to-fuel ratios, however, and thus permits a wider range of heat output while still providing high heat generation when necessary. The use of MAPP increases oxygen consumption, and fuel is more expensive than oxygen.

Bulk systems of supply for oxygen and fuel gases greatly reduce their cost, but of greater importance is the elimination of cylinder handling and of the residual losses usually attendant upon the use of gases in cylinders. Bulk systems also provide a more nearly constant supply of gas at uniform pressure. A disadvantage of acetylene is that it cannot be stored in bulk, thereby requiring manifolds of cylinders.

Depth of Heating. Shallow hardness patterns (less than 3.2 mm, or 0.125 in., deep) can be attained only with oxy-gas fuels. The high-temperature flames obtained with oxy-gas fuels provide the fast heat transfer necessary for effective localization of the heat pattern. Deeper hardness patterns permit the use of either oxy-gas fuels or air-gas fuels. Oxy-gas fuels will localize the heat, but care is required in their application to avoid overheating the surface during the development of the deeper-seated heat. Air-gas fuels, with their slower rates of heat transfer (lower flame temperatures), minimize or eliminate surface overheating but generally extend the heat pattern beyond the desired hardness pattern. For this reason, air-gas flame hardening is generally limited to steels of shallow hardenability. In this manner, the hardness pattern is controlled by the quench rather than by the heating. The deeper-seated heat produced by air-gas flames may preclude the use of air-gas mixtures because excessive distortion may occur. In consideration of these factors, the use of air-gas heating will depend primarily on the shape of the part insofar as the configuration favors heat localization and a lower rate of heat transfer.

Gas Consumption, Time, and Speeds. Gas consumption in flame hardening varies with the thickness of the case to be obtained; increasing or decreasing the depth of hardening increases or decreases the amount of gas used. Massive parts increase gas consumption because of their greater internal cooling effect. In order to take advantage of the maximum flame temperature from the oxy-fuel gas flame, the distance from the end of the inner cone of the flame to the work should be 1.6 mm ($\frac{1}{16}$ in.).

The speed of travel of the flame head over the work in the progressive method, as well as the time of heating in the spot and spinning methods, will vary with the thickness of the case desired and the capacity of the flame head. The proximity of the quench spray to the last row of flames will affect the speed somewhat in the progressive method. Progressive and progressive-spinning speeds usually vary between 0.8 and 5 mm/s (2 and 12 in./min) for most applications, although very thin parts may require speeds of 42 mm/s (100 in./min) or more to avoid overheating or burning. Because of the intense heat involved, the necessity for accurate control of the rate of travel in the progressive and progressive-spinning methods cannot be overemphasized.

Time-temperature-depth relationships for various fuel gases used in the spot (stationary), spinning, and progressive methods of flame hardening are shown in Fig. 5. The family of curves for the spot method (Fig. 5a) was obtained analytically by considering the flow of heat in three dimensions away from a heated spot on the surface of a rocker arm pad. The calculations were based on heat sources of different strengths, which were varied on the basis of the combustion intensity of the gases considered (acetylene, propane, and natural gas). It is understood that the strength of the heat source will also be affected by such factors as size of tip, distance from tip to work, total gas flow, and ratio of oxygen to fuel gas; hence, these curves are intended to indicate trends in time-temperature-depth relationships rather than to provide operational values for particular applications.

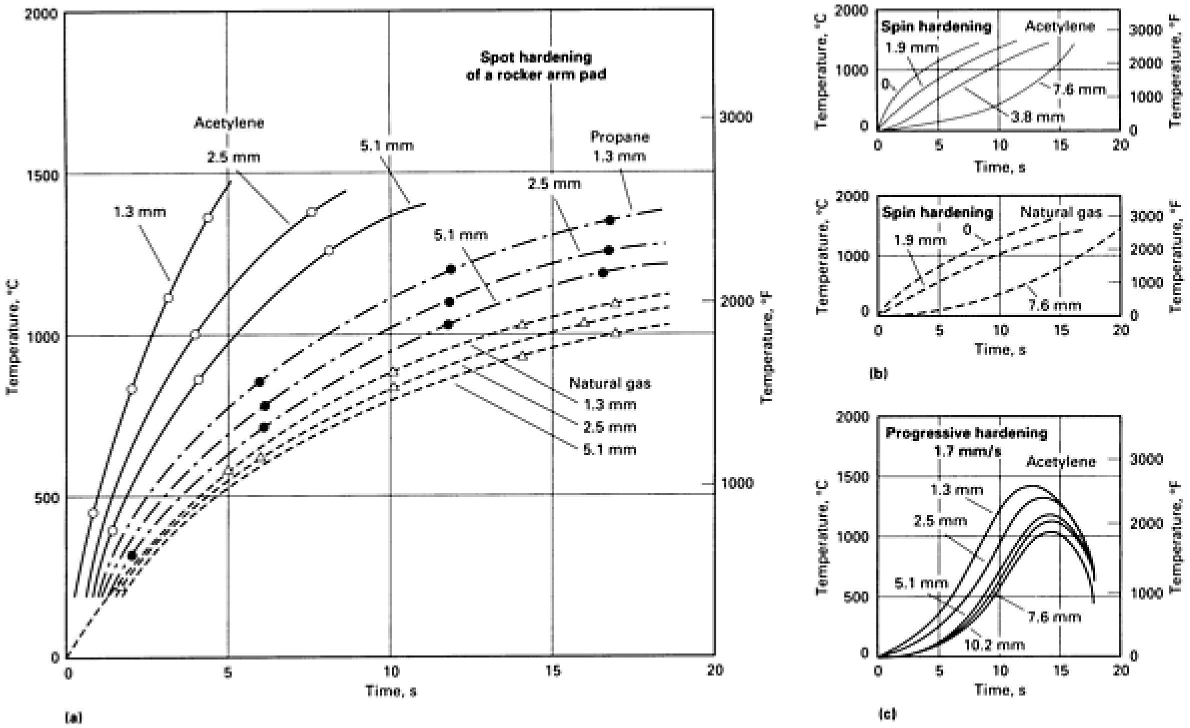

Fig. 5 Calculated time-temperature-depth relationships for spot (stationary), spinning, and progressive flame hardening. Depth of hardness given in millimeters

The curves for the time-temperature-depth relationships of fuel gases used in the spinning method, shown in Fig. 5(b), were obtained analytically by considering the flow of heat into a cylindrical body from a heat source supplying heat uniformly over the outer cylindrical surface. It was assumed that the temperature at the axis would not be raised appreciably during surface heating and that, in spin hardening, the cylinder would be rotated rapidly enough to give the effect of substantially uniform surface heating. No temperature decrease at high values of time is indicated, because in this type of process the body is quenched immediately when the surface temperature reaches a predetermined value.

The curves for the progressive method (Fig. 5c) were also obtained analytically by considering heat flow into a body from a line source moving along a flat side of the body. The heat source strength and body configuration were chosen to be representative of progressive flame hardening. In this instance, the time variable can be correlated with travel speed if the width of the flame zone is known. For example, a flame zone 25 mm (1 in.) wide will pass over a point on the work surface in 15 s when the travel speed of the tip is 1.7 mm/s (4 in./min). This width of flame zone indicates the probability of a multirow tip, and if the heat source is as strong as assumed for computing the curves, will undoubtedly damage the work surface. Consequently, a higher travel speed would be used, for example, 2.5 mm/s (6 in./min), which would heat a point on the work for 10 s and result in hardening to a depth of about 2.5 mm (0.100 in.). The rapid decrease in temperature at large values of time is due to the mass quenching effect, which, in practice, would be augmented by the use of water spraying or other quenching means.

Burners and Related Equipment

Burners are basic components of equipment for all methods of flame hardening. Burners vary in design, depending on whether they are fired by an oxy-fuel or an air-fuel gas mixture. Flame temperatures obtained by oxy-fuel gas combustion are 2540 °C (4600 °F) and higher. Heat transfer is by direct impingement of the flame on the surface of the workpiece. This is the reason oxy-gas burners are more commonly referred to as flame heads. Flame temperatures obtained by air-

fuel gas combustion are considerably lower (Table 1), and heat transfer is by impingement of high-velocity combustion product gases (no direct flame) or by radiation from an incandescent refractory surface.

There is no universal flame head, and no flame head is designed specifically for one particular gas. A well-designed flame head can be used with MAPP, acetylene, or propane, for example. Better flame head design usually results in an improved operation and lower gas consumption. Both acetylene and MAPP gas are somewhat reactive with copper-base alloys having more than 67% Cu. This concern is only a problem with piping systems, not torches or tips.

In general, a large number of small ports will produce a more efficient heat pattern than a few larger ports. Port spacing of 2.3 to 3.2 mm (0.090 to 0.125 in.) on centers is, in most cases, advisable. Counterboring permits higher flame velocities and is frequently advantageous or necessary when propane or MAPP is used. Because acetylene has a higher flame propagation rate, counterboring is usually unnecessary and is frequently undesirable. Counterboring reduces coupling distance and permits a stabilized flame at higher flame velocities. For effective operation, the ratio of counterbore area to throat area should be on the order of 2 to 1. Ratios as high as 4 to 1 may be used in some cases, however (Ref 2).

Oxy-Fuel Gas Flame Heads. Oxy-fuel gas combustion develops flame temperatures above those at which useful metals and refractory materials can survive. Accordingly, the flame head is designed to provide a flame pattern that avoids any direct heating of its parts.

Generally, the flame head consists of a tube or a shell with one or more orifices drilled into it. The number and arrangement of orifices depend on the required area of heat coverage. Flame heads for use with oxy-fuel gas are shown in Fig. 6.

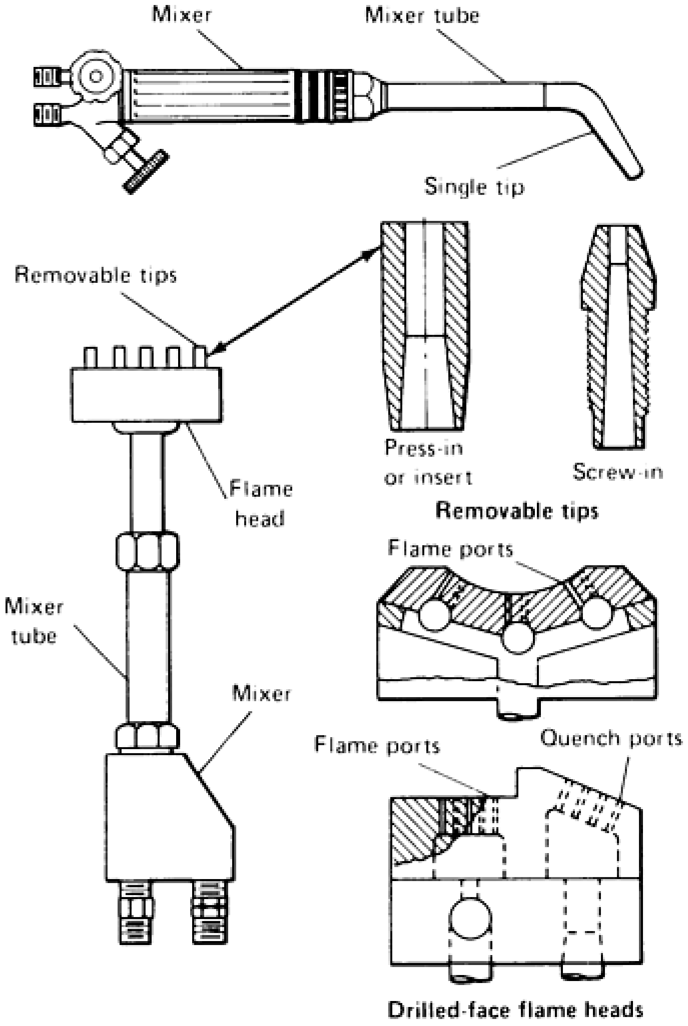

Fig. 6 Flame heads for use with oxy-fuel gas

The drilled-face flame head has a limited range of application and is usually designed to meet the requirements of one specific part to be flame hardened in appreciable quantity. For other applications, the flame head may be fitted with removable tips of the screw-in or insert type.

The screw-in type of removable tip shown in Fig. 6 is used widely enough that it is available in off-the-shelf commercial flame heads or is supplied as a standard item by manufacturers of flame-hardening equipment; it is also simple enough that it can be made to specification by plants applying the flame-hardening treatment.

The insert, or press-in, type of tip shown in Fig. 6 is smaller than the screw-in type and permits closer spacing of orifices, approaching that of a drilled flame head. Flame heads with removable and replaceable tips can be used over a wider range of applications by removing one or more tips and replacing them with plugs.

The heat output of the flame head is governed by the number and size of the orifices, other factors being equal. The individual orifices range from No. 73 to No. 51 drill size (0.6 to 1.7 mm, or 0.024 to 0.067 in., in diameter). Such small holes can readily become plugged, and when this occurs, the flame head will not function properly. Flame heads with removable tips have an advantage over fixed-tip heads in that oversize or out-of-round holes caused by mechanical or flame damage can be corrected without replacing the head.

Integral parts of the flame system are the mixer block and the mixer tube, which mix the component fuel gases and convey them through the orifices (Fig. 6). The capacities of mixer block and mixer tube must match the number and size of the orifices; if the mixer is too small, the flame will flash back, and if the mixer is too large, the flame head will not function efficiently.

To ensure identical velocity of mixed gases at all flame orifices, it is common practice to design a flame head with baffle orifices through which the gases must pass before they are burned at the flame orifices. Two rules apply to the design of baffle orifices: First, their total area must be 1.25 to 1.50 times the area of the flame orifices, and second, the number of baffle orifices within a single baffle should be one-fourth the total number of flame orifices.

Multiple-orifice flame heads are water cooled because otherwise the high temperatures developed at and around the flame head would cause early deterioration. On flame heads used for progressive hardening, the quench water cools the head. On multiple-orifice flame heads used in the spinning and progressive-spinning methods, the cooling water is circulated through chambers integrated into the head. Single-orifice flame heads (welding torches, for example) are generally not water cooled.

Typical flame-hardening installations that use oxy-fuel gas mixtures are shown in Fig. 7. The equipment in Fig. 7(a) was designed to handle the high production of similar parts. The equipment in Fig. 7(b) was designed to harden a variety of parts by changing the flame heads and work spindle.

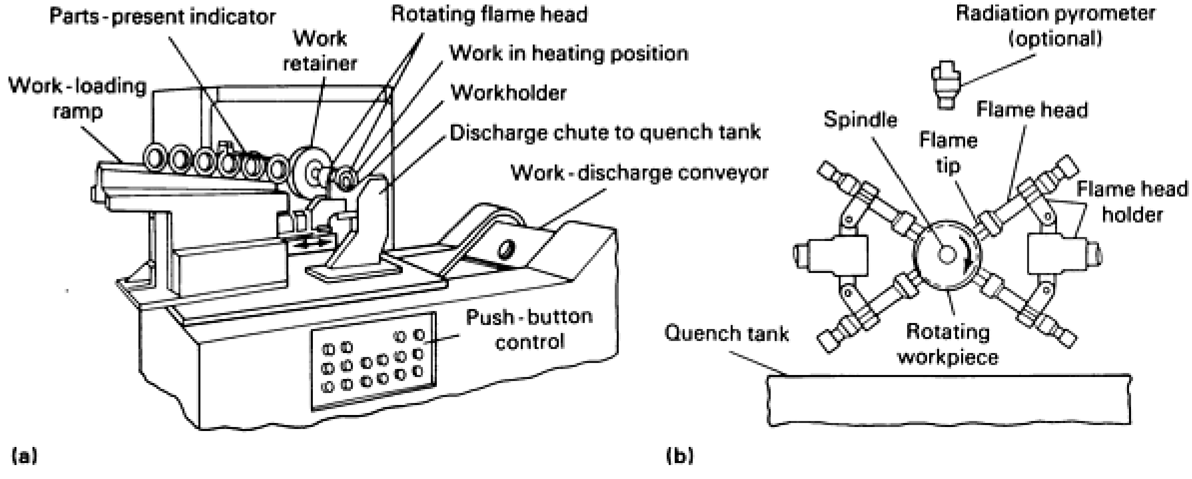

Fig. 7 Typical flame-hardening installations using oxy-fuel gas mixtures. (a) Installation for high production of similar parts: hardening the 54 mm ($2\frac{1}{8}$ in.) bores of hubs to a depth of about 3.2 mm ($\frac{1}{8}$ in.). Machine has a

standard, retractable spindle adapted with a rotary flame head. Spindle is driven by a variable-speed motor. Temperature of agitated quench is maintained by a water-cooled heat exchanger. (b) Installation for selective oxy-fuel gas heating of small production lots of gears, sprockets, and flanges within size limits of the equipment. A radiation pyrometer is used here to control heating cycle, but many operations use an electric timer instead. By changing work heads and spindles, equipment can be adapted to various parts.

New equipment configurations are being designed to handle specific problems. With conventional flame-hardening equipment, for example, it is difficult to obtain a zone of uniform temperature across the surface of the tooth gap in gears. The problem of obtaining uniform depth of hardness, not only from tooth to tooth but also across the entire face width, has been solved by the development of a two-chamber burner with individual control of energy input to each chamber. The system ensures uniform heating; particularly in the tooth root, and incorporates the separate control of nozzles for tooth-root and tooth-flank hardening (Ref 3).

With this system, complex components, too, can be processed by spin hardening. For example, both the straight and bevel gears of a double-pinion shaft can be hardened simultaneously if the quenching-bath immersion depth is adequate. By distributing heating power between spur wheel and bevel wheel, the austenitizing temperature can be reached under the tooth roots of both gears at the same time. This requires the selection of different heat-up times for the two gears and different rates of oxygen flow to the two sets of burners (Ref 3).

Air-Fuel Gas Burners. Air-fuel gas combustion develops lower flame temperatures that are compatible with available refractory materials. Thus, burners are designed with the aim of completely utilizing the heat generated. The burners, incorporating heat-resistant refractory liners, are of two types, generally designated as the radiant type and the high-velocity convection type (Fig. 8).

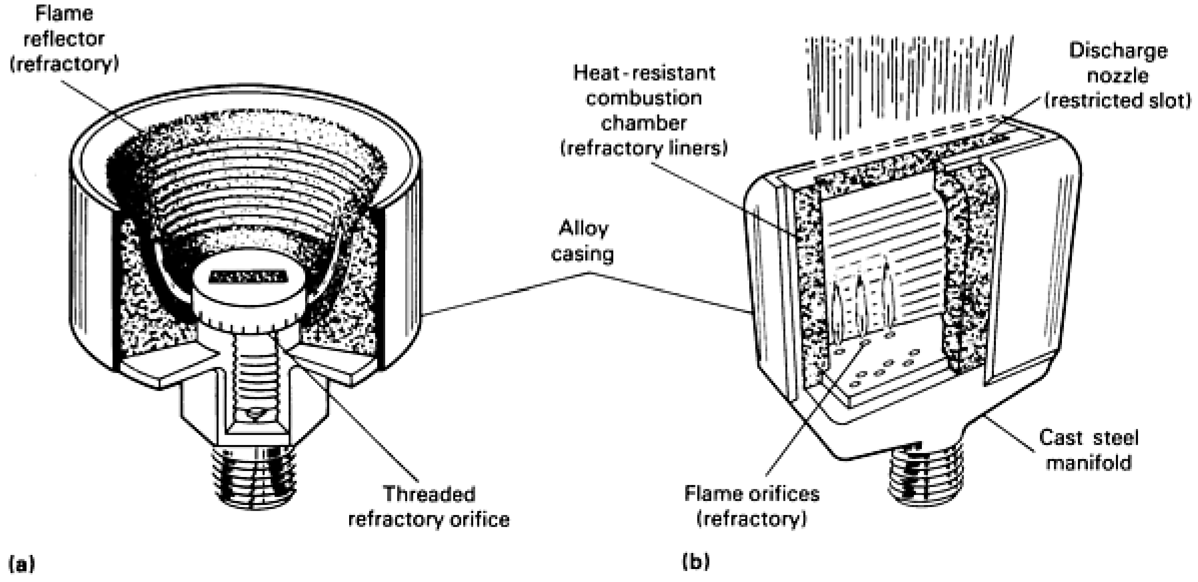

Fig. 8 Typical burners for use with air-fuel gas. (a) Radiant type. (b) High-velocity convection type (not water cooled)

The radiant-type burner (Fig. 8a) is essentially a refractory cup in a protective metal casing. Air-gas premixing is supplied through the pipe at the back and passed through an accurately molded ceramic tip that is screwed into the pipe and located at the bottom of the cup. With numerous narrow slots molded into its periphery, the tip essentially functions as the distributing head of a multiport burner. The many small flames wash the inner surface of the cup, making it highly incandescent for rapid heat transfer by radiation. Because combustion is completed within the cup, the burner may be positioned close to the work with no flame impingement.

The standard radiant burner used in flame hardening is approximately 75 mm (3 in.) in cup diameter. It is particularly effective for spin hardening the teeth of large gears. A single row of burners may be arranged in a ring surrounding a gear, as shown in Fig. 9(a), or multiple rows of burners may be arranged to cover completely the surface to be hardened.

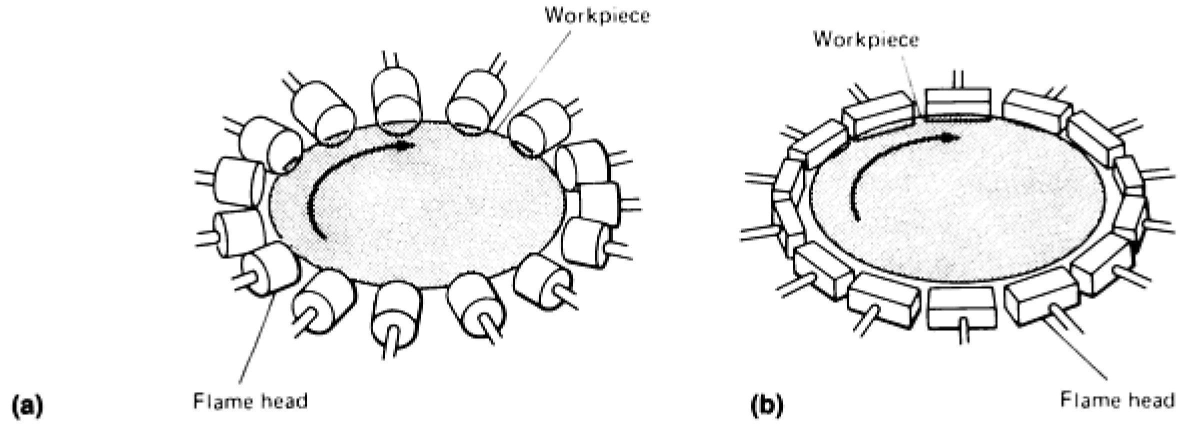

Fig. 9 Setups for flame-hardening gears, idler wheels, and sprockets. (a) Radiant burners. (b) High-velocity convection burners. Wide-face parts can be heated with double or staggered rings of burners.

The high-velocity convection burner is basically a miniature refractory-lined furnace in which heat is released at rates as high as 415 $MJ/m^3 \cdot s$ (4×10^7 $Btu/ft^3 \cdot h$). The air-gas premixture, supplied through a pipe connection, flows through the orifices of the ceramic port plate. The burner design is such that the burning gases heat the chamber lining to a temperature approaching the theoretical flame temperature. This permits preheating of the reacting gases and accelerates combustion. In this manner, gases at approximately 1650 °C (3000 °F) are discharged through a restricted slot opening to impinge on the workpiece at velocities up to 760 m/s (2500 ft/s). High-velocity convection burners are well adapted to the localized heating of parts in spin-hardening operations. Figure 9(b) shows their application for hardening the teeth of a thin gear.

Related Equipment. Burners for both the oxy-fuel gas and the air-fuel gas methods of flame hardening are implemented by pressure regulators, valves, flowmeters, and protection devices. For the air-fuel gas method, a separate mixer and compressor are used because the mixing function is not incorporated within the burners (Fig. 10).

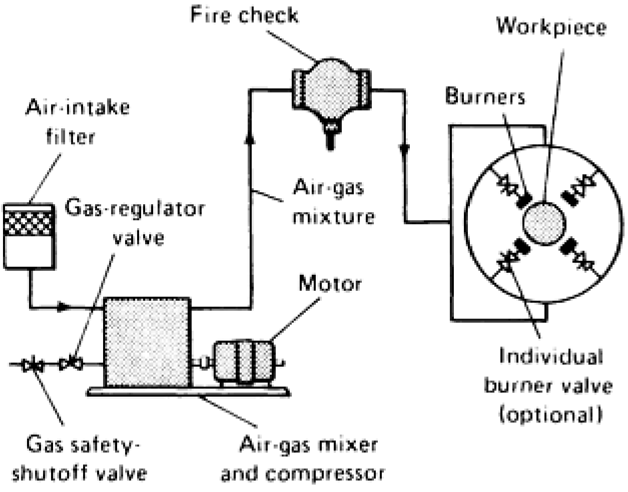

Fig. 10 Mixer-burner system for use with air-fuel gas

Materials of Construction for Burners. The metallic components of burners may be of a variety of materials, depending on the type of burner and the service to which it is subjected. The flame heads for oxy-fuel gas flame heating are in nearly all instances made of copper or a dense grade of lead-free brass (Ref 2). These metals are relatively inexpensive, have excellent thermal conductivity, and are readily machined. Because flame velocity is relatively low, there is little likelihood that the metal flame head will overheat and deteriorate as a result of the backwash of hot gases. Normally, the flow of gases within the head provides sufficient cooling to maintain a safe temperature. If additional cooling is required, the head may be water cooled. Under no circumstances should the flame head be permitted to overheat to the extent that the burner metal, brazed burner joints, or drilled flame ports are damaged.

The service life of oxy-fuel gas flame heads depends largely on the conditions of a particular application, such as containment of the heat resulting from the configuration of the piece being heated, and the degree of backwash of flame or hot gases impinging on the burner. Therefore, it is difficult to predict the exact service life that can be expected for a new application. Brass heads used for the progressive hardening of machineways have shown an average life of 1000 to 2000 h in continuous service.

The melting points and ranges of heat resistance of available materials are not greatly different (compared with the large differences between flame temperatures and metal melting points). Life expectancy, therefore, is a relatively unimportant basis for the selection of a particular metal. Availability, cost, and ease of fabrication are likely to be more important factors in material selection. A metal frequently used for flame heads is Muntz metal (60-40 lead-free brass); when cooling is a problem, however, copper is preferable.

Screw-in tips are usually made of copper, but when higher heat resistance is required, because of secondary flame, Monel K-500 can be used. Insert or press-in tips are usually made of copper, but when high wear resistance of the tip bore is desired, tips made of sintered carbide are employed.

Cast iron, stainless steel, and heat-resisting alloys are used for the casings that surround the refractory cups of radiation-type air-fuel gas burners. Heat-resisting alloys may provide reasonable life at temperatures up to 1150 °C (2100 °F). Casings of high-velocity convection burners are generally constructed of stainless steel, but may be of Inconel for more severe service. For the spin hardening of gears, either type of burner may have a useful life of 10 to 15 40-h weeks of continuous operation. In many applications, longer life for casings has resulted when the operator has exercised care in setting up and operating burners. Also, water cooling the burner casing can markedly extend its life and may be used if the added cost is justifiable and if space for the cooling arrangement is available in the heating setup.

The refractory parts of all types of air-gas burners are formed in steel dies and prefired in kilns and are capable of withstanding the most extreme temperatures generated in the burners. These parts generally fail from thermal or mechanical shock; hence, service life is unpredictable.

Operating Procedures and Control

The success of many flame-hardening applications depends largely on the skill of the operator. This is especially true when the volume of work is so small or varied that the cost of automatic-control equipment is not justified.

The principal operating variables are:

- Distance from inner cone of oxy-fuel gas flames or from air-fuel gas burner to work surface
- Flame velocities and oxygen-to-fuel ratios
- Rate of travel of flame head or work
- Type, volume, and angle of quench

These variables must be closely controlled to ensure the duplication of desired surface hardness and depth of hardness. It is highly desirable to develop a specific procedure for each item to be flame hardened. The procedure is developed by preliminary tests on the production piece itself, if warranted, or on mock-up sections of approximately the same cross section as the production piece. After the desired contour and depth of hardened zone have been developed, the procedure is applied to production pieces and, when established, is made a part of the heat-treating specification. The critical importance of developing strict procedures is demonstrated in the following case study conducted by a flame-hardening firm (Ref 4).

Example 1: Test on Flame-Hardening Procedure of 1045 Steel Bar.

Each of five experienced flame hardeners was asked to flame harden a 1045 steel bar 25 × 50 × 450 mm (1 × 2 × 18 in.) using only experience and visual examination to guide the process. Only the traditionally and normally controlled variables were preset: coupling distance, 11 mm ($\frac{7}{16}$ in.); water pressure, 620 kPa (90 psi); quench, water; and angle of quench, 30°. Flowmeter readings were taken, speeds of travel recorded, and flame velocities determined. After treatment, each bar was ground to determine the hardness level and depth of hardness. Results are given in Table 2. Surface hardness and depth of hardness showed little consistency: Surface hardness ranged from 50 to 61 HRC and at 3.18 mm ($\frac{1}{8}$ in.) from 30 to 52 HRC.

Table 2 Results of operator skill test

Operator	Flame velocity		Oxygen-to-fuel ratio	Travel speed		Surface hardness, HRC	Hardness at 3.18 mm (0.125 in.), HRC
	m/s	ft/s		mm/s	in./min		
1	95	313	3.6:1	3.4	8.0	61	30
2	99	324	3.1:1	2.5	6.0	50	41
3	137	451	3.1:1	1.7	4.0	57	50
4	124	407	4.2:1	1.9	4.5	55	38

Speed of travel of the flame head, or the duration of heating, should be held constant for uniform results. In the progressive method, the flames gradually heat the work-piece in front of the flame head, and sometimes this effect must be compensated for by gradually increasing the speed of travel or by precooling. At the beginning of a pass when the progressive or progressive-spinning method is being used, the flame head or heads should be manipulated or otherwise adjusted to ensure that the beginning of the area to be hardened attains the proper temperature and depth of heating as progression begins.

Gas Pressures. Oxy-fuel gas and air-fuel gas pressures should be controlled closely for uniform input of heat. Flat oxy-fuel flame heads are somewhat less efficient when used on circular or curved surfaces because each cone of flame is at a different distance from the work. Overheating causes cracking.

Oxygen-to-fuel ratio is a key factor in determining flame temperature. For example, propane produces flame temperatures of 2700 °C (4900 °F) at a 5-to-1 ratio, 2540 °C (4600 °F) at a 4-to-1 ratio, and 2370 °C (4300 °F) at a 3-to-1 ratio.

Flame velocity is one of the most important variables because when balanced with other variables, it is the main determinant of case depth. In Example 1 for flame hardening 1045 steel (Ref 4), the basic flame velocity required for establishing a case depth of 3.2 to 4.8 mm ($\frac{1}{8}$ to $\frac{3}{16}$ in.) is 152 m/s (500 ft/s).

In flame hardening cast irons, where high surface temperatures are undesirable, the use of lower flame velocities is a distinct advantage. In this regard, both MAPP and propane are easy to control and are effective over a wide range of velocities. The ability to control the flame over a wide velocity range not only provides flexibility but also makes the operation much safer and results in better heat pattern control.

Coupling distance is another key parameter in flame hardening. The relations between coupling distance and depth of hardening for three fuel gases are shown in Fig. 11. In general, the coupling distance for MAPP is equal to or very slightly greater than that for acetylene. The effect of counterboring is a shortening of the coupling distance. By the same token, coupling distance increases as flame velocity increases. Efficient coupling distances for MAPP generally range from 6.4 to 9.5 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.) depending on gas velocity and port size. A counterbored port of No. 69 drill size (0.74 mm, or 0.0292 in.) will operate efficiently at a coupling distance of 4.8 mm ($\frac{3}{16}$ in.).

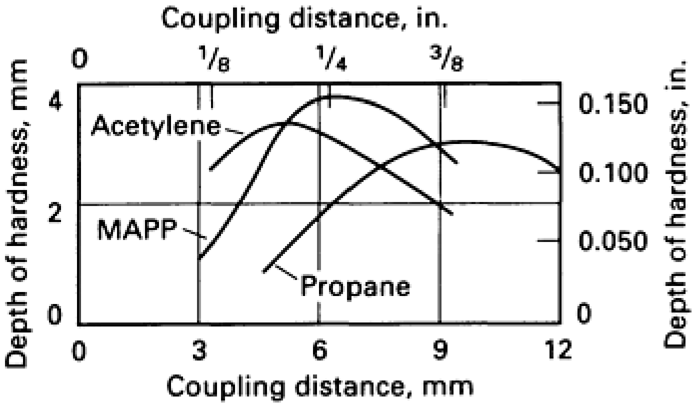

Fig. 11 Effect of coupling distance for MAPP, acetylene and propane. Flame velocity, 170 m/s (550 ft/s); port size, No. 69 drill (0.74 mm, or 0.0292 in.); material, 1052 steel. Oxygen-to-fuel ratios: MAPP, 4.5; acetylene, 1.33; propane, 4.5. Heating times: MAPP, 6 s; acetylene and propane, 8 s

Hardening temperatures can be judged by competent operators, but to the inexperienced the heated metal will appear colder than it actually is because of the light from the burning gases; the consequent tendency is to overheat unless the operator is equipped with didymium-tinted glasses. Radiation or optical pyrometers are often used to judge more accurately the temperatures being developed. Radiation-pyrometer systems of fast response are used extensively to control work temperatures and heating times. Metallurgical examination is the best method for establishing operating conditions. Overheated spots may appear under individual flames, but with properly designed flame heads and good scanning technique, this effect is minimized and not readily detectable by microscopic examination.

Examples of Flame-Hardening Procedures. The interrelationship of variables can best be illustrated by specific examples of procedures used for the production hardening of actual parts. The following six examples involve the hardening of gears, cams, shafts, and flat surfaces.

A small gear hub made of 1052 steel was flame hardened by the spinning method at a spindle speed of 140 rpm (Table 3). The aim was to harden to 52 HRC minimum to a depth of 0.9 mm (0.035 in.) maximum above the root of the gear teeth.

Table 3 Procedure for spin flame hardening the small converter gear hub (shown in Fig. 15a)

Preliminary operation
Turn on water, air, oxygen, power, and propane. Line pressures: water, 220 kPa (32 psi); air, 550 kPa (80 psi); oxygen, 825 kPa (120 psi); propane, 205 kPa (30 psi). Ignite pilots.
Loading and positioning
Mount hub on spindle. Hub is held in position by magnets. Flame head previously centered in hub within 0.4 mm ($\frac{1}{64}$ in.). Distance from flame head to inside diameter of gear teeth, approximately 7.9 mm ($\frac{5}{16}$ in.)
Cycle start
Spindle with hub advances over flame head and starts to rotate. Spindle speed, 140 rpm
Heating cycle
Propane and oxygen solenoid valves open (oxygen flow delayed slightly). Mixture of propane and oxygen ignited at flame head by pilots. Check propane and oxygen gages for proper pressure. Adjust flame by regulating propane. Heating cycle controlled by timer. Time predetermined to obtain specified hardening depth.
Propane and oxygen solenoid valves close (propane flow delayed slightly). Spindle stops rotating and retracts. Hub stripped from spindle by ejector plate. Machine ready for recycling
Propane regulated pressure, 125 kPa (18 psi); oxygen regulated pressure, 550 kPa (80 psi); oxygen upstream pressure, 400 kPa (58 psi); oxygen downstream pressure, 140 kPa (20 psi). Flame velocity (approximate), 135 m/s (450 ft/s). Gas consumptions (approximate): propane, 0.02 m^3 (0.6 ft^3) per piece; oxygen, 0.05 m^3 (1.9 ft^3) per piece. Total heating time, 9.5 s
Flame port design: 12 ports per segment; 10 segments; port size, No. 69 (0.74 mm, or 0.0292 in.), with No. 56 (1.2 mm, or 0.0465 in.) counterbore
Quench cycle
Hub drops into quench oil, is removed from tank by conveyor. Oil temperature, 54 ± 5.6 °C (130 ± 10 °F); time in oil (approximate), 30 s
Hardness and pattern aim
Hardness, 52 HRC minimum to a depth of 0.9 mm (0.035 in.) maximum above root of gear teeth

A large bevel ring gear of 8742 steel was flame hardened by the progressive method (Table 4). The hardness aim was 53 to 55 HRC.

Table 4 Progressive flame hardening of ring gear teeth

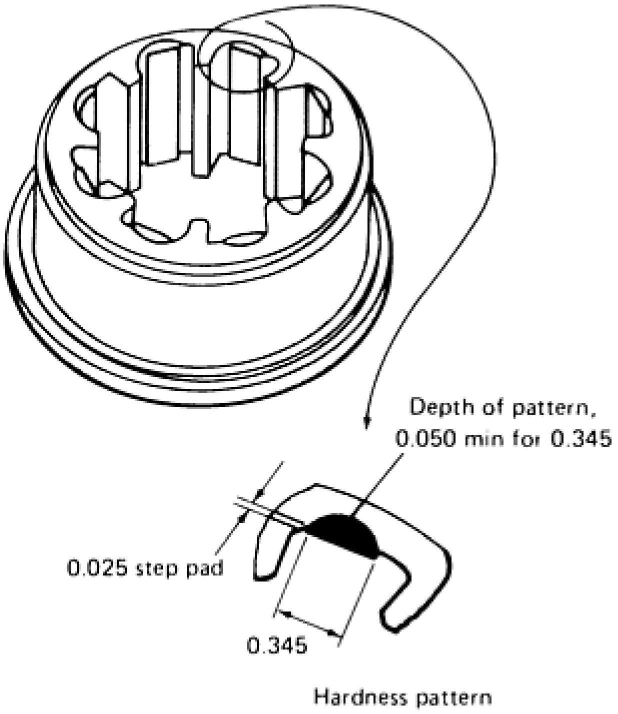
Workpiece
Bevel ring gear made of 8742 steel with 90 teeth. Diametral pitch, 1.5; face width, 200 mm (8 in.); outside diameter, 1.53 m (60.412 in.)
Mounting
Gear mounted on holding fixture to within 0.25 mm (0.010 in.) total indicator runout
Flame heads
Two 10 hole, double-row, air-cooled flame heads, one on each side of tooth. Flame heads set 3.2 mm ($\frac{1}{8}$ in.) from tooth
Operating conditions
Gas pressures. Acetylene, 69 kPa (10 psi); oxygen, 97 kPa (14 psi)
Speed. 1.9 mm/s (4.5 in./min). Complete cycle (hardening pass, overtravel at each end, index time, preheat return stroke on next tooth), 2.75 min
Indexing. Index every other tooth. Index four times before immersing in coolant.
Coolant. Mixture of soluble oil and water, at 13 °C (55 °F)
Hardness aim. 53 to 55 HRC

A free-wheel cam made of 1062 steel was flame hardened by the spot method (Table 5). The aim was 60 HRC minimum at the surface and 59 HRC at a depth of 1.3 mm (0.050 in.), for a width of 8.8 mm (0.345 in.) on the roller surface of the cam.

Table 5 Spot flame hardening of a 1062 steel free-wheel cam

Preliminary operation
Turn on water, air, oxygen, power, and propane. Line pressures: water, 205 kPa (30 psi); air, 550 kPa (80 psi); oxygen, 825 kPa (120 psi); propane, 205 kPa (30 psi). Ignite pilots.
Loading and positioning
Mount cam on flame head. Cam positioned on locating plate and two wear pads, and against three locating pins that are integral parts of flame head. Distance from flame head to cam surface, approximately 7.9 mm ($\frac{5}{16}$ in.)

Cycle start and heating cycle
Propane and oxygen solenoid valves open (oxygen flow delayed slightly). Mixture of propane and oxygen ignited at flame heads by pilots. Check propane and oxygen pressures. Adjust flame by regulating propane. Heating cycle controlled by timer. Time predetermined to obtain specified hardening depth. Propane and oxygen solenoid valves close (propane flow delayed slightly). Ejector plate (air operated) advances and strips cam from flame head.
Propane regulated pressure, 125 kPa (18 psi); oxygen regulated pressure, 585 kPa (85 psi); oxygen upstream pressure, 425 kPa (62 psi); oxygen downstream pressure, 110 kPa (16 psi). Flame velocity (approximate), 135 m/s (450 ft/s). Gas consumption (approximate): propane, 0.01 m^3 (0.4 ft^3) per piece; oxygen, 0.04 m^3 (1.3 ft^3) per piece. Total heating time, 11 s
Flame port design: nine ports per row; eight rows; port size, No. 69 (0.74 mm, or 0.0292 in.), with No. 56 (1.2 mm, or 0.0465 in.) counterbore
Quench cycle
Cam drops into quench oil, is removed from tank by conveyor. Oil temperature, 54 ± 5.6 °C (130 ± 10 °F). Time in oil (approximate), 30 s
Hardness and pattern aim
Hardness, 60 HRC minimum at surface and 59 HRC minimum at a depth of 1.3 mm (0.050 in.) below surface, for width of 8.8 mm (0.345 in.) on cam roller surface. Dimensions below given in inches



A 52100 steel shaft was flame hardened by the progressive method to 61 to 63 HRC (Table 6).

Table 6 Progressive flame hardening of a 52100 steel shaft

Setup

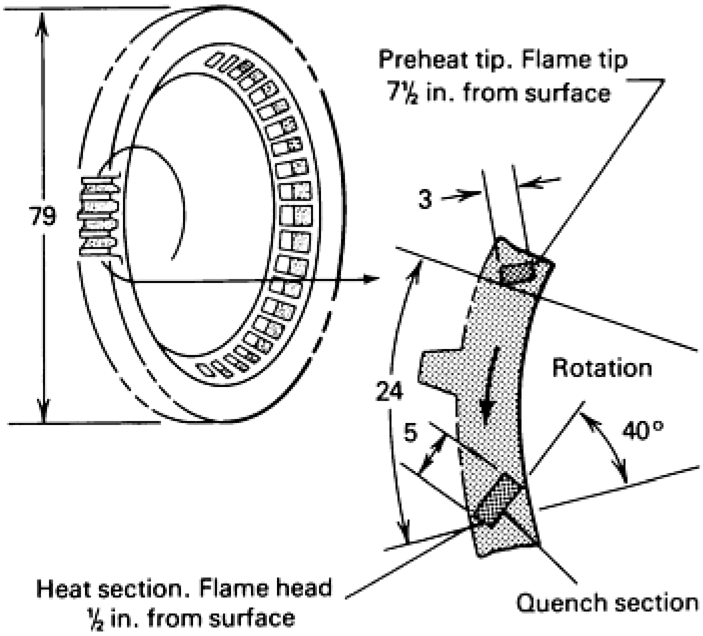
Shaft held vertically between centers to within 0.1 mm (0.005 in.) total indicator runout
Flame heads
Three water-cooled flame heads, each with eight holes 1.3 mm (0.052 in.) in diameter. One torch for each flame head. Flame heads set 6.4 mm ($\frac{1}{4}$ in.) from shaft
Operating conditions
Gas pressures. Acetylene, 55 kPa (8 psi); oxygen, 76 kPa (11 psi)
Speeds. Flame head travel, 1.3 mm/s (3 in/min); speed of shaft revolution, 20 rpm
Quench. Water nozzles directly below flame heads
Hardness aim. 61 to 63 HRC

The roller path of a large cast alloy steel ring gear was hardened according to the procedure outlined in Table 7. The hardness aim was 515 to 600 by portable Brinell, as specified in the last item above the schematic in Table 7.

Table 7 Flame hardening of roller path on side of large ring gear

Mounting on positioner
Gear should be centered on positioner in a vertical position, to approximately 1.7 mm (0.065 in.) total indicator runout on tooth outside diameter (see sketch).
Preheating
Flame head gap. Set 75 mm (3 in.) maximum flame head at 190 mm ($7\frac{1}{2}$ in.) gap from flame-hardened surface and approximately 610 mm (24 in.) ahead of hardening tip.
Gas pressures. Acetylene, 89 kPa (13 psi); oxygen, 185 kPa (27 psi)
Flowmeter. 2.1 divisions for acetylene; 2.65 divisions for oxygen
Tube readings (neutral flame). Flutter, approximately $\frac{1}{8}$ division, plus or minus
Speed setting. No. 9 notch on positioner; equivalent to 2.7 mm/s (6.42 in./min) on 5.79 m (228 in.) circumference of 1.84 m ($72\frac{1}{2}$ in.)

flame-hardened pitch circle (~35 $\frac{1}{2}$ min/rev)
Heat cutoff. Kill preheat when spread of flame toward oncoming hardened surface produces blue-purple temper color at flame-hardening starting point. (Air-block flame head may be set up for the same purpose.)
Flame hardening
Heating-head gap. (*Caution: Must be kept parallel with flame-hardened surface.*) Set and hold 125 mm (5 in.) flame head at 13 mm ($\frac{1}{2}$ in.) gap from flame-hardened surface and at an angle of about 35 to 40° to radius; adjust during flame hardening to follow in line with roller-path warp.
Gas pressures. Acetylene, 89 kPa (13 psi); oxygen, 185 kPa (27 psi)
Flowmeter. 2.7 divisions for acetylene; 3.2 divisions for oxygen
Tube readings (neutral flame). Normal flutter, approximately $\frac{1}{8}$ division; watch frequently for signs of gas failure.
Water pressure (flame-hardening quench). Set pressure-reducing valve for 205 kPa (30 psi).
Speed setting. Same as for preheating. (Note: Double-check setting just before flame hardening.)
Heat cutoff. (No overlap permissible; aim at 13 mm, or $\frac{1}{2}$ in.), maximum soft gap; use extreme caution.) As flame head approaches finish junction, gradually back off tip 1.6 mm ($\frac{1}{16}$ in.) during final 13 mm ($\frac{1}{2}$ in.) of gear travel and kill flame *abruptly* when nearest row of flames *just reaches* 6.4 mm ($\frac{1}{4}$ in.) clearance from starting point of flame hardening; immediately speed up table to fastest-speed notch.
Hardness aim (except at flame-hardening junction), 515 to 600 on portable Brinell at points 50 mm (2 in.) from inside diameter of flame-hardened roller path (50 HRC at a depth of approximately 5.1 mm, or 0.2 in.); total depth of contour, 7.9 mm ($\frac{5}{16}$ in.) Schematic shows ring gear (in vertical position) and position of flame heads for hardening roller path (located on side face of ring) by procedure summarized in table. Gas cost was approximately 25% of total processing cost. Hardening extended to a depth of 4.8 mm ($\frac{3}{16}$ in.). Hardness at surface, 530 HB. For hardness gradients, see Fig. 12.



Drop-forged wear blocks of 1040 steel were flame hardened on a conveyor to 53 to 58 HRC (Table 8).

Table 8 Flame hardening of 1040 steel wear blocks

Preliminary operation

Clean blocks until free of scale and rust, preferably by sand or shot blasting.
Loading
Load blocks on one end of conveyor belt.
Flame head
Head contains 2 rows of No. 54 drill size (1.4 mm, or 0.055 in.) flame holes; total of 49 holes, of which 24 are plugged; 150 mm (6 in.) between centers of end holes. Head also contains single row of water-quench holes. Head set at 16 mm ($\frac{5}{8}$ in.) total gap; cone point clearance of flame, 4.8 mm ($\frac{3}{16}$ in.)
Gas pressures
Acetylene, 83 kPa (12 psi); oxygen, 150 kpa (22 psi)
Speed
Conveyor speed, 2.47 mm/s (5.83 in./min); total flame-hardening time, 1.5 min per pad
Hardness and pattern aim
Hardness, 53 to 58 HRC; total depth of hardening to core, 4 mm ($\frac{5}{32}$ in.)

Preheating

In flame-hardening parts of large cross section, difficulty in obtaining the desired surface hardness and hardness penetration can often be overcome by preheating. When available power or heat input is limited, the hardened depth can be increased by preheating. The hardness data in Fig. 12 shows the effectiveness of preheating in developing hardness penetration in the ring gear discussed in Table 7.

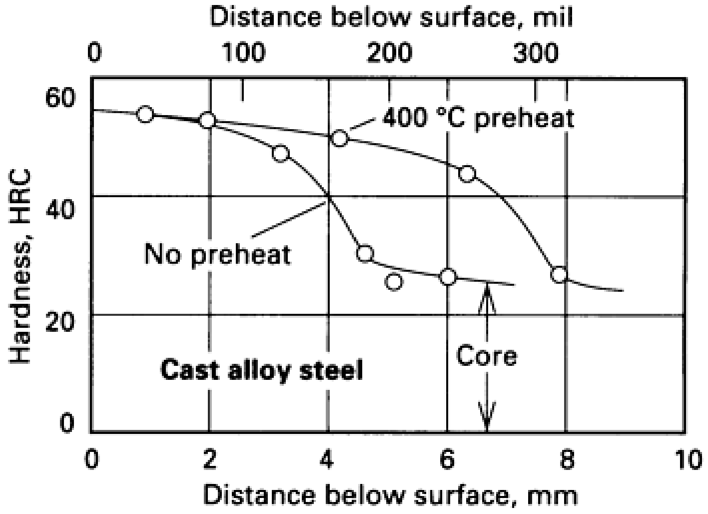

Fig. 12 Effect of preheating on hardness gradient in a ring gear. See Table 7 for preheating procedure.

The flame hardening of prehardened and tempered steels, especially some of the alloy steels, requires careful control of heating to avoid cracking. Preheating the part may be advisable to minimize cracking in such steels. Hardenable cast iron is also susceptible to cracking. In one application, cast iron crane wheels had to be preheated to 480 °C (900 °F) to prevent the rupture of the spokes caused by nonuniform expansion during the spin heating of the tread area.

In another application, the difficulty of heat treating the internal teeth of a planetary-gear housing was overcome by spin hardening. The component had an irregular mass distribution, which led to large distortions when heat treating was done by ordinary flame-hardening or induction-hardening equipment. The case hardening of teeth also failed. The problem was solved by using a specially designed gear wheel spin-hardening machine with close control over heating time and power and by preheating the part with the largest mass and cross section to an accurately predetermined temperature (Ref 3).

3. Surface Hardening Gets Better, *Iron Age Metalworking International*, Dec 1969, p 34-35

Depth and Pattern of Hardness

In some instances, the flame-hardening procedure results in a greater depth of hardness than desired. Figure 5(a), for example, shows that spot hardening a rocker arm pad after heating 4 s at 870 °C (1600 °F) with oxyacetylene flame produces a depth of hardness of 5.1 mm (0.200 in.). If excessive, this depth may be reduced by heating the steel to the same temperature but in a shorter time. Thus, with a reduction in heating time to 3.2 s at 870 °C, the depth of hardening will be 2.5 mm (0.100 in.) (Fig. 5a). Because of the shorter heating period, the cost of hardening each pad will also be reduced.

The problem of excessive depth resulting from a spin-hardening operation may be resolved similarly, as shown in Fig. 5(b). In this operation, heating with an oxyacetylene flame for 13.5 s at 870 °C (1600 °F) produces a hardness depth of 7.6 mm (0.300 in.). Heating at the same temperature for a period of 8 s results in a hardened depth of about 3.8 mm (0.150 in.).

In a progressive-hardening operation with a rate of travel of 1.7 mm/s (4 in./min), a hardness depth of 5.1 mm (0.200 in.) will be produced when the heating time is 12 s at 870 °C (1600 °F), as shown in Fig. 5(c). The flame head contains two

rows of flame holes that produce a heating zone 20 mm (0.8 in.) wide. If the rate of travel is increased 20% to 2 mm/s (4.8 in./min), the heating time is proportionately reduced to 10 s. This results in a hardened depth of about 2.5 mm (0.100 in.).

Variation in depth of hardness may occur in steels of the same nominal composition but from different heats. This is demonstrated in Fig. 13, which shows the variation in depth of hardness obtained in flame hardening hubs made of 1062 steel from three different heats. The inside diameters of these hubs were flame hardened for 12 s to produce a minimum hardness of 59 HRC at a depth of 1.9 mm (0.075 in.).

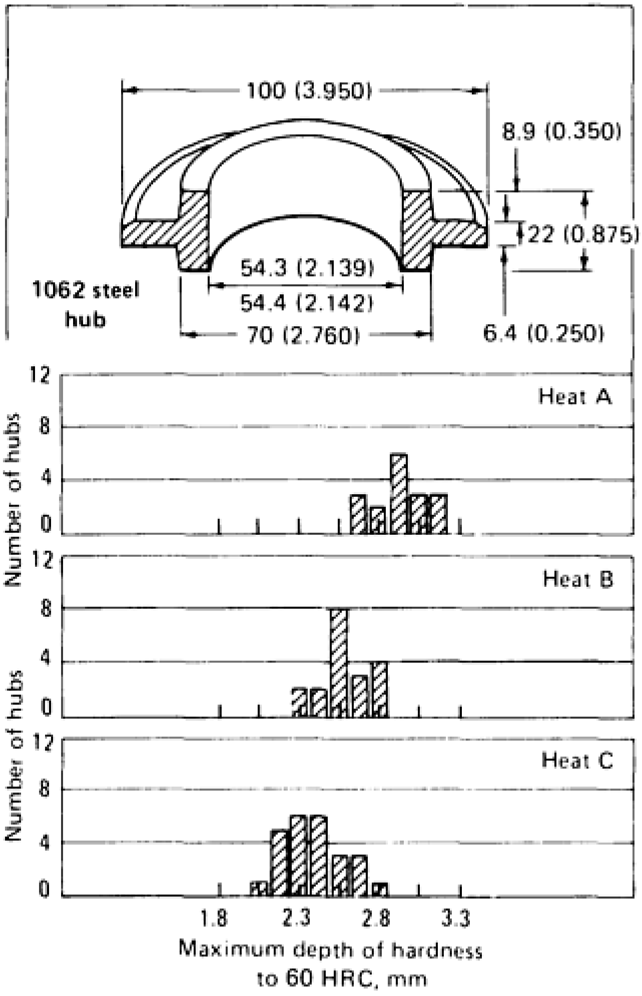

Fig. 13 Heat-to-heat variations in depth of hardness among three heats of 1062 steel hubs flame hardened on the inside diameter to a minimum of 59 HRC at 1.9 mm (0.075 in.) below the surface. Hubs were heated 12 s and quenched in oil. Hardness was measured on cross sections of heated area. Dimensions given in millimeters and, in parentheses, inches

Surface Hardness Pattern. The hardness pattern of any portion of a flame-hardened surface can be determined by lightly blasting the area with fine sand. The hardened portion of the surface will be less affected than the unheated area by the cutting action of the sand. This procedure may also be employed to indicate soft spots when the entire surface has been subjected to flame hardening. (Soft spots may result from nonuniform heating or the interference of scale on the surface.) Another procedure for determining the surface hardness pattern is to etch the area with a 10% nitric acid solution. The hardened area will appear darker than the unhardened area.

These procedures are also applicable to cross sections of hardened areas for an indication of heat penetration, and they are useful as preliminary checks on the performance of the flame-hardening setup.

Variations in the hardness of the surface are exemplified by the data shown in Fig. 14. These hardness readings taken on the surface of races made of 4063 steel cover a one-month period. The races were heated for 9 s to produce a minimum hardness of 59 HRC at 1.3 mm (0.050 in.) below the surface.

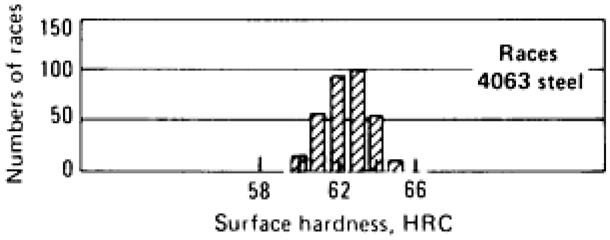

Fig. 14 Distribution of surface hardness. Results obtained during 1 month of testing flame-hardened races (4063 steel) that were heated for a total of 9 s to produce a minimum hardness of 59 HRC at a depth of 1.3 mm (0.050 in.)

Summary. Hardness of the case in flame hardening is a function of the carbon content of the steel and will range up to 65 HRC. Medium-carbon steels with 0.40 to 0.50% carbon are ideal for flame hardening, but steels with carbon contents as high as 1.50% also can be flame hardened with special care. Normally, hardening depth ranges from 1.3 to 6.4 mm (0.05 to 0.25 in.). Heavier sections, such as large rolls and wheels, can have case depths of up to 13 mm (0.5 in.). Manganese-bearing alloys aid in the depth of hardening by decreasing the critical cooling rate, which contributes to deep hardening. Therefore, manganese and free-machining grades of steel are considered excellent for flame hardening.

When hardening depths are required beyond the capabilities of ordinary carbon steels (0.60 to 0.90% Mn), elevated manganese ranges such as 0.80 to 1.10%, 1.00 to 1.30%, or 1.10 to 1.40% can be used efficiently. Wear resistance in many cases is not the only critical design criterion. Under high compressive loading, the hardened layer must be deep enough not only to provide the required wear life of the part, but also to contribute to the support of heavy contact loads. The case must be fully martensitic, and the material supporting the hardened layer must be of sufficient strength. However, increased hardenability may lead to cracking problems, at least with water quenching.

Maintenance of Equipment

Oxy-Fuel Gas Type Flame Heads (Nonferrous). Experience with nonferrous flame heads of three types of construction (drilled face, screw-in tips, and press-in tips) has shown carbon deposit, lack of proper cooling, erosion, and corrosion to be the main causes of maintenance problems common to all.

Carbon Deposit. The intermittent igniting and extinguishing of the flame causes a small deposit of carbonaceous material to build up on the sidewalls of the port, from the retrogression of the burning fuel below the orifice of the port as the flame is extinguished. Although small for each cycle, the deposit builds up gradually until it causes a restriction in the port and thus a variation in the velocity of the gas and therefore in the heating performance. Several thousand cycles may be completed before it is necessary to clean the head.

A slight amount of cleaning can be done without removing the head from the mixer tube. This is done by pushing through the ports a wire of the proper size or a drill one size smaller than the ports. However, care must be exercised to prevent bell mouthing or increasing the size of the port. Cleaning by this method deposits loose carbonaceous material in the fuel chamber, and this material, propelled by the velocity of the oxygen and fuel-gas mixture, may become lodged in other ports.

Flame heads operating on volume production should be removed from the machine and thoroughly cleaned after 40 to 120 h of operation. The interval depends on the installation, the oxygen and fuel gas mixture, and the heating cycle time.

Drilled-port and insert-port heads, when removed, can be cleaned by inserting in the ports a wire of the proper size or a drill one size smaller than the ports and then immersing the heads in a suitable solvent or cleaner that will loosen the carbonaceous deposits. Again, care must be exercised to prevent bell mouthing or enlarging of the port. Also the cleaner

or solvent must not attack the head itself. After cleaning and rinsing in clean water, all traces of dirt and moisture should be blown from the ports, fuel chamber, and water lines. Screw-in tips and heads may be cleaned in the same manner.

Erosion and Corrosion. All types of heads are subjected to the by-products of combustion, which may attack the face of the burner or the tips, causing erosion and corrosion. A flash plate of chromium on the burner face has proved to be helpful in reducing erosion and corrosion. In time, the face of a drilled-port burner may erode to a point at which it is necessary to reface the head by machining and reworking the counterbore. If there is enough space between ports on drilled-port heads, the port can be repaired by drilling oversize and pressing in an insert. These inserts can be removed and replaced when necessary.

Because the oxy-fuel gas type of flame head is water cooled, it may be necessary, in localities where extremely hard water is supplied, to soften the water to keep scale from forming in the cooling passages; commercial water softeners of the zeolite or polyphosphate type may be used. Recirculating systems with heat exchangers are sometimes required.

Air-Gas Type Burners. Failures of air-gas burner liners occur by spalling, erosion, and cracking of the refractory cup or tunnel and outlet. These liners should be inspected periodically, at intervals determined by experience with the individual installation; when conditions are severe, inspection may be required as often as once every shift.

The causes of deterioration of burner liners are thermal shock from repeated rapid heating or cooling (or both) and mechanical shock from work striking the burners. The burner casings deteriorate mainly from prolonged exposure to escaping hot gases that heat the casings locally, causing more or less progressive oxidation, cracking, growth, and, infrequently, burning. If installation space permits the use of water or air cooling, these can usually be expected to increase the life of burners. Shielding, designed to conduct hot gases away from the burners and other parts of the machine, is also valuable in reducing maintenance costs.

Mechanical Components. Because both oxy-fuel and air-fuel gas systems employ pressure gages, pressure regulators, valves, flowmeters, and safety devices, the maintenance problems associated with these accessories are common to both methods of flame hardening. Symptoms and probable causes of trouble with several mechanical components used in flame hardening are listed in Table 9.

Table 9 Maintenance problems in flame-hardening equipment

Component	Symptom of trouble	Probable cause
Pressure gage	Erratic behavior	Mechanical damage to mechanism
Gas supply pressure regulator	Failure to hold pressure setting at outlet	Broken or hardened diaphragm
		Too taut diaphragm
		Sticking stem or valve parts
		Damaged or dirty valve seat or plugged orifices or vents
		Broken or damaged spring
Solenoid valve	Failure to close or open	Defective valve mechanism or wiring
Fuel valve	Flame lingers after shutoff	Dirty seat or stem; damaged seat

Oxygen valve	Flame popping after shutoff	Damaged seat

Air-gas systems also have maintenance problems related to their compressors and blowers. Devices for protection against backfire and explosion should be serviced according to manufacturer instructions.

Electrical Components. Electrical contacts should be cleaned periodically; when the heating cycle is controlled by a timer, periodic checks of the timer are advisable. Generally, if the heating cycle is inaccurate, it will be evident in the inspection of the parts. If the heating cycle is controlled by a thermopile, several items must be checked: Excessive flow of cooling water through the housing will cause condensation on the lens; a deposit of any type on the lens will cause erratic results; and in high-production work, the lens should be cleaned at least twice each shift, and the temperature recorder should be balanced once each shift.

Spindle and Movable Holding Fixtures. It is important that positioning of the parts and the flame head be consistent. Therefore, holding fixtures and spindles should be periodically cleaned, checked, and lubricated. Any worn part should be replaced before it becomes improperly located.

Piping. Types of piping and fittings recommended by underwriters should be used in installing the gas lines from the gas source to the site of use. In long gas lines, means should be provided for purging accumulated condensate from the line before the gas reaches the mixing chamber or torch.

Preventive Maintenance

A typical schedule of preventive maintenance for flame-hardening equipment includes:

Daily

- Check all solenoids for leaks; clean, repair, or replace, as necessary
- Replace damaged screw-in flame tips; clean dirty or clogged tips or ports
- Remove foreign material from surfaces of flame heads and movable machine parts
- Check for stable pilots
- Check for leakage of fuel gas, water, oxygen, and air
- Check level, circulation, and temperature of quench oil
- Clean lens of radiation pyrometer and balance the recorder
- Check oil level and flow of oil to spindle

Weekly

- Check liquid level in backflash arrestor
- Check relief valve on backflash arrestor
- Lubricate all movable parts as required
- Check all fuel-gas, oxygen, and air connections for leaks (using soap solution)

Bimonthly

- Remove and clean flame heads (frequency will vary with installation and use)

Semiannually or annually

- Remove, clean, and repair oxygen and fuel-gas regulators
- Remove, clean, and repair all solenoids
- Check electrical contacts and wiring

- Clean heat exchanger and quench tank
- Check orifice in mixing blowpipe
- Repack motor bearings

Safety Precautions

All fuel gases are explosive when mixed with either air or oxygen within their flammable limits. However, they are widely used throughout industry and are safe when properly handled, stored, and transported in compliance with established laws of safe practice. Stabilized MAPP combines the safety and handling ease of propane with the high heat energy of acetylene.

The following organizations have published information on cylinder storage, cylinder manifolding, acetylene generators, housing and piping systems, equipment, and operating procedures:

- American Gas Association,
- 1515 Wilson Boulevard,
- Arlington, VA 22209

- American Insurance Association,
- (formerly National Board of Fire Underwriters),
- 1130 Connecticut Avenue,
- Washington, D.C. 20036

- Compressed Gas Association,
- Crystal Gateway No. 1,
- Suite 501, 1235 Jefferson Davis Highway,
- Arlington, VA 22202

- Industrial Risk Insurers,
- (formerly Factory Insurance Association),
- 85 Woodland Street,
- Hartford, CT 06102

- National Fire Protection Association,
- Batterymarch Park,
- Quincy, MA 02169

Most state and local governments follow the recommendations of these organizations in adopting regulations pertaining to gases. A study of local regulations should be made to determine whether there is any variance from standard procedures.

Operators should be taught to keep equipment clean, free of grease and oil, and in good condition and to avoid leaks of oxygen or fuel gas by regularly testing them with soapy water free of oil and grease. They should open oxygen or fuel-gas valves slowly and be sure that the lines are purged before igniting. An air hose should be available for dispersing fuel gas that has been bled from the lines. Any spaces in and around the machine in which gases might accumulate should also be purged with the air hose. No flame or other source of ignition should be allowed in proximity to the area where fuel gas or oxygen is released into the air, and good ventilation is of primary importance.

Operators should recognize backfires or backflashes immediately and shut off the gases; the cause and extent of damage must be determined, and corrections made, before the torch is reignited. To prevent major explosions, a backflash arrestor must be installed in the fuel line.

Hand friction lighters should not be used to ignite the gases, except for very small flame heads of low gas capacity. A flame from an acetylene torch or a burner using some other gas should be used. The pilot flame should be very close to the heating head to prevent the accumulation of gas and oxygen before ignition. For automatic flame-hardening machines, the pilot light can be permanently mounted (in which case a flame detector and alarm system should be installed to give warning when the pilot light is extinguished accidently), or electric spark ignition can be used. When operations are stopped for any length of time, the valves in the main supply lines should be closed. These valves must not leak because even a small leak can cause a dangerous accumulation of gas.

Oil or grease may ignite violently in the presence of oxygen under pressure and must be kept away from cylinders, regulators, hoses, and other apparatus. The storage of fuel-gas cylinders must be in accordance with standards established by the Occupational Safety and Health Administration and the National Fire Protection Agency. The allowable amounts of indoor gas storage is limited, and cylinder manifold design must meet the appropriate requirements.

The cylinders in a manifold should be secured with clamps or chain to prevent them from tipping or falling. A fall or any severe bump can detonate acetylene, with disastrous consequences. Propane is not likely to detonate, but any gas under pressure is dangerous if the valve is damaged or knocked off the cylinder. In some instances, noise can be a problem in a gas-air system. Equipment should be designed to keep the noise level within generally accepted limits to avoid injury to nearby personnel.

Quenching Methods and Equipment

The proper application of a suitable quench in flame hardening is as important as proper heating. The quench must remove heat at a rate that will produce the desired structure and assist in controlling the depth of the hardened case.

The method of quenching and type of quenchant vary with the method of flame hardening. In spot hardening, immersion quenching is generally used, but spray quenching may be used.

Quenching after Progressive Heating. Parts heated by the progressive method are usually quenched by a spray integrated into the flame head, although for steels of high hardenability, or when it is desirable to vary or adjust the distance between the heated zone and the quench, a separate spray-quench head is sometimes used. The spray quench should issue from the head at an angle away from the flame head to prevent interference with heating and must provide full coverage over the heated band. The integrated type commonly sprays the quenching medium on the work 19 to 32 mm ($\frac{3}{4}$ to 1 $\frac{1}{4}$ in.) behind the last row of flames. When the surface to be hardened by the progressive method is vertical or overhead, additional cooling may be required after the usual spray quench.

Quenching after Spin Heating. Parts heated by the spinning method can be quenched by several different procedures. In one, the heated part is removed from the heating area and quenched by immersion in a separate quench tank. Another method integrates quenching by making the quench tank a part of the flame-hardening machine. Parts may be heated on the machine spindle or arbor and then quenched by being dropped into a quench tank located immediately below the arbor. Parts that are either too heavy or too fragile to be dropped may be lowered into the quench by means of arms or may be lowered into the quench while still on the arbor. Parts may be removed manually from the quench or automatically by means of a conveyor belt. A spray-quenching ring is sometimes submerged in the quench bath to increase the cooling rate.

Parts heated by the spinning method may also be quenched with quench blocks on the same plane as the flame heads. When the heating cycle is completed and the flames are extinguished, the quench is turned on. The quench blocks should cover the heated band and provide enough quenching liquid to obtain suitable and uniform hardness. There should be enough quench points around the periphery of the block to envelop the area completely with quenchant. Water or a polymer quench solution is usual for this type of quench because of the hazard of contaminating the heating heads with oil. When oil quenching is used, the oil should not contact the heating head. This may be avoided by indexing the heated part to a separate quenching station or by retracting the heating heads into a shielded area.

When air-fuel gas mixtures are employed in spin-hardening operations, the heat pattern developed, in many instances, extends beyond the limits desired. Immersion quenching in such instances could extend the hardening into areas requiring subsequent machining or contribute to an excessive amount of distortion. Localized quenching, such as that provided by quench rings, is a solution to this problem. For example, this quenching method was used in hardening the teeth of large sprockets weighing about 205 kg (450 lb). The entire tooth surface, including the root, was hardened to a depth of 4.8 mm

($\frac{3}{16}$ in.). The 10-min heating cycle completely heated the teeth and backup rim. When quenching was done by rotation of the sprocket in a ring of water spray nozzles, hardening was confined to the desired surfaces and the backup rim remained soft. A similar practice is used for hardening large gears. Parts heated by the combination progressive-spinning method are usually quenched by a spray integrated in the flame heads or by separate quench blocks located below the flame heads.

Quenching Media

With spray quenching, either integrated in the flame head or by separate quench blocks, water or a dilute polymer solution is used as the quenching medium. Quenching oils should not be allowed to come into contact with oxygen or to contaminate equipment using it. As with conventional hardening, the alloy content of the steel determines the type of quench that should be used. The quenchant may be water, a brine solution, the glycol-base polymer quench, or air.

By reducing the pressure of the quenchant, the rate of cooling by spray quenching can be reduced from the maximum for which the integrated or separate quench blocks are designed. Increasing the distance between the last row of flames and the point at which the quenchant impinges will allow the mass of metal below the area to be hardened to extract heat and thus will decrease the severity of quenching.

Quenching distance is another factor the operator must consider because the quenchant must strike the heated area while it is still at the critical temperature to avoid the formation of pearlite or other undesirable transformation products in the microstructure. If the spray head is angled too close to the flame, spotty hardness and blowouts can occur. If the angle of spray is too far away, the case may not be fully hardened.

Forced Air. In progressive hardening operations, forced air is frequently used as the quenchant for steels normally considered to be oil-quenching steels. Water is not used immediately after heating because the fast cooling action would result in surface checks. Because most of these steels have relatively low Ar_3 transformation temperatures, the forced air quickly reduces the surface temperature to a point at which water can be applied without causing surface checks. The resulting hardness is usually close to that obtained with a direct oil quench. For example, 52100 steel quenched with forced air and then with water attains a surface hardness of 60 to 61 HRC.

Forced-air quenching is also used in applications in which intermediate hardnesses are required. One example is the hardening of railroad rail ends to reduce "end-batter" by the impact of car wheels. The rails are indexed under the burners in four preheat stations and one high-heat station (high-temperature, high-velocity burner), which heats the rail to the hardening temperature of 870 °C (1600 °F) in 95 s. In a sixth station, air at 690 kPa (100 psi) is directed against the heated surface. This treatment results in a hardened structure of fine pearlite that provides wear resistance and sufficient ductility to withstand the impact of moving wheels. Water is unsuitable in this application because the high-carbon rail steel is susceptible to cracking. Rail lengths for curves, crossovers, and switches are similarly hardened; however, for these, hardening is done progressively, using oxy-gas burners and air quenching.

Immersion quenches vary in type in relation to the metal used, the hardness and depth desired, and the mass, design, and dimensional tolerances of the part. The quenching medium can be a caustic or brine solution, water, a soluble-oil emulsion, or any of a large variety of oils or simulated oils such as polymer quenches.

Self-Quenching. During any type of flame hardening other than through hardening, the mass of cold metal underneath the heated layer aids quenching by withdrawing heat. Thus, cooling rates are very high compared with rates for conventional quenching. During the progressive hardening of the teeth of gears made from medium-carbon steels such as 4140, 4150, 4340, and 4640, for example, the combination of rapid heating and the temperature gradient between the surface and the interior of the gear results in a subsequent self-quench that is equivalent to quenching in oil.

For uniform quenching, a coolant can be used at some distance from the tooth being heated. In one application involving hardening the teeth of 4150 steel gears in the size range of 4 to 12 pitch, one tooth at a time was heated and cooled by conduction. The coolant was directed at the body of the gear. With this procedure, the hardness of the teeth was 50 to 55 HRC after the gears had been tempered at 200 °C (400 °F).

Flame-Hardening Problems and Their Causes

Problems that may occur in flame hardening and their causes are:

Overheating

- Controlling pyrometer set too high
- Millivolt compensator of controlling pyrometer set incorrectly
- Heating cycle too long
- Flame heads too close to work
- Oversize flame ports
- Excess oxygen in flame
- Excessive fuel-gas pressure
- Improper pattern of flame tip

Hardness below minimum required

- Controlling pyrometer set too low
- Millivolt compensator of controlling pyrometer set incorrectly
- Heating cycle too short (underheating)
- Severity of quench too low
- Delay before quenching too long
- Part not thoroughly quenched
- Material hardenability too low for quench
- Surface decarburized

Spotty or uneven hardening

- Nonuniform heating
- Time interval between heating and quenching too short
- Quenching medium not sufficiently agitated
- Water in quenching oil
- Scale on work
- Improper quenching medium
- Surface decarburized

Distortion

- Shape of part or relationship of portion to be hardened to remainder of section not well adapted to flame hardening
- Metallurgically unsuitable prior structure
- Heating cycle too long
- Nonuniform heating
- Nonuniform quenching
- Excessive rate of quenching
- Material hardenability excessive

Shallow depth of hardening

- Material of low hardenability
- Excessive rate of gas flow; check for oxidizing flame
- Flame-port velocity too high
- Controlling pyrometer set too low
- Millivolt compensator of controlling pyrometer set incorrectly
- Short heating cycle or excessive scanning speed
- Severity of quench too low

- Delay before quenching too long

Excessive depth of hardening

- Low flow rate of gas; check for reducing flame
- Excess fuel gas in flame
- Controlling pyrometer temperature set too high
- Millivolt compensator of controlling pyrometer set incorrectly
- Flame port velocity too low

Excessive scaling

- Heating cycle too long
- Rates of gas flow too low
- Flame velocity too low
- Delay before quenching too long
- Improper arrangement of flame heads around periphery; overheating or banding

Tempering of Flame-Hardened Parts

It is usually desirable to temper parts that have been flame hardened; the need for tempering martensite is the same regardless of the heat-treating method used to produce it. Flame-hardened steel will respond to a tempering treatment in the same manner as it would if hardened to the same degree by any other method. Standard procedures, equipment, and temperatures can be used. However, for work that is flame hardened because it is too large to be heated in a furnace, flame tempering may be the only feasible method of tempering available.

Flame Tempering. Large articles are usually hardened by the progressive method and can be tempered immediately by reheating the hardened surface with a flame head placed a short distance behind the quench. The reheating or tempering flame head must be designed correctly in regard to number and size of orifices or tips (flame ports) to produce the desired work temperature and temperature gradient in the flame-hardened zone at the flame-hardening speed.

Exact final adjustments can be made by varying the flow of gases through the flame head and by adjusting the distance between flame head and work surface. Tempering flame heads must have smaller heat outputs than hardening flame heads because the too-rapid heating of the hardened zone can cause cracking and because, for tempering, the temperatures required are lower and temperature control is usually more critical.

Self-Tempering. On large parts flame hardened to depths of about 6.4 mm ($\frac{1}{4}$ in.) or more, the residual heat present after quenching may be sufficient to accomplish satisfactory relief of hardening stresses, and subsequent tempering in a separate operation may be unnecessary. Air-fuel gas heating, because of its lower rates of heat transfer, promotes the development of the deep-seated heat required for self-tempering.

When residual heat cannot be used and it is desirable to eliminate the separate tempering operation, the use of a lower-carbon steel is suggested if hardness requirements permit. The preheating of heavy parts increases the residual heat available for tempering. For this purpose, preheating may be accomplished by either heating the part in a furnace, if feasible; or by spinning the part in the burner ring with the burners firing at reduced or idling input. The choice depends on the availability of equipment and the economics involved. The exact preheat temperature will vary, depending on the size and configuration of the part and the degree of stress relief or temper desired. In each application, the exact schedule may be established on a trial basis as a preliminary step.

Surface Conditions

For wrought and cast steel parts, the surface conditions likely to be detrimental to successful flame hardening are, in general, those that interfere with heating or quenching, cause localized overheating, initiate cracking, or result in the presence of a soft surface skin after proper heating and quenching.

Table 10 summarizes the more common defects or conditions, their origins, and the detrimental effects to be expected when they are present on flame-hardened areas. The extent of these defects determines the amount of difficulty they may cause.

Table 10 Surface conditions detrimental to flame hardening of steel parts

Defect or condition	Probable origin of condition	Detrimental effects to be expected on flame-hardened areas
Laps, seams, folds, fins (wrought parts)	Rolling mill or forging operations	Localized overheating (or, at worst, surface melting), with consequent grain growth, brittleness, and greater hazard of cracking
Scale (adherent)[(a)]	Rolling or forging; prior heat treatment; flame cutting	Insulating action against heating, with resulting underheated areas and soft spots
		Localized retardation of quench, causing soft spots
Rust, dirt[(a)]	Storage and handling of material or parts	Similar to scale condition as noted above left
		Severe rusting may result in surface pitting that will remain after hardening.
Decarburization	Present in as-received steel bar stock; heating for forging or prior heat treatment of parts or stock	In severely decarburized work, no hardening response will be found when parts are tested by file or other superficial means[(b)].
Pinholes, shrinkage (castings)	Casting defects	Localized overheating (or, at worst, surface melting), with consequent grain growth, brittleness, and greater hazard of cracking
Coarse-grain gate areas (castings)	Casting gates located in areas to flame hardened (avoid, if possible)	Increased cracking hazard during quenching, compared with nongated areas; shrinkage defects also likely in these areas
Improper welds	Parts welded with an alloy dissimilar to base metal	Weld zone reaction dissimilar to base-metal reaction. Weld may separate, requiring rewelding or scrapping of the part[(c)].

(a) In addition to having detrimental effects on flame-hardened surfaces, scale, rust, or dirt in the path of the flame may become dislodged and cause fouling of oxy-fuel gas burners or react chemically with ceramic air-fuel gas burner parts (causing rapid deterioration). When such materials enter a closed quenching system, they may clog strainers, plug quench orifices, and cause excessive wear of pumps.

(b) Partial decarburization lowers surface hardness as a direct function of actual carbon content of stock lost at surface, provided that steel was adequately heated and quenched.

(c) To avoid these and other problems, it is mandatory that the flame hardener be given accurate and complete information on any changes in composition and past processing of the part. For example, previously hardened parts should never be flame hardened unless they have been

annealed; otherwise, cracking is inevitable.

Dimensional Control

Because of its ability to heat specific areas of a part selectively, flame hardening in many applications affords greater control of dimensional stability than is obtainable by furnace heating and quenching. The magnitude of the dimensional changes that occur in flame hardening is influenced by such factors as size and shape of the part, area heated, depth of heating, hardenability, and quenching medium. Figure 15, for example, shows the various dimensional changes that occurred from the flame hardening of converter gear hubs.

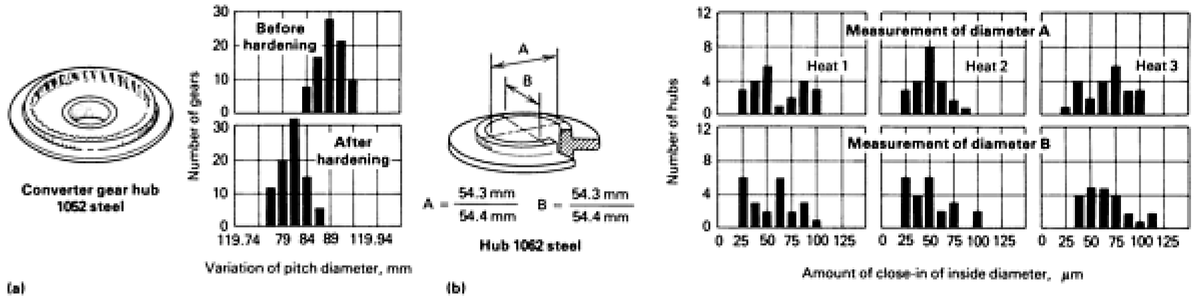

Fig. 15 Distribution of dimensional change as a result of flame hardening. (a) Change in pitch diameter of converter gear hubs made of 1052 steel. Gear teeth on inside diameter were heated for a total of 9.5 s, before being quenched in oil to provide a depth of hardness of 0.9 mm (0.035 in.) above the root. (b) Close-in of inside diameters of converter hubs made of 1062 steel. Inside diameter was heated for a total of 12 s and then oil quenched to harden to 59 HRC min at a depth of 1.9 mm (0.075 in.) below the surface. Inside diameter was finish ground after hardening.

Selection of Process

Flame hardening is basically adaptable to surface hardening and to the through hardening of selected areas. Manufacturing specifications often call for the heat treatment of an entire part, but in many cases this is not necessary. Crane wheels, mill rolls, and gears are examples of items for which flame hardening can be used to harden only the working surfaces. Dies often require hardening only along parting lines or in forming areas.

Other hardening processes that may be applicable for accomplishing the same purposes include:

- Induction hardening for surface or through hardening
- Carburizing, nitriding, and other furnace processes in which surface composition is altered to permit hardening of the case
- Application of hard facing materials to surfaces
- Through hardening of selected sections by partial immersion in molten lead or salt baths

Table 11 lists the different processes in use and describes the benefits realized from each.

Table 11 Relative benefits of five hardening processes

Carburizing	Hard, highly wear-resistant surface (medium case depths); excellent capacity for contact load; good bending fatigue strength; good resistance to seizure; excellent freedom from quench cracking; low-to-medium-cost steels required;

	high capital investment required
Carbonitriding	Hard, highly wear-resistant surface (shallow case depths); fair capacity for contact load; good bending fatigue strength; good resistance to seizure; good dimensional control possible; excellent freedom from quench cracking; low-cost steels usually satisfactory; medium capital investment required
Nitriding	Hard, highly wear-resistant surface (shallow case depths); fair capacity for contact load; good bending fatigue strength; excellent resistance to seizure; excellent dimensional control possible; good freedom from quench cracking (during pretreatment); medium-to-high-cost steels required; medium capital investment required
Induction hardening	Hard, highly wear-resistant surface (deep case depths); good capacity for contact load; good bending fatigue strength; fair resistance to seizure; fair dimensional control possible; fair freedom from quench cracking; low-cost steels usually satisfactory; medium capital investment required
Flame hardening	Hard, highly wear-resistant surface (deep case depths); good capacity for contact load; good bending fatigue strength; fair resistance to seizure; fair dimensional control possible; fair freedom from quench cracking; low-cost steels usually satisfactory; low capital investment required

Source; Ref 5

Induction hardening and flame hardening are the most effective methods for selectively hardening portions of a part (gear teeth, for example) without affecting other areas. A 4150 steel shaft, 760 mm (30 in.) long, with a 25 mm (1 in.) long gear at one end, can be core hardened to 26 to 32 HRC all over (a good machining hardness), and the gear can be hardened to 55 to 60 HRC by flame or induction hardening. If carburizing or nitriding were used instead, the main shaft would have to be masked with copper, which would have to be stripped away after hardening.

The differences between these three basic types of surface-hardening processes can be small enough for certain applications that their feasibilities overlap. For example, a ring gear used in almost identical applications has been made for four customers using four different surface-heating procedures: induction hardening a 4150 steel gear, with or without separate core hardening, depending on the specific application; flame hardening the teeth of a 1045 steel gear; carburizing an 8620 or 9310 steel gear, and then finish grinding; and core hardening a 4150 steel gear to 32 to 34 HRC and then nitriding.

Careful analysis, however, would no doubt show that one of the four variations would be most economical. Examples of false economy are common. A company might save 25¢/kg on steel but have to pay twice that amount for hot or cold straightening to correct the distortion caused by the lower heat treatability of the lower-cost steel.

In selecting a flame-hardening process, consideration must be given to the method of applying the flame to the work and to the choice of gas mixture. Oxy-gas equipment differs significantly from air-gas equipment in the design of the systems that control, deliver, and burn the gas mixtures.

The heating characteristics of the combustion mixture largely determine the degree to which the hardening and heat-affected zones can be localized in the workpiece. Shallow hardness patterns (less than 3.2 mm, or $\frac{1}{8}$ in., deep) can be obtained with oxy-gas mixtures because the higher-temperature flames produced will provide a sufficiently rapid heat transfer to localize the heat pattern effectively. Deeper hardness patterns may permit the use of either oxy-gas or air-gas mixtures. With oxy-gas mixtures, the heat is localized, but care is required in controlling the heat release rate to avoid overheating the surface during the development of the deeper-seated heat.

Air-gas mixtures, because of the lower rate of heat transfer obtained with them, reduce the tendency toward surface overheating but generally extend the heat-affected zone well beyond the desired hardness pattern. For this reason, air-gas flame hardening is generally limited to those applications in which the portion to be hardened may be through heated or in which materials of shallow hardenability are used. In the latter instance, the depth of the hardness pattern is primarily controlled by quenching rather than by heating intensity. Because of potential excessive distortion, the deeper-seated heat developed in a part by air-gas flames may preclude the use of this heating medium.

In view of these considerations, the success of air-gas flame hardening largely depends on the configuration of the part insofar as that configuration favors heat localization with its lower rates of heat transfer. In selective through hardening of gear and sprocket teeth, flanges, ribs, edges, and similar projections, air-gas flame heating may be applied. On the other hand, the surface hardening of gear teeth, rolls, journals, shaft areas, machineways, wear areas of forming dies, inside and outside diameters of hubs, and massive sections is usually done with oxy-fuel flame equipment. Small parts frequently require the very small, easily controllable flame characteristics obtainable with oxy-fuel burning equipment.

When more than one mode of flame application or combustion-gas mixture can be used for a flame-hardening operation, the selection of process and equipment becomes primarily an economic consideration. The equipment may then be chosen on the basis of the expected cost involved in meeting immediate and anticipated production requirements.

Whether or not a flame-hardening process is selected in preference to other hardening processes for a specific application is commonly determined on the basis of the suitability of the process for producing the required results, control of distortion, and cost. A specific example of the selection of flame hardening as a method of hardening is described below.

Example 2: Flame Hardening versus Induction Hardening of Sprocket Teeth.

Because of service failures and to avoid a design change, a sprocket manufacturer changed from induction hardening to flame hardening of sprocket teeth (Fig. 16). When induction hardened, the sprockets were failing in the web area. Failure was attributed to high stress concentration resulting from the induction through hardening of the teeth and rim. Continued use of induction hardening would have required major redesign of the part and remaking of a costly forging die.

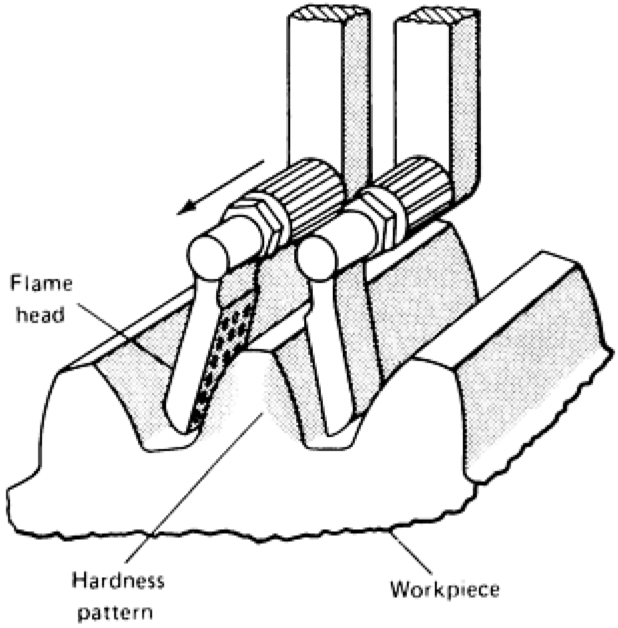

Fig. 16 Hardness pattern developed in sprocket tooth when standard flame tips were used for heating. When space permits the use of this methods, hardening one tooth at a time results in low distortion.

For flame hardening, the sprocket was indexed on a small positioner, and standard flame-hardening tips were moved across the face of the tooth by means of a small flame-cutting dolly. Warm-water quenching was used to eliminate the slight surface checks that had developed with cold-water quenching. Figure 16 shows the hardness pattern developed by the standard flame tips. Failures were eliminated, sprockets hardened by this method had excellent wear qualities, and the cost of hardening was not increased.

Selection of Material

The use of flame hardening is limited to hardenable steels (wrought or cast) and cast irons. Typical hardnesses obtained for various grades of these materials by flame heating and quenching in air, oil, or water are given in Table 12.

Table 12 Response of steels and cast irons to flame hardening

Material	Typical hardness, HRC, as affected by quenchant		
	Air[a]	Oil[b]	Water[b]
Plain carbon steels			
1025-1035	. . .	. . .	33-50
1040-1050	. . .	52-58	55-60
1055-1075	50-60	58-62	60-63
1080-1095	55-62	58-62	62-65
1125-1137	. . .	. . .	45-55
1138-1144	45-55	52-57[c]	55-62
1146-1151	50-55	55-60	58-64
Carburized grades of plain carbon steels[d]			
1010-1020	50-60	58-62	62-65
1108-1120	50-60	60-63	62-65
Alloy steels

Class 80-60-03	. . .	52-56	55-60

(a) To obtain the hardness results indicated, those areas not directly heated must be kept relatively cool during the heating process.

(b) Thin sections are susceptible to cracking when quenched with oil or water.

(c) Hardness is slightly lower for material heated by spinning or combination progressive-spinning methods than it is for material heated by progressive or stationary methods.

(d) Hardness values of carburized cases containing 0.90 to 1.10% C

Maximum hardness is not the sole criterion used in selecting flame hardening as a heat treatment. Proper steel selection is essential to minimize distortion, for example. Plain carbon steels should be used, if possible, instead of steels whose deep-hardening characteristics are more likely to incur higher internal stresses.

Some flame hardeners feel it is important to stress relieve all alloy steels and other steels with more than 0.40% carbon at 175 to 245 °C (350 to 475 °F), depending on customer specifications. This low-temperature tempering decreases hardness, but it also removes internal stress and restores toughness and ductility.

Selective heating has the disadvantage of developing residual tensile stresses in the surface. As one area of a piece of metal is heated while the remainder stays cold, the hot metal expands; if restraint is sufficient, the heated metal will upset itself. Upon cooling, this upset metal becomes short. As it cools to room temperature, it often stabilizes in a state of tension, which can be high enough to crack the part.

When a part is to be induction or flame hardened, the materials engineer should work closely with the designer to keep the level of hardness, and the necessary carbon, as low as possible, while still meeting engineering requirements. Carbon content is the most important factor determining the level of hardness that can be attained in steels by induction or flame heating. It controls hardness level, the tendency of the part to crack, and the magnitude of the part to crack, and the magnitude of residual surface stresses.

The practical level of minimum surface hardnesses attainable with water quenching for various carbon contents is shown in Fig. 17. The curve is applicable for induction hardening as well as for flame hardening. It applies also for alloy steels, except those containing stable carbide formers such as chromium and vanadium.

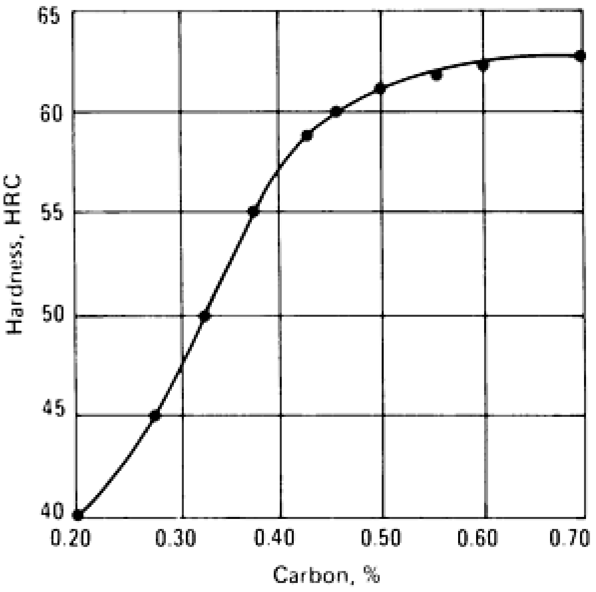

Fig. 17 Relationship of carbon content to minimum surface hardness attainable by flame or induction heating and water quenching. Practical minimum carbon contents can be determined from this curve.

For best results, steels to be induction or flame hardened should be as-rolled, normalized (particularly from a high temperature), air-blast quenched, or quenched and tempered. These preferred heat treatments result in microstructures conducive to rapid and complete austenitization and full hardening. In selecting steels for either induction or flame hardening, it is important that the necessary steps be taken to ensure that the areas to be hardened are free of decarburization. Depending on stock size, steel grade, producing mill, and several other factors, the depth of decarburization for as-rolled bar may run from near 0 to 3.2 mm (0.125 in.). It should not be assumed that turned and polished bar is free of decarburization unless it is specifically ordered with this requirement. Carbon-restored and cold-finished bar is available from mills in various carbon and alloy grades.

When maximum resistance to fatigue is desired, the hardened surface should contain residual compressive stresses; a recommended level is 172 MPa (25 ksi). Because surfaces hardened to depths of less than 1.9 mm (0.075 in.) are commonly residually stressed in tension, it is suggested that depth of hardening be at least 2.7 mm (0.105 in.) to ensure that residual stresses are compressive. This depth is particularly appropriate for manufacturers not equipped with residual stress-measuring equipment. Further, microstructure should be at least 90% martensite, with no ferrite visible at a magnification of 500×.

Carbon Steels. Plain carbon steels in the range of 0.37 to 0.55% C are the most widely used for flame-hardening applications. They can be through hardened in sections up to 13 mm ($\frac{1}{2}$ in.). This response permits the use of carbon steel for selectively flame-hardened small gears, shafts, and other parts of small cross section in which uniform properties are needed throughout the section. These same steels can be used for larger parts in which hardness is necessary only to shallow depths from 0.8 to 6.4 mm ($\frac{1}{32}$ to $\frac{1}{4}$ in.).

Carbon steels 1035 to 1053 are suitable for flame hardening; 1042 and 1045 are the most widely available and are recommended for all flame-hardening applications except when they would be incapable of meeting requirements, for example:

- Failure of a 1045 steel part to harden with a given quench would necessitate the use of a steel of higher hardenability, for example, one with higher carbon or manganese or both, or possibly an alloy steel
- If increased depth of hardening is required, 1042 or 1045 may be inadequate where heavy sections are progressively hardened; therefore, the substitution of 1541, 1552, or an alloy steel would be necessary
- In applications in which wear resistance is of prime importance, it might be advisable to use a steel with

0.60% C or more to produce maximum surface hardness. Steels this high in carbon content are often quenched in oil or simulated oil to avoid the possibility of cracking due to water quenching. Thus, greater hardenability may be needed with the higher carbon content

- When a severe quench in brine or caustic is required for hardening 1042 or 1045 steel and such quenching causes cracking, a steel of higher hardenability--either carbon or alloy, which can be hardened by a less severe quench--should be selected

Alloy Steels. The use of alloy steels for flame-hardening applications is justified only when:

- High core strength is required (through heat treatment before flame hardening) and carbon steels are inadequate to achieve this strength in the section sizes involved
- The mass and shape of a part, restrictions on distortion, or the hazard of cracking preclude the use of carbon steel quenched in water
- Certain alloy grades may be more readily obtainable than carbon grades (particularly the higher-manganese carbon grades) appropriate for the application. Steels such as 4135H, 4140H, 6150H, 8640H, 8642H, and 4340H are typical of the more readily obtainable alloy steels

Carbon and alloy steel castings are widely used for flame-hardening applications. The selection of a specific composition or grade is made on much the same basis as for wrought carbon and alloy steels.

Cast Iron. Gray cast irons, ductile irons, and pearlitic malleable irons having combined carbon contents of 0.35 to 0.80% can be flame hardened and will respond the same as steel.

Cast irons having less than 0.35% combined carbon will not respond readily to flame hardening because of the inability of austenite to dissolve graphite during the extremely rapid heating that occurs during flame hardening. Flame hardening these irons produces a typical hardness of about 40 HRC. Malleable iron, in which all the carbon is in graphitic form, is not amenable to flame hardening for this reason.

Cast irons having combined carbon contents greater than 0.80% are difficult to flame harden because of their inherent brittleness and susceptibility to cracking when heated and quenched rapidly. The low melting point of cast iron and the presence of graphite in the microstructure make cast iron susceptible to "burning" or even localized melting during flame hardening; therefore, extreme care must be taken to reduce the rate of heating when cast iron is hardened using equipment designed specifically for flame hardening steel. For example, the distance between the inner cone and the workpiece can be increased, or the flame velocity can be decreased. The use of a flame head with smaller orifices will also decrease the heating rate.

Perhaps the most significant factor in the response of cast irons to flame hardening is prior microstructure. Irons without free ferrite in their microstructure respond almost instantly to flame or induction heating and require very little holding time at the austenitizing temperature in order to be fully hardened. With a moderate amount of free ferrite, the response may be satisfactory, but an entirely ferritic matrix, typical of grades with high ductility, requires several minutes at 870 °C (1600 °F) to be fully hardened by subsequent cooling. A matrix microstructure of fine pearlite, readily obtained by normalizing, has a rapid response to surface hardening and provides excellent core support for the hardened case.

Other Materials. Flame hardening can be applied to other hardenable ferrous materials, for example, alloy cast irons, martensitic stainless steels, and tool steels. The nature of flame hardening, however--especially the relatively high-temperature gradients and higher-than-normal surface temperatures--may cause the retention of excessive amounts of austenite in many of the highly alloyed materials, with possible low hardness and transformation to untempered martensite in service, which is accompanied by brittleness.

Carburized parts made of plain carbon or alloy steels can be flame hardened to provide a hard case of high carbon content. The depth of carburized case may vary from a few hundredths of a millimeter to 1.6 mm ($\frac{1}{16}$ in.) or more. The flame-hardening procedure is adjusted to heat the carburized case to its full depth for hardening. Because the core of low-

carbon steel thus treated does not harden substantially, the method provides a means of accurately controlling the depth of hardened case.

Flame Annealing

The chemical reaction between oxygen and steel during flame cutting evolves intense heat, raising the temperature of the cut edge to the melting point on the surface and above the transformation temperature to a shallow depth. If the carbon or alloy content of the steel is high enough, hardening results when the heated zone is cooled rapidly.

Carbon steels containing 0.30% C or less do not harden sufficiently to prevent the use of flame-cut pieces in structures or in subsequent fabrication where bending is involved. When cut by flame, steels containing alloying elements and steels containing more than 0.30% C may harden sufficiently to prevent the use of flame-cut pieces for some purposes.

When hardening is likely to occur along a cut edge, oxyacetylene flames applied by suitable equipment can be used either to prevent hardening or to soften an already hardened cut surface. The term flame annealing is applied to this process and to the selective flame softening of areas of hardened steel parts. Tool steels and certain highly alloyed steels will crack during flame cutting, or very soon after, unless they are heated to temperatures ranging from 200 to 425 °C (400 to 800 °F) before being cut.

Laser Surface Hardening

Ole A. Sandven, Consultant, Trumpf Industrial Lasers, Inc.

Introduction

LASER SURFACE HARDENING of ferrous materials is an established process used to enhance the mechanical properties of highly stressed machine parts, such as gears and bearings. Surface hardening increases the wear resistance of the material, and under favorable circumstances, increases the fatigue strength caused by residual compressive stresses that are induced in the workpiece surface by the transformation hardening process. The surface hardening process is not fundamentally different from conventional through hardening of ferrous materials. In both processes, increased hardness and strength are obtained by quenching the material from the austenite region to form hard martensite. Surface hardening differs from conventional through hardening in that only a thin surface layer is heated to austenitization temperatures prior to quenching, leaving the interior of the workpiece essentially unaffected.

Because ferrous materials are fairly good heat conductors, it is necessary to use very intense heat fluxes to heat the surface layer to austenitization temperatures without unduly affecting the bulk temperature of the workpiece. This heat input is commonly obtained by the use of very hot flames or by high-frequency induction heating. By selectively heating the workpiece surface to austenitization temperatures, desired surface hardening is obtained by application of a quench medium to the hot surface, or by self-quenching. Self-quenching occurs when the cold interior of the workpiece constitutes a sufficiently large heat sink to quench the hot surface by heat conduction to the interior at a rate high enough to allow martensite to form at the surface.

In recent years, industrial lasers have become available for metalworking uses, including surface hardening. A laser can generate very intense energy fluxes at the workpiece surface, and the resulting temperature profiles in the workpiece usually can be made steep enough to negate the need for external quench media. The laser beam is a beam of light, which is essentially independent of the workpiece, easily controlled, requires no vacuum, and generates no combustion products. However, laser surface hardening also has some disadvantages that might limit its practical use in a heat-treating shop. These disadvantages may include the need for complex optics and the use of coatings because of the low infrared absorption characteristics of steel. In Europe, work has focused on an alternate technique using a Brewster-angle treatment without coatings.

Fundamentals of Laser Surface Hardening

When a laser beam impinges on a surface, part of its energy is absorbed as heat at the surface. If the power density of the laser beam (usually given in watts per square centimeter) is sufficiently high, heat will be generated at the surface at a rate higher than heat conduction to the interior can remove it, and the temperature in the surface layer will increase rapidly. In a very short time, a thin surface layer will have reached austenitizing temperatures, whereas the interior of the workpiece

is still cool. Even with a relatively moderate power density of 500 W/cm^2 (3200 W/in.^{2}), temperature gradients of 500 °C/mm (25 °F/mil) can be obtained. By moving the laser beam over the workpiece surface (see Fig. 1), a point on the surface within the path of the beam is rapidly heated as the beam passes. This area is subsequently cooled rapidly by heat conduction to the interior after the beam has passed. By selecting the correct power density and speed of the laser spot, the material will harden to the desired depth.

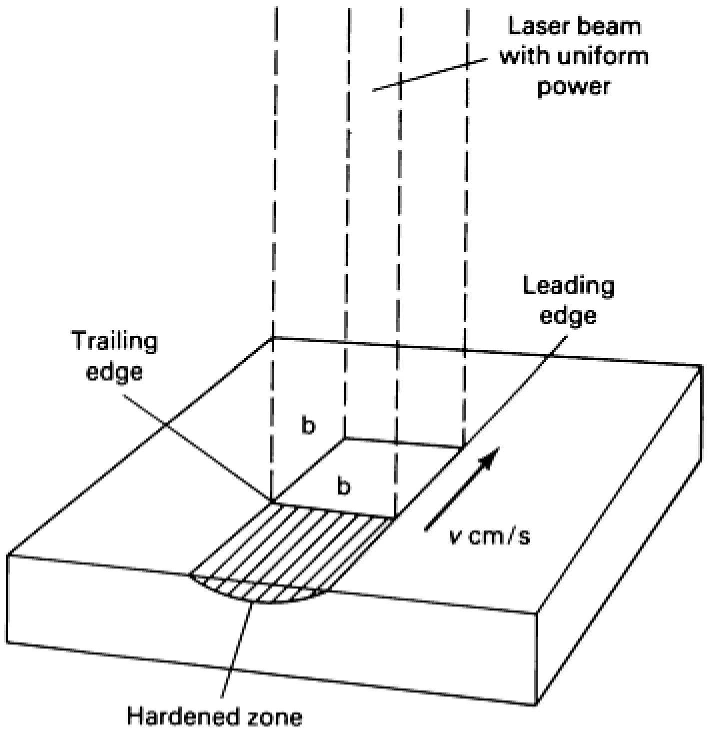

Fig. 1 Square laser beam with uniform power density on a flat plate

A relatively broad area beam, often in the shape of a square or a rectangle, is used in the laser hardening process. The power density of a focused laser beam used for hardening is much lower than the power density of the small, intense focused spots used for welding and cutting. The power density is typically in the 1000 to 2000 W/cm^2 (6400 to 13,000 W/in.^{2}) range, occasionally as high as 5000 or as low as 500 W/cm^2 (32,000 to 3200 W/in.^{2}).

The resulting depth of case will depend on the hardening response of the material, but it will rarely be more than 2.5 mm (0.1 in.). For steel with low hardenability, such as low- and medium-carbon steel, the depth of case obtainable is much smaller, varying from perhaps 0.25 mm (0.01 in.) in mild steels to 1.3 mm (0.05 in.) in a medium-carbon steel. Because of the very high heating and cooling rates obtainable, it is possible to harden steels not normally considered hardenable, such as SAE 1018. For the same reason, the hardness obtainable by the laser hardening process can, in some instances, be slightly higher than that considered possible with conventional methods.

Ferrous materials are not good absorbers of infrared and far-infrared electromagnetic radiation. For instance, polished pure iron has an absorptivity of about 4% at room temperature. Grit-blasted cast iron has an absorptivity of 25% at room temperature, and this value increases to about 40% at 800 °C (1470 °F) in an inert atmosphere. The formation of oxides on the ferrous surface can increase absorptivity beyond these values, but efficient use of the laser energy demands the introduction of a controlled high-value absorbing coating on the material surface. Chemical coatings, such as manganese phosphate and paints of graphite, silicon, and carbon, have all been used successfully. Some of these coatings may burn off during the heating process, and some may leave a residue which in itself can be an indicator of the maximum surface temperature reached. In any event, the absorptivity of these coatings at the beginning of the heating cycle is high (90% or better) and continues to be higher than that of the bare material throughout the temperature excursion. The overall absorptivity of these coatings, applied like a spray paint, is typically about 80%.

For shorter wavelengths (1.06 μm near-infrared radiation), the room-temperature absorptivity may be as high as 60% (as would be the case in yttrium-aluminum-garnet, or YAG, laser transformation hardening), but an absorbing coating is still recommended for efficient use of the laser energy.

The major advantages of laser surface hardening include: close control of the power input with metal-working lasers; the laser can provide high power density in selected areas, which in turn minimizes the total energy input, and thereby, dimensional distortion; and the ability of the laser to reach normally inaccessible areas on the workpiece surface. Because no vacuum or protective atmosphere enclosure is needed, and the distance from the workpiece to the last optical element of the laser system can be quite long, it is possible to process very large or irregular-shaped workpieces. The laser beam can also be optically shaped or split to accommodate different geometries.

On the negative side, the depth of case obtainable is limited to about 2.5 mm (0.1 in.), usually less than half of this, and the capital cost of the equipment may be high. Therefore, careful analysis of a potential application for laser hardening is needed to ascertain the cost-effectiveness of the process.

Metallurgy of Laser Hardening

As stated earlier, the surface hardening process is not fundamentally different from the conventional hardening processes because the same metallurgical reactions occur. In surface hardening, however, the heating portion of the process cycle must, out of necessity, be much shorter than that of conventional hardening. This is particularly true for laser hardening, where heating to the austenitizing temperatures occurs within seconds or even fractions of a second. In fact, in laser surface hardening the heating period is frequently shorter than the cool-down time.

The response of ferrous materials to rapid cool-down from the austenite region has been studied in great detail for many decades and is well understood. The same cannot be said for the heating period of the process. Basically, the problems associated with these high heating rates are that the formation of austenite as well as the redistribution of carbon, necessary to form a homogeneous γFe-C solid solution, are processes that require small but definite time intervals. The kinetics of these processes under very high heating rates are still somewhat uncertain, making the design of a laser surface hardening process more difficult than that of a conventional through hardening procedure.

The basic reaction taking place during the heating period is the transformation of the bcc (α) iron into fcc (γ) iron. This occurs by nucleation and growth of the new phase in the matrix of the old phase. In slow heating, the process will start at A_1 (723 °C, or 1335 °F) in a carbon steel and will be complete at the A_3 line. However, when the heating rate is high, the system is far from equilibrium conditions and the A_3 line will tend to be displaced upward to higher temperatures. Thus, although the temperature may be sufficiently high to form austenite under conditions of slow heating, the same temperature level may be insufficient even to initiate austenitization under high heating rates. Laser hardening parameters are, therefore, usually designed to give peak temperatures well above those employed in conventional hardening to ensure austenitization, but not high enough to initiate surface melting.

The equilibrium room-temperature structure of iron and steel will contain carbon in the form of iron carbide or graphite as a separate phase. To bring about hardening upon quenching, this carbon must be uniformly dissolved in the austenite. To do so, the carbon must be redistributed by diffusion into areas that originated from practically carbon-free ferrite.

This requires time, even at the high temperatures used in laser hardening, and under certain conditions, laser processing may occur too rapidly to allow for complete diffusion. This problem is obviously most prevalent when the carbon molecules have larger molecular distances to travel in order to dissolve evenly in the iron matrix, such as in coarse pearlitic structures, structures containing proeutectoid cementite, spheroidized materials, and cast irons, particularly cast iron with a high content of free ferrite. Figure 2 shows the structure of a ductile cast iron after laser processing. The extent of carbon diffusion that occurred during the processing is clearly revealed by the region of martensite surrounding the graphite nodules.

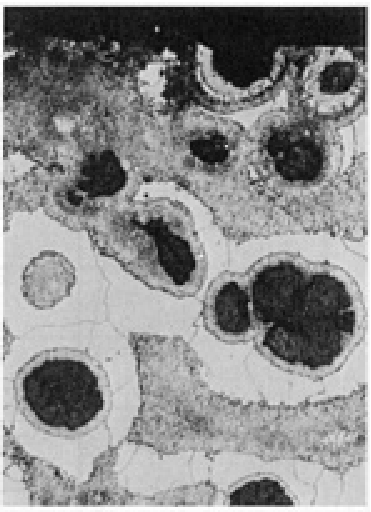

Fig. 2 Structure of laser-hardened ductile cast iron. 250×

The intrinsically high heating rates associated with laser hardening, combined with the need to allow sufficient time above the A_3 point to form homogeneous austenite, necessitate high peak temperatures. Retained austenite is found in laser hardened materials as revealed by x-ray analysis, and it appears that the amount of retained austenite increases with increasing maximum processing temperatures. Attempts to increase the case depth by increasing the energy input may therefore result in an undesirable structure if carried too far.

The upper limit for the surface temperature in laser processing is set by the melting point of the material because surface melting is undesirable in most instances. On simple plane surfaces, this is easy to avoid, but on workpieces with more complex design the surface temperature may vary across the beam-impingement area, even if the power density over the beam cross section is uniform. This can occur when the surface is curved, and in particular when the beam strikes an area with abrupt angles. The projected power density will then be nonuniform, and the heat flow uneven, so that part of the illuminated surface may reach the melting point before the remaining area has reached adequate temperatures to austenitize to a sufficient depth. Sharp edges and corners can be troublesome because they tend to concentrate the heat flow and lead to blunting of the edges by melting.

Another problem associated with some laser surface hardening applications is the necessity to overlap hardening passes. This may occur at the closure of a path around a cylindrical workpiece, or in the overlap zone between parallel paths being processed sequentially. Because lateral heat flow from the moving laser spot is unavoidable, backtempering will take place by the heat flow into areas already hardened by previous passes, or, in the case of closed paths, at the start of the pass. The lower the processing speed, the more pronounced the effect because relatively more heat will have time to diffuse into the previously hardened area. Even at high speeds and with the application of external heat sinks or water cooling, this effect cannot be entirely eliminated. Figure 3 shows the hardness profile across the boundary between parallel hardened tracks. As the figure shows, leaving a space between the tracks results in unreacted, and therefore soft, material in the boundary. If, on the other hand, the tracks are overlapping, backtempering will occur, as shown on the right side of the boundary in the bottom curve. The use of special optics may eliminate the necessity of forming overlap areas. However, this will always entail illuminating the entire width of the work area with laser radiation, and the available power of the laser limits the size of the workpiece that can be processed by the use of such optics. In some applications, the formation of a backtempered zone is not detrimental, provided that the processing is done in such a way that the backtempered area is located in a position of low service stresses or wear. Thus, for example, the interior walls of internal combustion engines may be hardened by straight or spiral laser passes, leaving unhardened material between the passes without harmful effects.

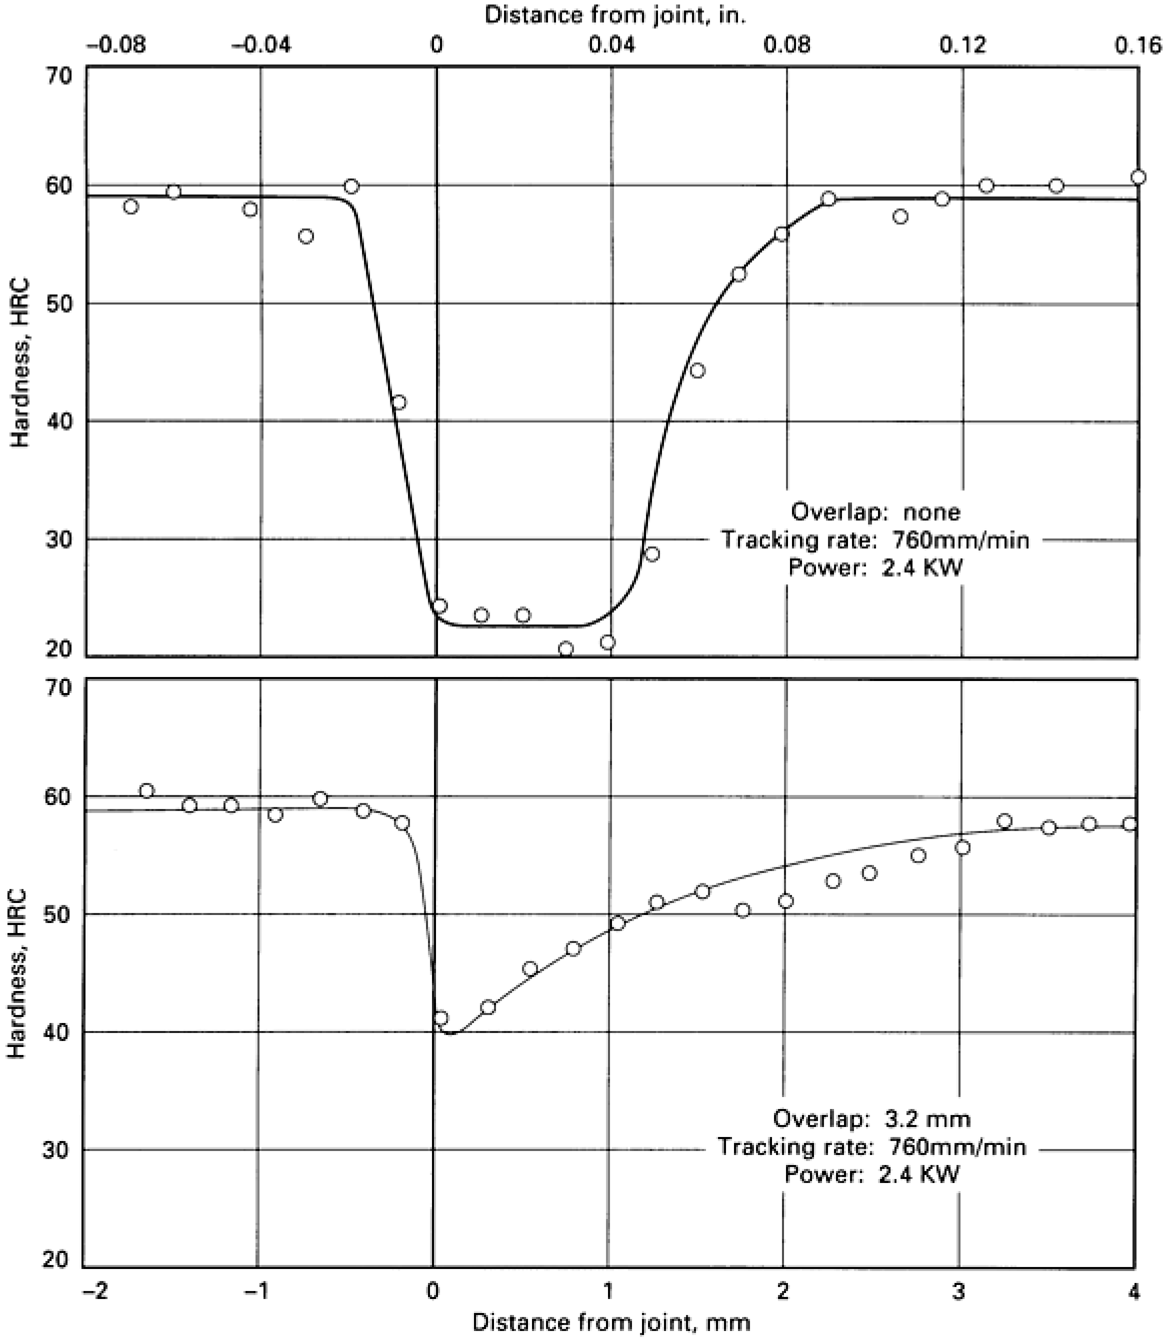

Fig. 3 Overlap zones between parallel laser tracks. Square laser spot size 12.7 mm × 12.7 mm

Heat Flow in Laser Hardening

In laser surface hardening, thermal energy is generated by absorption of the laser radiation at the surface. The increase of temperature in the interior of the workpiece is by way of conduction only; no sources of thermal energy exist below the surface. Thus, if the rate of absorbed power and the thermal properties of the material are known, it is possible, at least in principle, to calculate the temperature distribution in the workpiece. This is of considerable value, because it is then possible to predict the results of laser processing in advance and to calculate the optimum processing parameters, such as power density, processing speed, and spot size.

The long wavelength electromagnetic radiation (infrared) from a typical carbon dioxide laser is not efficiently absorbed by ferrous metals at room temperatures. It is, therefore, necessary to coat the workpiece with a substance that will aid in absorbing the laser energy or to use a Brewster-angle treatment without coatings. Commonly used coating materials are

manganese phosphate, graphite, or carbon-black paint. The paint, in the form of flat, black spray paint, is by far the most convenient coating to use. It is easy to apply and is fairly insensitive to variation in coating thickness.

When laser energy is absorbed at the surface at a rate of 500 W/cm^2 (3200 W/in.^{2}) or more, surface temperature rises very rapidly because the conduction of heat to the interior cannot keep up with the influx of energy to the surface. The higher the input flux, the more rapidly the temperature rises in the surface layer, and as a consequence, the temperature gradient in the workpiece will be steeper. The maximum surface temperature allowable is the melting point of the material, although in practical applications temperatures should be held well below this value. This clearly acts as a constraint on the depth of austenitization that can be achieved. If lower laser power density is used and the processing speed is correspondingly decreased, the surface temperature will rise more slowly and the temperature gradient will be less steep. This allows austenitization to a greater depth, as shown in Fig. 4. However, the rate of cooling by self-quenching will be slower, and it may be insufficient to trap the dissolved carbon in a martensitic matrix without some carbon precipitation. This would not allow the material to harden fully. Thus, the two physical limitations of melting temperature (T_m) and necessary cooling rates act to impose a limit on the obtainable depth of case regardless of the power available for the processing.

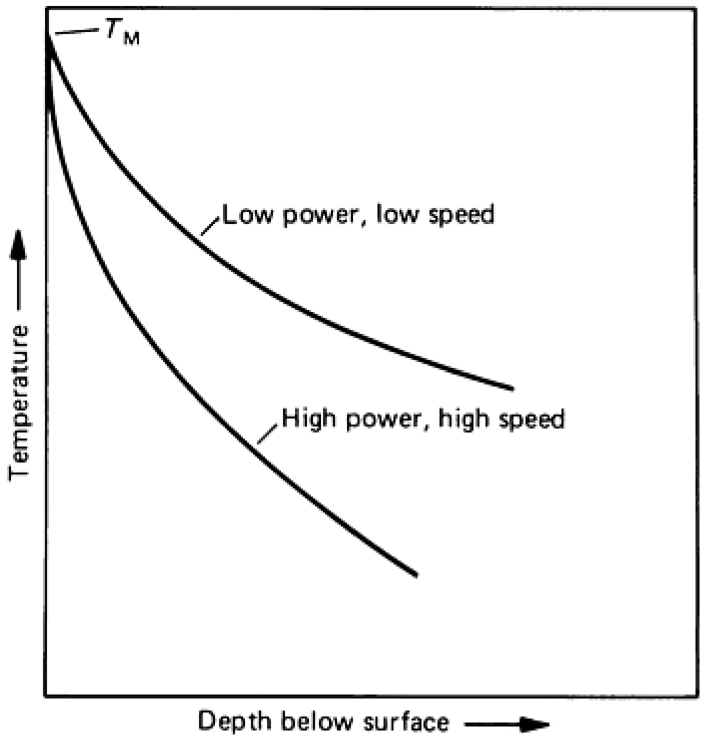

Fig. 4 Influence of processing parameters on heat penetration in laser surface transformation hardening

To obtain good self-quenching, it is generally necessary to use high power density and high processing speed for steels of low hardenability. Steels of high hardenability can be processed to greater depth by relatively low power densities and low processing speed. For many such steels, the slow processing rate will be necessary to give the material time to form homogeneous austenite. Thus, deep case depth in plain carbon steels may be difficult to achieve. It is possible to use external quench procedures, thereby obtaining deeper case depths in steels of low hardenability. This is achieved at the cost of greater dimensional distortion because the total power input increases with decreasing speed for constant maximum surface temperature.

Temperature Distribution. If the absorbed power density, laser spot dimensions, processing speed, and thermal properties of the material are known, the temperature distribution in the workpiece can be calculated by means of several expressions found in the literature. The simplest expression is obtained if it is assumed that heat only flows normal to the workpiece surface, that is, one-dimensional heat flow. If the workpiece is large in this direction, the temperature is given by:

$$T = T_0 + 2Q / K\sqrt{a\,t_D}\,ierfc\frac{d}{\sqrt{a\,t_D}} \qquad \textbf{(Eq 1)}$$

where T is temperature in celsius, T_0 is room temperature in celsius, Q is absorbed power in W/cm^2, K is thermal conductivity in W/cm · °C, αis thermal diffusivity in cm^2/s, δis depth below the surface in cm, and t_D is dwell time in s.

Dwell time is the amount of time a given spot on the surface will be exposed to the laser beam. This is, therefore, equal to the length of the laser spot in the direction of travel divided by the speed of travel. The expression ierfc(x) is the integrated complementary error function defined by:

$$ierfc(x) = \int_x^{\infty} erfc(f)\,df$$

where erfc(f) is the error function complement:

$$\text{erfc}(f) = 1 - \text{erf}(f)$$

and the error function erf(f) is given by:

$$erf(f) = \frac{2}{\sqrt{p}}\int_0^m e^{-m^2}\,dm$$

These functions are tabulated in many sources and can easily be evaluated. Figure 5 shows a plot of ierfc(x).

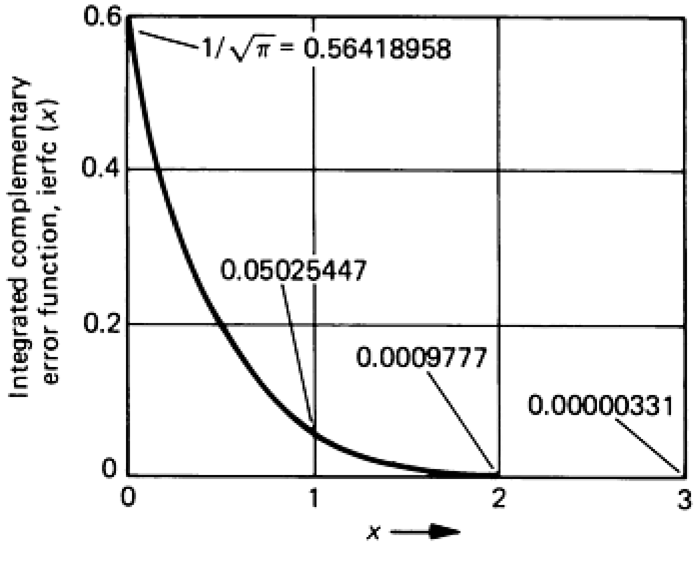

Fig. 5 The integrated complementary error function

If we apply Eq 1 to a moving laser spot on a plane surface, it becomes clear that as the leading edge of the spot reaches a given spot on a plane surface, the temperature will rapidly start to increase, and the maximum temperature will be reached at the trailing edge of the spot, as shown in Fig. 6. A similar, but smaller, temperature increase will be experienced at points below the surface. If Eq 1 is solved for various values of the depth δ under the trailing edge of the spot, a temperature-profile can be constructed representing the maximum temperature conditions in the vicinity of the surface (see Fig. 7). Knowing the transformation temperature A_3, it is then a simple matter to determine the largest obtainable depth of hardened case δ.

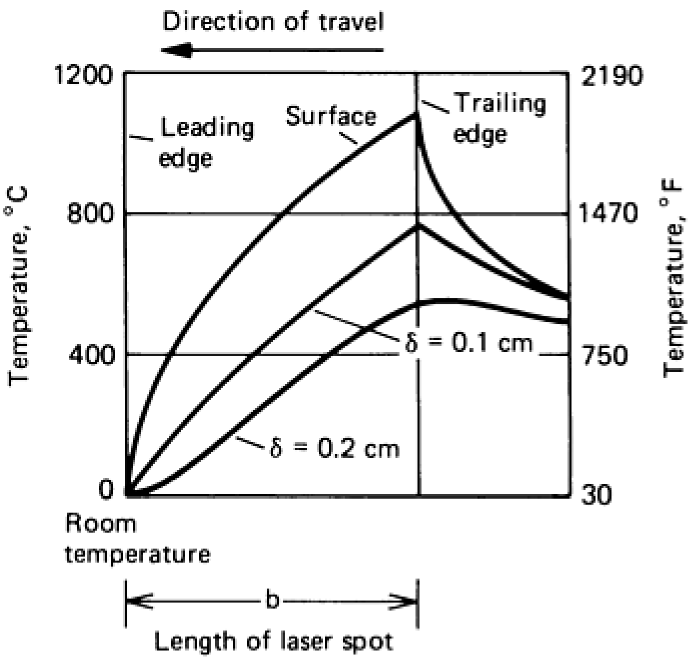

Fig. 6 Temperature distribution along the centerline of a 1 cm × 1 cm (0.4 in. × 0.4 in.) laser spot. Power density, 1200 W/cm^2 (7700 W/in.^{2}); speed, 1 cm/s (0.4 in./s)

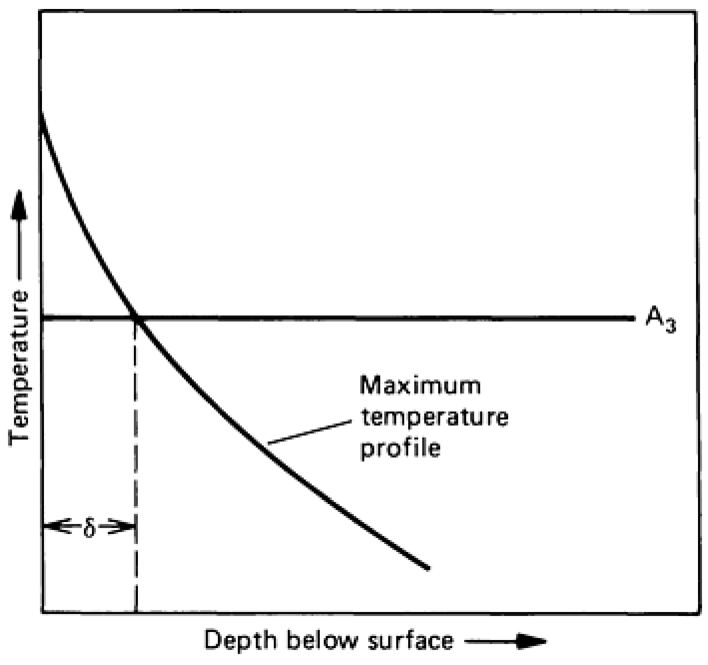

Fig. 7 Predicting depth of case in laser transformation hardening

In reality, heat diffuses in all directions into the workpiece from the moving laser spot, not only normal to the surface. Furthermore, heat is lost by radiation from the surface, and the thermal properties are not constants but are temperature dependent. Finally, in many instances, the workpiece is not large enough to be considered infinite, as Eq 1 assumes. All of these factors can contribute to make the estimates obtained from Eq 1 unreliable. Nevertheless, at high processing speeds (that is, low dwell time, t_D) and for reasonably thick specimens and large laser spots, Eq 1 gives a good estimate for depth of obtainable case. It is possible to develop expressions that take into account the three-dimensional nature of the heat flow. Such expressions can take the form of complex analytical solutions to the heat flow equation, or are based on finite-element analysis. The practical application of such analysis requires the use of computers.

Cooling Rates. By a relatively simple expansion of Eq 1, the cooling rate of any given point in the workpiece can be estimated if only one-dimensional heat flow is considered. This is done by means of the expression:

$$T = T_0 + 2Q/K\left\{\sqrt{a\,t_D}\,ierfc\frac{d}{2\sqrt{a\,t_D}} - \sqrt{a\,(t-t_D)}\,ierfc\frac{d}{2\sqrt{a\,(t-t_D)}}\right\} \quad \textbf{(Eq 2)}$$

In this equation, the symbols have the same meaning as in Eq 1, except that t is the time elapsed since the leading edge passed over the spot for which we need to know the temperature; and t - t_D is the time elapsed since the trailing edge passed over the spot, that is, the time elapsed after cooling by self-quenching began. When using this equation, it is very important that the workpiece be large enough to provide an adequate heat sink.

Equation 2 can be used in conjunction with C-T diagrams to predict whether or not the cooling rate by self-quenching will be adequate for hardening under a given set of circumstances. To aid in the use of Eq 1 and 2, Fig. 8 gives the values of the thermophysical constants for hypoeutectoid carbon steels. The plotted values are the integral average values from room temperature to 1000 °C (1830 °F) and are given in units convenient for calculation of temperatures by Eq 1 and 2 when the power input (Q) is in W/cm^2. It should be noted that Q is not the applied power density but the estimated absorbed power in W/cm^2.

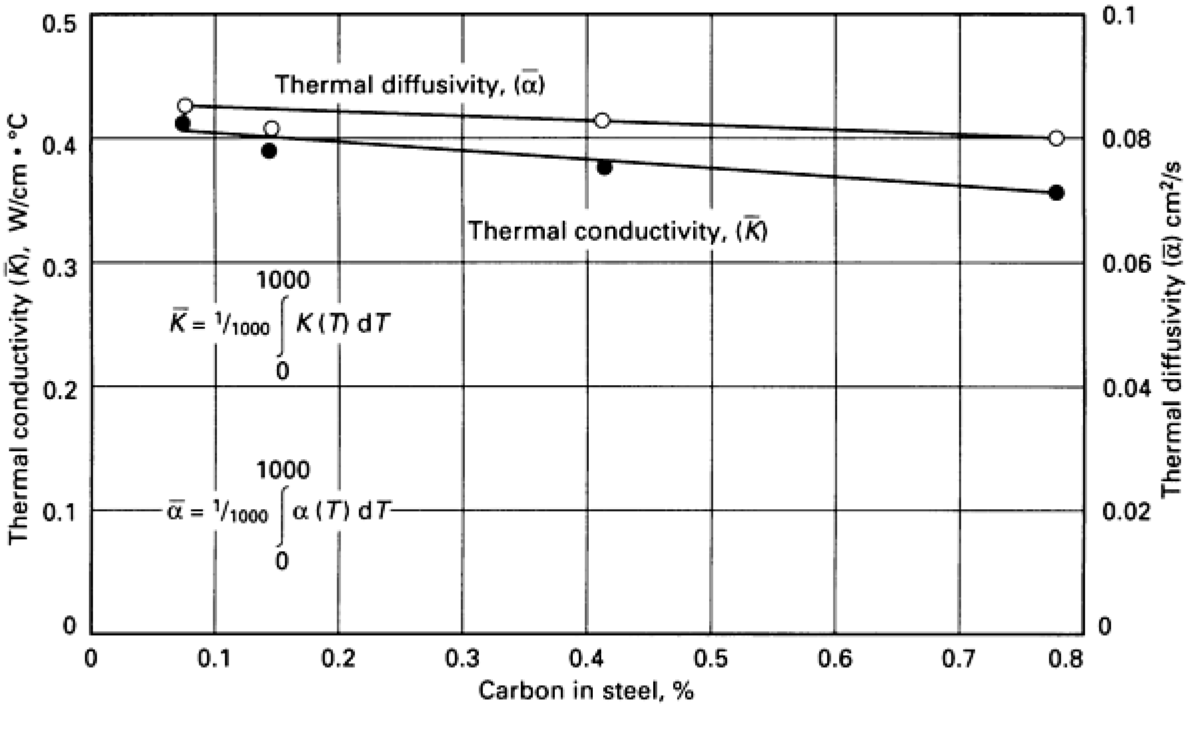

Fig. 8 Thermophysical constants of carbon steels (integral averages between 0 and 1000 °C)

Processing Parameters

Many factors influence the results of laser surface transformation hardening including size of the laser spot, power density, uniformity of power density, processing speed, thermal properties of the material, and laser hardenability of the material. The last factor encompasses the material's response to rapid eating and quenching and is, in part, dependent on the starting condition of the material--that is, whether the material is normalized, annealed, and so on.

The parameters of principal interest are power density, its uniformity, and processing speed. It is obvious that processing speed should be as high as possible to attain high production rates. However, the speed at which the laser spot moves over the surface is not a good measure of the production rate by itself because the dimensions of the spot normal to the direction of travel are equally important in determining the area coverage rate. Another important factor in determining the results of processing is the dwell time. The relative dimensions of a rectangular spot do not influence the coverage rate as long as the power density stays constant. Therefore, the area of the laser spot that will give a specific result is limited

by the available power. An exception to this is when the spot is very narrow in the direction of travel and/or when the speed is very low. Under such conditions, lateral heat losses become large and the spot dimensions influence the results. The conditions under which this effect becomes noticeable is:

$$B = vb/4\alpha < 6$$

where b is the spot dimension in the direction of travel, v is the speed of the spot, and α is the diffusivity, all in cgs units.

The following are general guidelines for choice of processing conditions:

- Usable power densities in laser surface hardening are in the 500 to 5000 W/cm^2 (3200 to 32,000 W/in.^{2}) range. Corresponding dwell times are in the range 0.1 to 10 s. For carbon steels, the power density is usually from 1000 to 1500 W/cm^2 (6400 to 9700 W/in.^{2}), and the dwell time 1 to 2 s
- Materials with high hardenability can be processed at low power density and high dwell time (low speed), whereas materials with low hardenability should be processed at high power density and low dwell times
- Rectangular, square, or sometimes round laser spots with uniform power density are suitable in obtaining uniform hardened case
- High power density and low dwell time give shallow case, but high cooling rates. The reverse is true for low power densities
- Maximum surface temperature is approximately proportional to the square root of the processing speed. Hence, a doubling of the power density requires a quadrupling of the speed to obtain equivalent maximum surface temperatures. Figure 9 shows the results of laser treatment of SAE 1078 steel at various power levels and speeds
- Increasing the power density results in lower total energy input for the same maximum surface temperature
- Steel with normalized, annealed, or spheroidized structures; steel with proeutectoid cementite; cast irons and steels with stable alloy carbides require longer dwell times than steels that have been hardened and tempered
- Small workpieces will require higher power densities and lower dwell times than large pieces, unless external quenching media are used

Metalworking Lasers

Several models of metalworking lasers of both domestic and foreign manufacture are commercially available. The majority of these are of either the Nd:YAG solid-state type, or the carbon dioxide gas type. These lasers may have pulsed or continuous output power. Both types, whether pulsed or continuous wave, can be used for surface hardening.

The power output of metalworking lasers at the present time is in the 50 W to 25 kW range. Capabilities and operating ranges for CO_2 and Nd:YAG lasers are shown in Tables 1 and 2. The minimum size of a laser system for a potential industrial application is determined on the basis of such factors as required production rate, minimum practical spot size, and power density necessary to achieve the desired results. The laser is also a versatile tool, which can be used for a number of metalworking processes such as welding, cutting, and hardfacing.

Table 1 Process capabilities of CO_2 lasers by power range

	200-300 W	**300-500 W**	**500-800 W**	**800-1500 W**	**1500-3000 W**	**>3000 W**

Lasers emit electromagnetic radiation in the infrared portion of the spectrum, and the laser beam from these machines is invisible. The carbon dioxide laser emits radiation with 10.6 μm wavelength, and this radiation is easily absorbed in a variety of nonmetallic substances. A thin sheet of lucite between the operator and the beam/workpiece interaction zone can absorb potentially harmful stray radiation. The output of the YAG laser has a much shorter wavelength (1.064 μm), and therefore, the operator is required to wear protective eyeglasses for the shorter wavelength. YAG lasers are limited to relatively low power levels. Therefore, in metalworking processes requiring more than 500 W of power, the carbon dioxide laser is usually employed because it can deliver much higher continuous output, although YAG lasers as powerful as 1800 W (continuous wave) have recently been brought to market (MARTEK).

Although many applications utilize defocused beams, the primary output beam from the laser is more often focused in metalworking applications. The output beam is directed and shaped by optical systems to generate a laser spot of the desired size and shape on the workpiece surface. Such an arrangement allows substantial flexibility in the use of a laser system. Because the coherent radiation from a laser has low loss of power with distance (depending on ambient conditions such as humidity), the laser itself can be situated at a considerable distance from the work area. Furthermore, different types of metalworking applications can be performed with the same laser by changing the optical system. Several jobs can be performed simultaneously with one laser by using several work stations (Fig. 10), each with its own optical system designed for a specific application. In most multiple work stations, each work station has its own control console, allowing manual or automatic control of beam power, duration of power delivery to the workpiece, rate of increase of power at the start of the run, rate of decrease at the end (ramp-up and ramp-down), and manipulation of the workpiece fixture and protective gas flow, if required. The laser power is automatically maintained at the desired level by a feedback control device in the laser. Positive feedback from temperature sensors, monitoring the temperature in the beam workpiece interaction zone, also can be used. The entire operation can be controlled by microprocessors. By directing the laser beam to the individual work stations in sequence and utilizing the time when the power is used at another station for workpiece manipulation, maximum usage of the laser can be achieved.

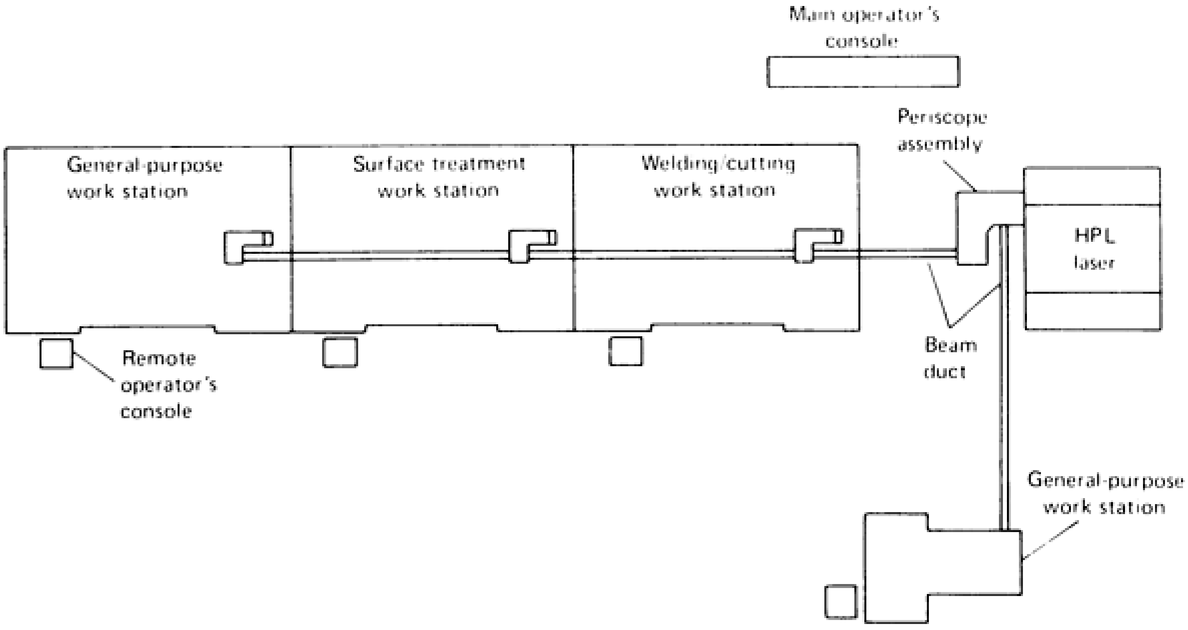

Fig. 10 Metalworking laser with multiple work stations

Optical Systems

In laser welding and cutting operations, a focused beam of intense power is used. For laser transformation hardening, this focused spot is replaced with a broad beam of much lower power density, partly because the hardening process requires lower power densities and partly to obtain reasonable rates of area coverage.

The simplest way to obtain such a spot is to position the workpiece surface in such a way that it intercepts the beam some distance from the focal plane of a converging beam. However, the power density distribution of a spot obtained in this manner is rarely sufficiently uniform and at the same time large enough to give satisfactory results.

The most suitable laser spot for surface hardening is a square or rectangular spot with uniform power density, sometimes referred to as top hat profile (see Fig. 1). Such a laser spot requires reshaping of the output laser beam that is attained by the use of various optical systems.

Transmissive optical elements, such as lenses and windows, can be used. However, because of the long wavelength of the radiation typical for CO_2 lasers, these elements must be made from special materials such as zinc selenide to avoid excessive absorption.

Depending on the laser power, reflective optical components are less fragile and better adapted to industrial environments. They consist of flat, spherical, or parabolic mirrors made from copper or molybdenum, which have excellent reflective characteristics to laser radiation. By the use of these mirrors, the beam can be reshaped and redirected to suit the particular application requirement.

The simplest way of creating uniform power density in the focused beam is with the use of so-called "binary optics." Another simple way to form a square or rectangular beam is to use mirrors or lenses to form a focused spot and then to scan this spot rapidly back and forth in two perpendicular directions, as shown in Fig. 11. If scanning is done at a sufficient rate, the result will be equivalent to spreading the power of the focused spot over the area being scanned, because the thermal lag of the metal will act to even out the power input to a uniform power density. The scanning can be performed conveniently by electromechanical vibration of one or more of the mirrors in the optical system. In this way, it is possible to generate spots of desired size and shape on the workpiece surface.

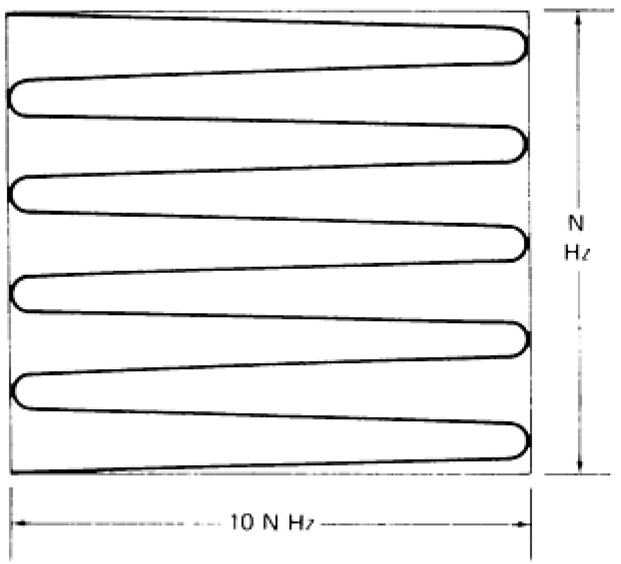

Fig. 11 Scanning a small focused laser spot to generate a square, broad area beam

Devices that scan in only one direction are line sources The width of the line is equal to the diameter of the focused laser spot that is being scanned. This can be varied by defocusing. The length of the line can also sometimes be varied by changing the scan amplitude. Such devices are therefore quite flexible, and because they form laser spots with high power density, they are very useful when only shallow cases are required. In particular, such devices are used when the workpiece has low mass and can only support self-quenching if the total energy input is low. Figure 12 shows two types of scanners used to generate high-intensity line sources.

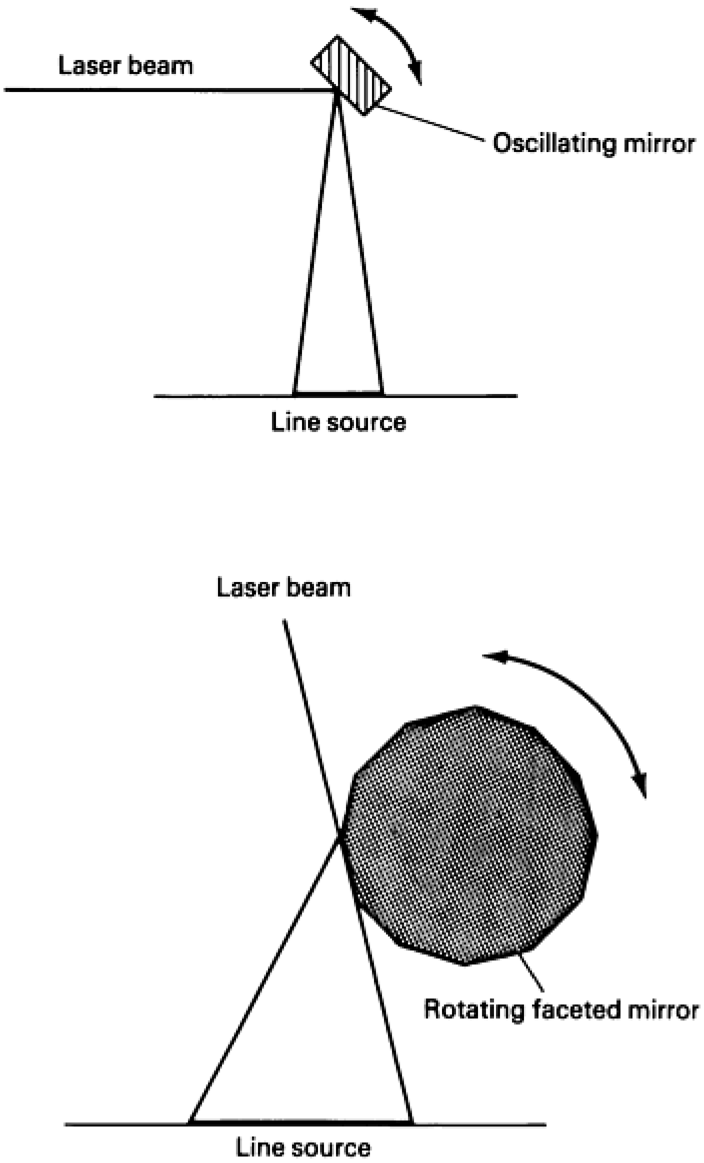

Fig. 12 Laser beam scanners for generating line sources

Another method of forming a square or rectangular beam is to use a device known as an optical integrator. This device, shown in Fig. 13, is an array of flat mirrors mounted on a spherical surface placed to intercept the output laser beam. Each mirror forms an image of the part of the output beam that it intercepts, and all of the images from the array will be formed in the same position. In this way, the output beam is reshaped to form the desired square or rectangular spot in the focal plane of the integrator, having uniform power density over the illuminated area on the workpiece surface.

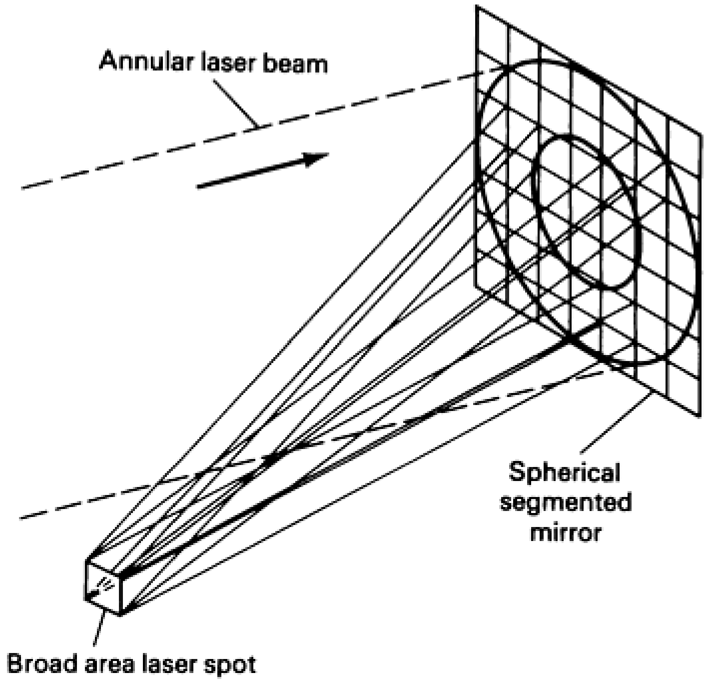

Fig. 13 Optical integrator

Presently, new techniques are being developed, both in Europe and the United States, for generating laser spots with "programmed" power density. Computer-generated patterns can be transferred to metal mirrors that allow the formation of a variety of laser spot shapes in the focal plane, and the power density of such laser spots can be given desired power density distributions.

One application of this technique is in generating a square spot with a higher-than-normal power density in the leading edge of the spot. Traversing such a spot over a steel surface will, if the power density ratio between the edge and the rest of the spot is about two to one, result in a very rapid temperature increase followed by a period of nearly constant temperature increase until the trailing edge is reached. This allows the material to be kept at austenitizing temperatures longer than is the case for a spot with uniform power density with equal maximum processing temperature, as shown in Fig. 14. The longer austenitizing time available with the "hot" leading edge is particularly useful for laser hardening of nodular cast irons and low- or medium-carbon steels with relatively large amounts of free ferrite. The increased time above the transformation temperature allows for the diffusion of carbon to occur in such cases, which is necessary for the formation of homogeneous austenite.

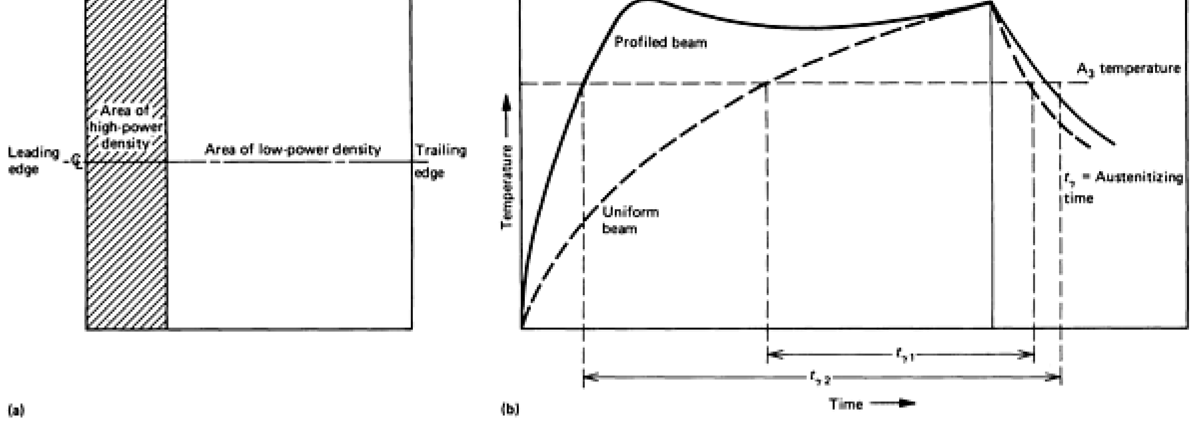

Fig. 14 Laser surface transformation hardening with a profiled laser beam. (a) Power density distribution in the profiled laser spot. (b) Temperature profiles along the centerline of the laser spot

Both scanning optics and integrator optics form beams that can be redirected by flat mirrors or refocused by appropriately curved mirrors (Fig. 15). In this way, the laser spot can be generated in the exact shape at desired location. The complexity of this use of optics, however, can prevent the use of lasers in a heat treat shop.

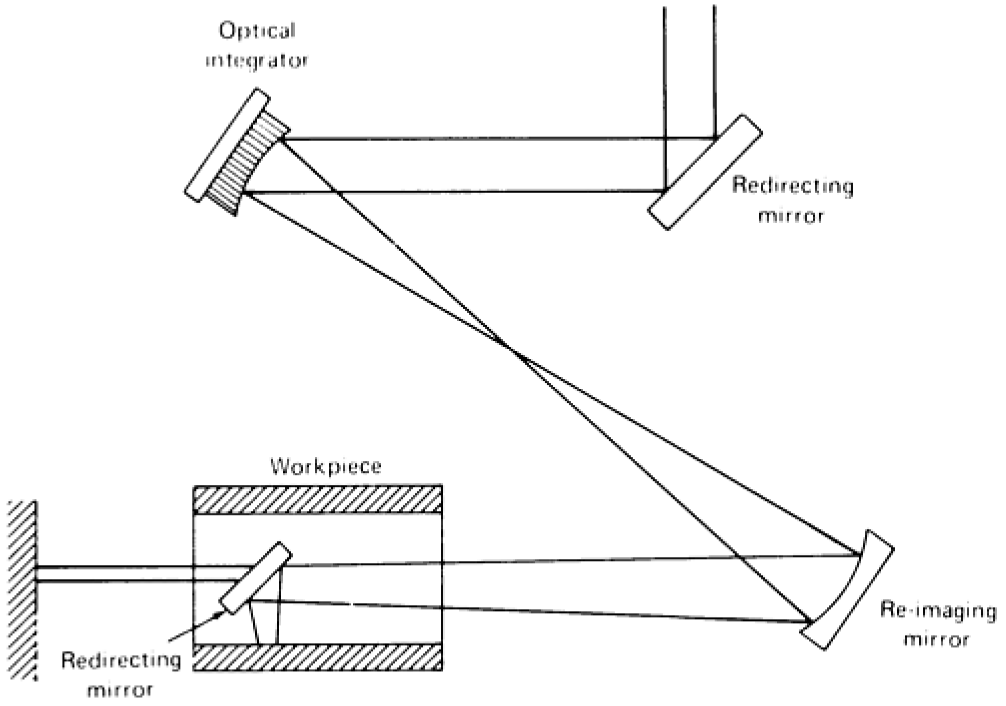

Fig. 15 Optical system for laser heat treatment of the inner surface of a cylinder

For workpieces of cylindrical design, special optical components called toric mirrors can be used. These mirrors take advantage of the fact that the output beam from the laser can be made hollow or annular in cross section. Directing the beam by suitable mirrors onto the workpiece causes a continuous band of laser irradiated surface to form around the periphery of the workpiece, either on the inner surface of a hollow cylinder or on the outer surface of a cylinder, as shown in Fig. 16. The complete surface can be laser treated by moving the workpiece in the axial direction through the ring-shape laser spot. No backtempering is encountered because no start/stop or parallel spiral zones are generated. The relatively large area of the ring-shape laser spot limits the size of workpieces that can be processed with this technique to about 25 mm (1 in.) diameter for each 8 kW of power available.

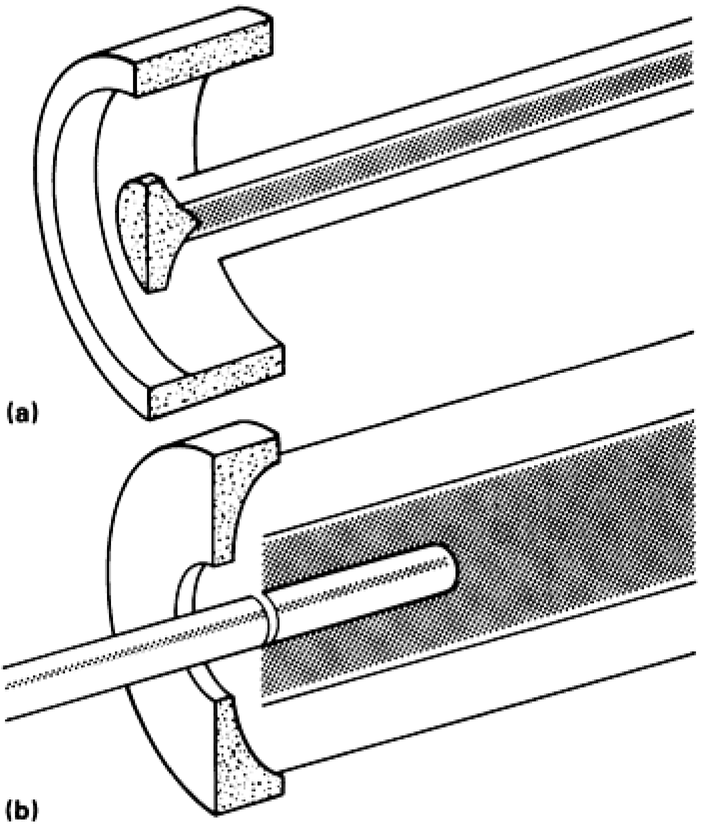

Fig. 16 Toric mirrors for treating cylinders. (a) Outer surface of cylinders. (b) Inner surface of hollow cylinder

Another technique that can be used for nonplanar surfaces is beam splitting. The laser beam is split into two equal parts by a copper prism, and the individual parts of the beam are directed at different angles to the workpiece surface by suitable reflective mirrors. Figure 17 shows the application of this technique to heat treating a wide semi-circular groove. If only a single beam, normal to the bottom of the groove, had been used, the angle of incidence of the laser beam at the left and right top of the groove would have been too shallow to generate sufficient heat. By using two beams as shown, this problem can be overcome.

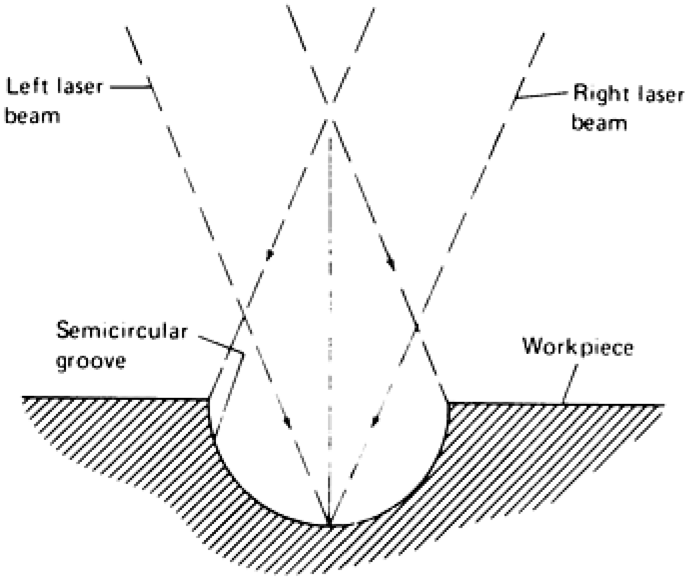

Fig. 17 Using two equal laser beams to surface harden a semicircular groove

Application

Lasers have become commonplace in many fields, but their use in surface treatments is relatively limited. This is probably due to the high cost of the large lasers that are required for most metalworking operations. Lasers are also not very efficient from the energy standpoint. The output energy may be only 10% of the input energy from flashlamps or arc sources. This is another reason why lasers can be expensive.

Nonetheless, the flexibility of laser delivery systems, low distortion, and high surface hardness have made lasers very effective in selective hardening of wear and fatigue-prone areas on irregularly shaped machine components such as camshafts and crankshafts. Molian (Ref 1), for example, has tabulated the characteristics of 50 applications of laser transformation hardening. The materials hardened include plain carbon steels (1040, 1050, 1070), alloy steels (4340, 52100), tool steels, and cast irons (gray, malleable, ductile). The energy-absorbing coatings are listed, and typical case depths for steels are 250 to 750 μm and for cast irons about 1000 μm.

Some of the techniques used in laser hardening applications are described in the following three examples. These examples do not necessarily convey predominant commercial usage but rather the type of systems required in a particular application. Further information on laser systems and their application in metalworking is given in the Selected References listed at the end of this article.

Laser Surface Hardening of 4140 Cylinder with Conical Top. The object was to surface harden the conical part of the workpiece shown in Fig. 18 to increase the wear resistance. The minimum required case depth was 1.1 mm (0.044 in.); the hardness at this depth should be 45 HRC. The workpiece had been hardened and tempered to 40 to 42 HRC prior to laser processing to obtain strength and ductility.

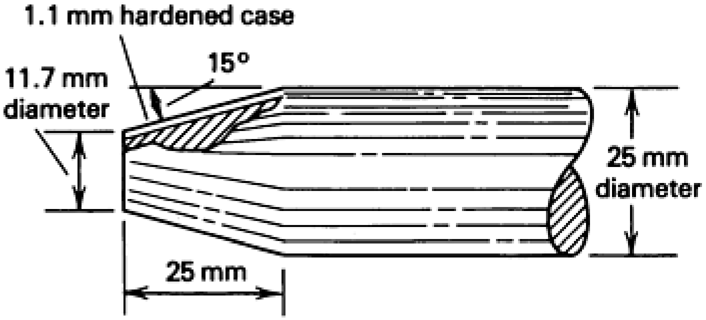

Fig. 18 Laser hardening of conical SAE 4140 workpiece

Because the workpiece was cylindrical and had a maximum diameter of 25 mm (1 in.), a toric mirror could be used in conjunction with a 15 kW CO_2 laser. The processing arrangement is shown in Fig. 19. In this fixture, the workpiece was rotated at 1300 rev/min under the ring-shape laser spot formed by the toric mirror. This was done to ensure uniform power density around the periphery of the workpiece. The ring-shape spot had a width of 5 mm (0.2 in.), and hardening of the desired area could be obtained by moving the workpiece in the axial direction. In this way, the entire area could be covered without forming any overlap zones.

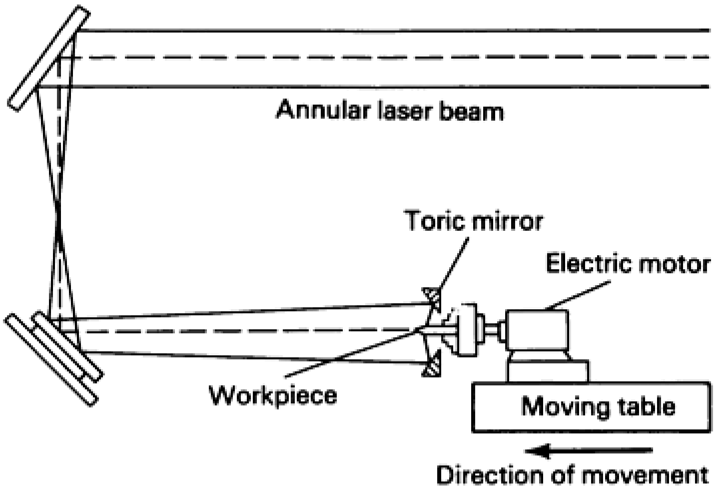

Fig. 19 Arrangement for laser heat-treating SAE 4140 cylinder with conical tip

Because the area under the ring-shape laser spot will increase as the beam sweeps from the tip of the cone to the cylindrical part of the workpiece, the power input had to be increased linearly with the distance in order to maintain constant power density.

Theoretical calculations, using Eq 1 with a thermal conductivity of 0.35 W/cm · °C (0.49 W/in. · °F) and a thermal diffusivity of 0.070 cm^2/s (0.01 $in.^2/s$), showed that a processing speed of 229 mm/min (9 in./min) and a power density of 1620 W/cm^2 (10,450 $W/in.^2$) would give a surface temperature of 1360 °C (2480 °F). This is only an estimate, as Eq 1 assumes a plane workpiece rather than a cylindrical one. To process at a slower rate and at lower power density would give deeper heat penetration, but the self-quenching rate would be lower. On the other hand, processing at higher speed and power would lead to shallower heat penetration.

The workpiece was coated with flat, black spray paint and processed at the following parameters:

- Axial speed: 221 mm/min (8.7 in./min); or 3.8 mm/s (0.15 in./s)
- Power: 3500 W at the tip, increasing to 7600 W at the cylindrical portion
- Rate of power increase: 620 W/s

The hardened case obtained ranged from 1.65 mm (0.065 in.) at the tip to 2 mm (0.08 in.) at the tip to 2 mm (0.08 in.) at the cylindrical portion of the workpiece. The surface hardness was 58 to 59 HRC.

Laser Surface Hardening of 4140 Cylinder Using a Square Laser Spot. When the use of toric mirrors is not practical because of laser beam shape (not annular) or because the diameter of the bar to be hardened is too large, the treatment can be performed with a square beam, as shown in Fig. 20.

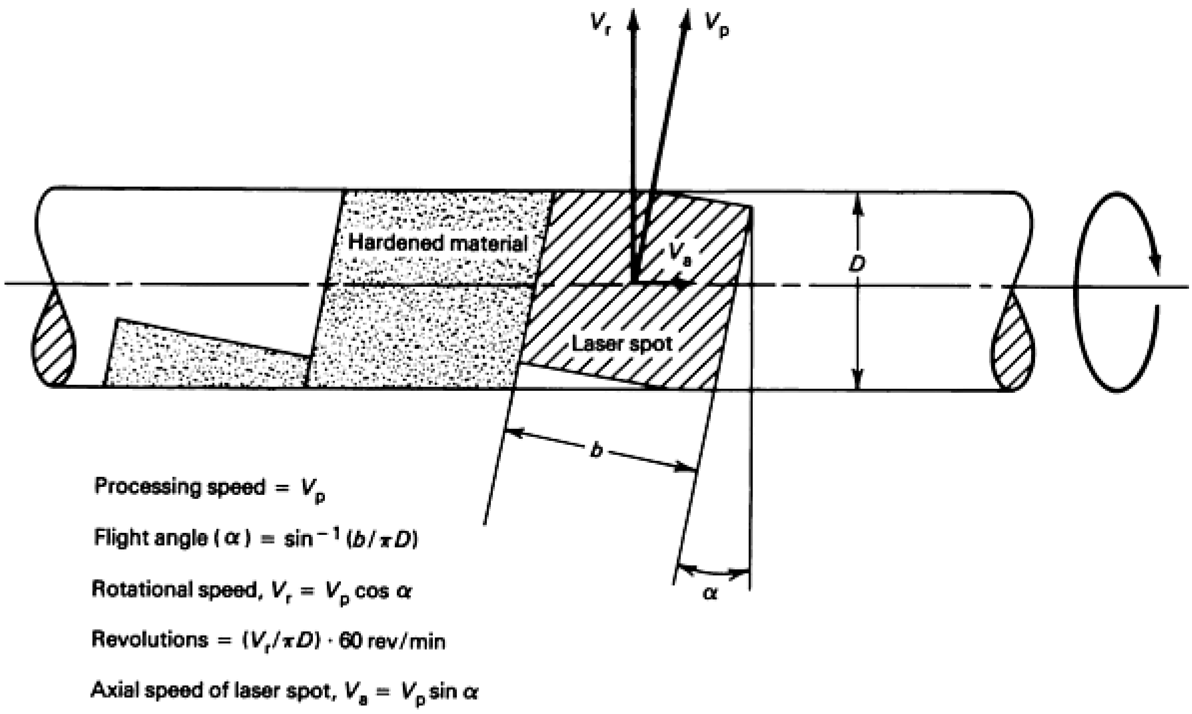

Fig. 20 Laser hardening of SAE 4140 steel bar using a square laser spot

Such spiral pattern "candystriping" can be used on any bar of reasonable size, but the zones between flights of the spiral pattern will have low hardness due to lack of closure, or, if positive overlap is used, due to back tempering.

In this processing, the laser spot must be angled in order to obtain uniform heat input to all spots on the surface of the bar. The angle depends on the size of the laser spot and the diameter of the bar.

In the present example, the bar had a diameter of 1.59 cm ($\frac{5}{8}$ in.) and the laser spot was 1.27 cm (0.5 in.) square. The tilt angle of the laser spot was 14.75°, and the desired processing speed was 2.12 cm/s (0.835 in./s) at 3.6 kW power. The axial translation speed of the laser spot was then calculated to be 0.53 cm/s (0.2 in./s), and the rotational speed was 2.05 cm/s (0.807 in./s) or 25.46 rev/min.

The resulting case was 1.8 mm (0.07 in.). This is much deeper than would be expected from using the prediction model described earlier. In this case, such a simple model cannot be used due to the geometry of the workpiece.

Laser Surface Hardening of Cast Iron Camshaft Lobes. The surface of the lobes of an automotive camshaft made from ductile cast iron (see Fig. 21) was to be surface hardened to increase wear resistance. The desired case depth, defined as the depth where the hardness was 50 HRC, was 0.5 to 1.0 mm (0.02 to 0.04 in.).

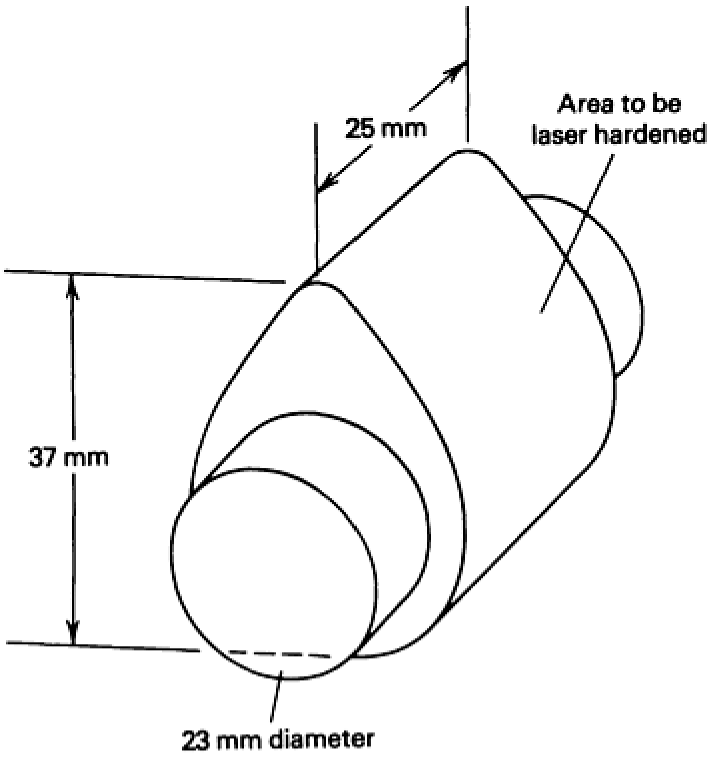

Fig. 21 Ductile cast iron cam from automotive camshaft

A 15 kW CO_2 laser was used for the processing. The optical system delivered a focused spot, with a diameter of 10 mm (0.4 in.) to the workpiece. This spot was scanned over a distance of 22 mm (0.9 in.) normal to the direction of processing and 25 mm (1 in.) in the direction of processing. The frequency of scanning was 125 Hz in the normal direction and 700 Hz in the processing direction, forming a rectangular spot 22 mm by 25 mm (0.9 in. by 1.0 in.) on the camlobe surface.

To obtain an even hardened case around the periphery of the camlobe, it was necessary to vary the angular speed of rotation of the lobe under the laser beam. The reason is that the angle of incidence of the laser beam to the workpiece changed during rotation, from nearly normal incidence at the cylindrical portion of the lobe to a grazing incidence of only 20 to 30° at the flat portion. Furthermore, at constant rotational speed, the linear speed of processing would vary as the lobe rotated. This was obtained by mounting the workpiece on a rotary table. The speed of rotation was varied by means of an electromechanical controller in a pre-determined manner.

The camlobe was laser hardened using a manganese phosphate coating to increase energy absorption. Because of the design of the workpiece, it was difficult to predict the optimum processing parameters by calculations and the parameters were, therefore, evaluated by trial and error. The results were:

Power input	9 kW
Power density	1600 W/cm^2 (10,300 W/in.^{2})
Linear speed of processing	

at the cylindrical portion	760 mm/min 30 (in./min)
at the flat portion	180 mm/min (7 in./min)
Depth of case	0.55 mm (0.022 in.)

The hardness profile of the surface layer of the camlobe is shown in Fig. 22.

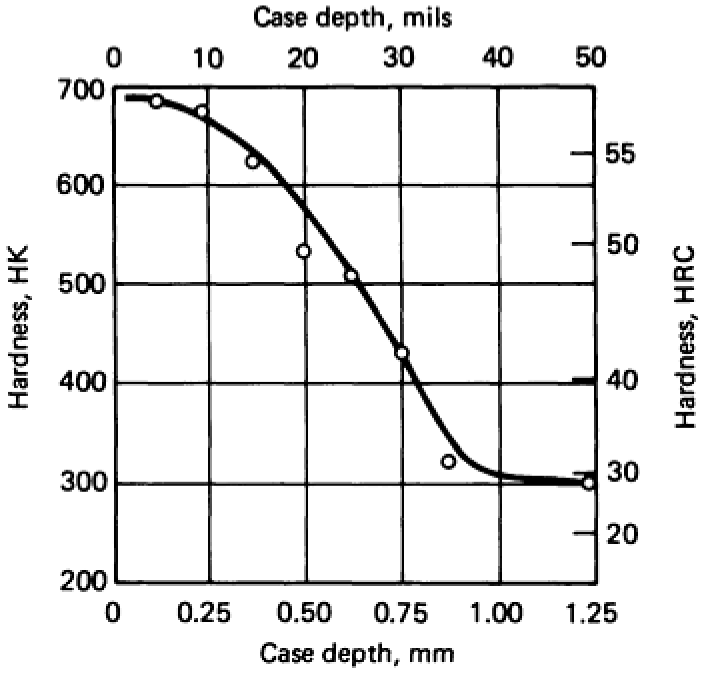

Fig. 22 Hardness profile of laser surface hardened cast iron camlobe

Laser Surface Hardening of a Large Gear. The gear, made from SAE 1045 steel, had a diameter of 28 cm (11 in.) and a thickness of 10 cm (4 in.). The gear had 34 teeth and a diametral pitch of 3.35. To increase fatigue and wear properties, a hardened case of 1 mm (0.04 in.) was desired, extending in a continuous manner from the tip of one tooth to the tip of an adjacent tooth, as shown in Fig. 23.

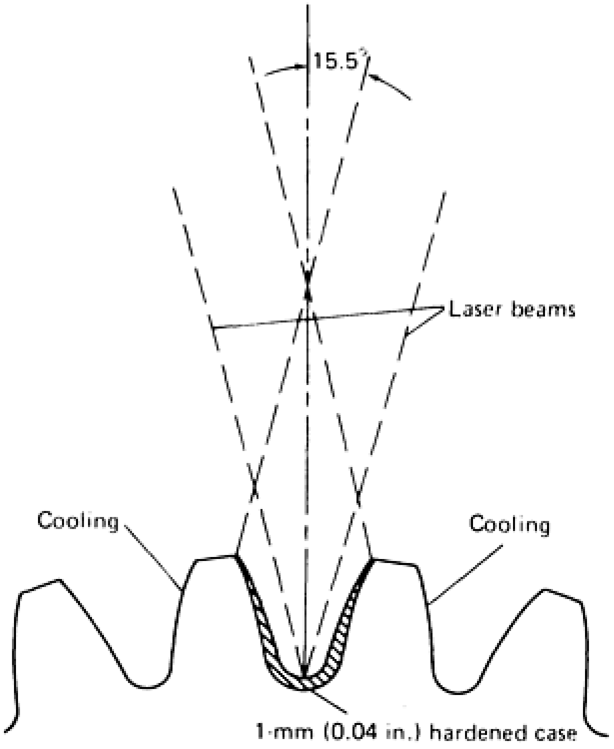

Fig. 23 Laser hardening of SAE 1045 gear

In this application, two laser beams had to be directed toward the surface of the gear teeth at an angle of 15.5° from the normal to the root area, as shown in Fig. 23. These two beams must be abutting but not overlapping at the root between the teeth. A single beam with normal incidence to the root area could not be used because the angle of incidence at the adjacent fillets would be too shallow to generate a hardened case in this critical area, where fatigue cracks are likely to originate.

The output beam from a 15 kW CO_2 laser was split into two equal parts by a reflective copper wedge. Each beam was then directed to the workpiece surface in the form of a 12.5 mm by 12.5 mm (0.5 in. by 0.5 in.) spot by two optical integrators, as shown in Fig. 24. The projected area of each beam on the workpiece surface was approximately 12.5 mm by 25.4 mm (0.5 in. by 1 in.); thus, the total irradiated area was 3.18 cm^2 (0.5 $in.^2$).

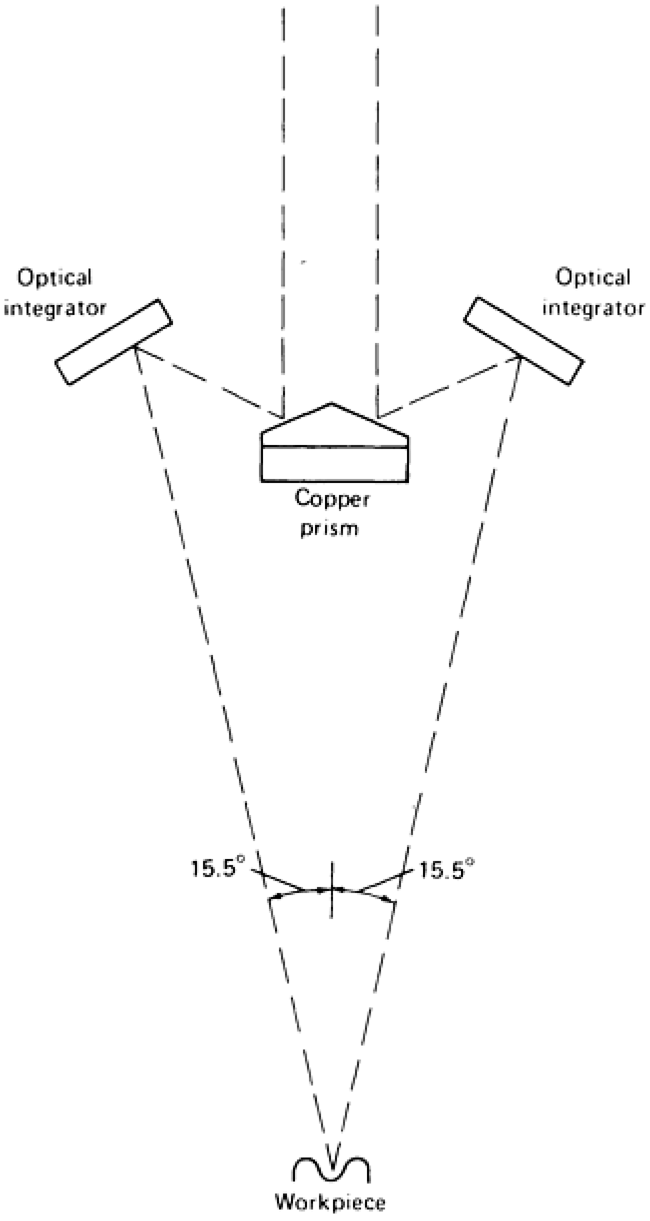

Fig. 24 Dual beam optics for laser gear heat treating

After surface preparation with flat, black spray paint, the gear was laser processed at a total power input of 8.8 kW and with a translation speed of 500 mm/min (20 in./ min). The calculated overall power density was 1380 W/cm^2 (8900 W/in.^{2}), but the actual power density varied somewhat over the interaction area because of the variation of incidence angle to the curved surface.

Sequential runs were made on teeth 120° apart to minimize heat distortion. Water cooling was used on tooth flanks adjacent to the processing area to prevent backtempering of previously processed teeth. The obtained case depth (45 HRC) was 1.2 to 1.3 mm (0.046 to 0.052 in.) at mid flank and at the root and 1 mm (0.04 in.) at the fillets. Surface hardness was 59 to 60 HRC.

Electron Beam Surface Hardening of Steels

S. Schiller and S. Panzer, Forschungsgesellshaft für Elektronenstrahl-und Plasmatechnik mbH, Dresden B. Furchheim, Sächsische Elektronenstrahl, GmbH, Chemnitz, Germany

Introduction

ELECTRON BEAM HARDENING TREATMENT (EBHT) is a short surface hardening procedure for martensitically hardenable ferrous materials. Austenitizing occurs through the energy transferred by electron beams. Precise application of the energy with respect to workpiece location and elapsed time using a focused and deflectable electron beam makes it the process of choice, especially for the partial hardening of highly stressed surface regions in components. The austenitizing process advances from the surface toward the inner core regions of the component via heat conduction, thus allowing for a defined adjustment of the hardness penetration by selecting a suitable energy transfer duration. Typical hardening depths obtained by the EBHT process range from 0.1 to 1.5 mm (0.004 to 0.006 in.). The rapid cooling of the austenite required for martensite formation occurs through a self-quenching process that is dependent on the thermal conductivity and starts after the energy transfer has ceased. Depending on the material selected, the workpiece thickness required should be at least 5 to 10 times the austenitizing depth.

Although developed in 1970 (Ref 1), this technique has only recently found practical application in the metals industry. Because it offers the advantages of extremely low hardening distortion and relatively low energy consumption, electron beam hardening provides the metallurgist with an additional option to conventional hardening techniques. For certain specialized applications, electron beam hardening is competitive with both case hardening and induction hardening processes in the heat-treating marketplace.

Energy Absorption and Heat Conduction

As shown in Fig. 1, the electrons of the beam hit the component surface and penetrate into the metal surface. Because of the intense interaction between the beam electrons and the atoms of the material being bombarded by the beam, the electrons lose their energy rapidly. The majority of the energy lost by the electrons is transformed into heat in the absorption volume. Approximately 75% of the power generated by an electron beam is converted to heat when the beam is incident perpendicular to a steel surface (Ref 2). Substantial energy losses are incurred chiefly by the backscattering of incompletely decelerated electrons. The efficiency of this energy conversion is independent of the optical properties of the workpiece surface and the temperature of the material. When the incident beam is inclined to the steel surface, energy losses are increased because of enhanced electron backscattering.

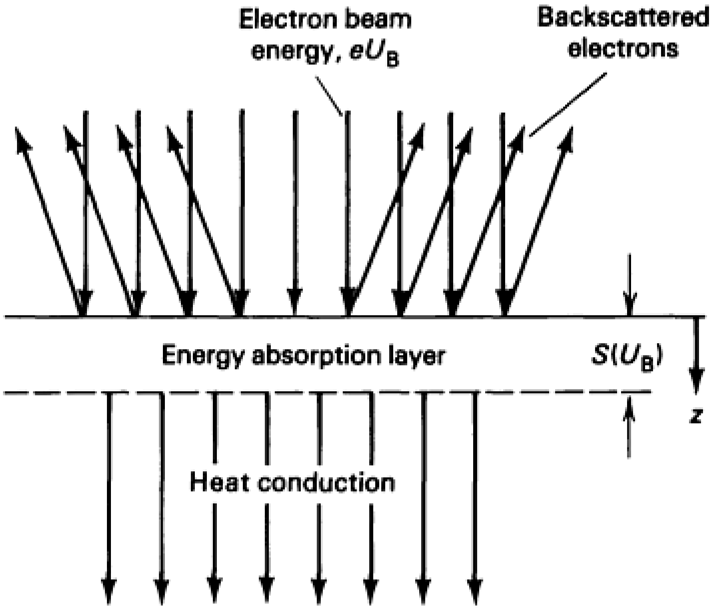

Fig. 1 Energy absorption zone and heat conduction zone generated by an electron beam on the surface of a workpiece

The thickness of the energy absorption layer is fixed by the electron range, *S* (in µm), which is given by the equation:

$$S = 2.1 \text{ x } 10^{-8}\left(\frac{U_B^2}{r}\right) \qquad \textbf{(Eq 1)}$$

where the constant 2.1 × 10^{-8} is dimensionless, U_B is the acceleration voltage of the electron beam in volts, and ρ is the density of the material in g/cm^3 (Ref 2). For ferrous metals, typical acceleration voltages of the beam range from 60 to 150 kV and typical electron range values are 10 to 50 µm (0.0004 to 0.002 in.).

As a result of the energy transfer, it is the material in the energy absorption volume which is heated first. This results in a temperature gradient toward the interior of the component. Because of the heat conduction in the direction of this gradient, the regions adjacent to the absorption volume are heated accordingly. The longer the duration of the energy transfer, the farther the heated zone of the material extends beyond the actual energy absorption volume. The temperature field, *T* (*x*, *y*, *z*, *t*), that results is described by the heat conductivity equation:

$$\left(\frac{\partial}{\partial t} - a\frac{\partial^2}{\partial r^2}\right)T$$

$$T = \left\{ {}_0\frac{v(x,y,z,t)}{rc} \; for \; 0 \le t \le t_H, a = \frac{l}{rc} \right\} or \; t>t_H \qquad \textbf{(Eq 2)}$$

where **r** is a vector in space defined by $|\mathbf{r}|^2 = (x^2 + y^2 + z^2)$ and *a* is the temperature diffusivity resulting from the heat conductivity (λ), the specific heat (*c*), and the density (ρ) of the material. The term *v* (*x*, *y*, *z*, *t*) describes the heat source distribution in the energy absorption volume which extends over the energy transfer duration, $t = 0$ to $t = t_H$. The solution to the equation of heat conduction (Eq 2) for different source distributions *v*and various boundary conditions is available in technical literature covering thermodynamics (Ref 3).

However, one general result of the resolved heat conductivity equation (Eq 2) shall be dealt with here in more detail because it is of great significance for electron beam hardening. This is the sudden energy transfer which occurs within a time $t_H \rightarrow 0$. In this case, the energy absorption layer is heated and gives an energy accumulator that discharges at a time constant:

$$t \approx \frac{S^2}{a} \quad \textbf{(Eq 3)}$$

because of the heat conduction. This means that the energy absorption layer maintains the energy transfer into the interior of the workpiece for a certain time even after the pulsed beam action has ceased. As a result, it is immaterial whether a particular energy flow density is transferred to the surface either continuously or pulsed, provided the timed pulse spacing lies within the time τ given by Eq 3 for the generation of the temperature field in a distance $z > S$ to the surface. Because of the interdependence of Eq 1 and Eq 3, however, the heat-retaining capacity of the energy absorption layer and the discharge time constant will strongly increase with the acceleration voltage of the electron beam. Depending on the acceleration voltage and material, this results in values of τ in a range of a few μs to a few hundred μs.

Energy Transfer and the Temperature-Time Cycle

The energy transfer mechanism to the workpiece surface with respect to location and time determines the time-dependent spatial thermal profile in the workpiece and, therefore, both austenitizing and martensite formation in the material is quite extensive. Two important cases of the transferred areal energy and its effects on the thermal profile in the outer layer of the workpiece are shown in Fig. 2. The energy flow densities were chosen so that the surface is kept just below the melting temperature. With a time-invariant energy flow density, the surface temperature varies directly with the square root of the action time and attains the allowable ultimate temperature only at the end of the transfer duration t_H (see Fig. 2a). With an adequate degressive energy flow density, the surface can be kept at the permissible temperature throughout the energy transfer duration (see Fig. 2b). (However, because the energy flow density diverges as $t \rightarrow 0$, this case can be implemented in practice only approximately.) Such an isothermal energy transfer offers the advantage of a rather high rate of temperature rise desired for austenitizing at the highest possible energy utilization for this process.

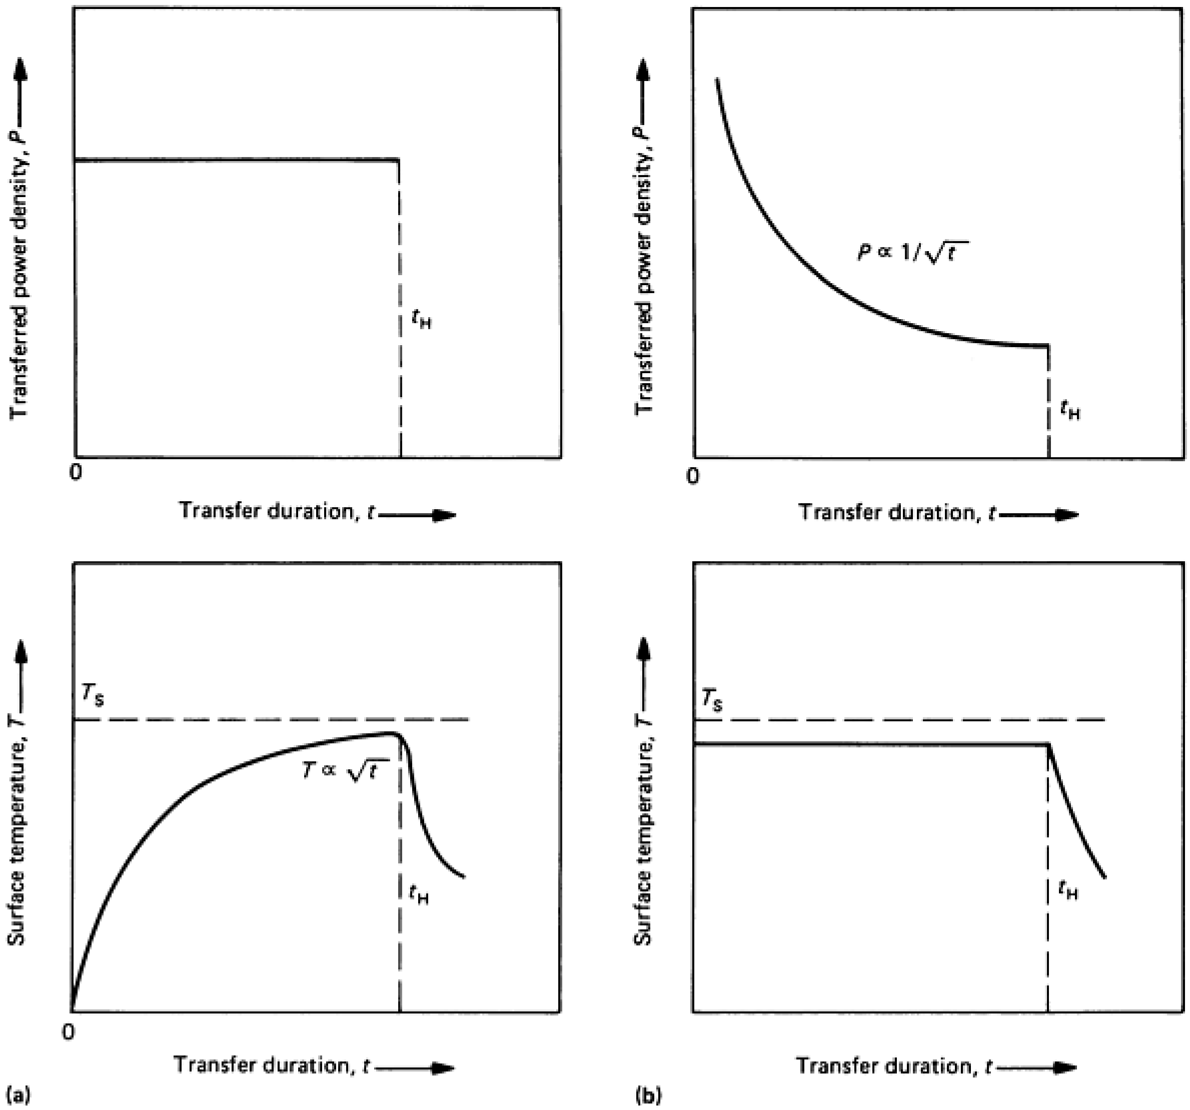

Fig. 2 Relation between time response of the transferred power density, *P*, and the surface temperature, *T*, for two cases. (a) Constant power density, where *P* does not vary but *T* varies directly with $\sqrt{t}$. (b) Isothermal energy transfer, where *T* does not vary but *P* is inversely proportional to 1/ $\sqrt{t}$ Melting temperature, T_s

Pulsed Energy Transfer. When the energy is transferred to the surface in a pulsed mode, a temperature oscillation occurs in the rhythm of a pulse train both in the energy absorption volume and on the surface itself. If the energy pulses have been chosen so that the allowable maximum temperature on the surface, T_S, is attained just at the pulse end, the surface temperature will oscillate between this temperature and a time-dependent minimum. The time dependence of this minimum surface temperature is illustrated in Fig. 3 for various pulse spacings, Δt, and electron ranges, *S*. The effect of both parameters on the rise of the minimum surface temperature up to the tolerable final value of approximately (T_S - 100) °C or (T_S - 212) °F becomes clearly evident. At a given electron range and energy transfer duration, or austenitizing depth, there is a minimum rate for the energy transfer. Below this value, the temperature oscillation cannot be tolerated.

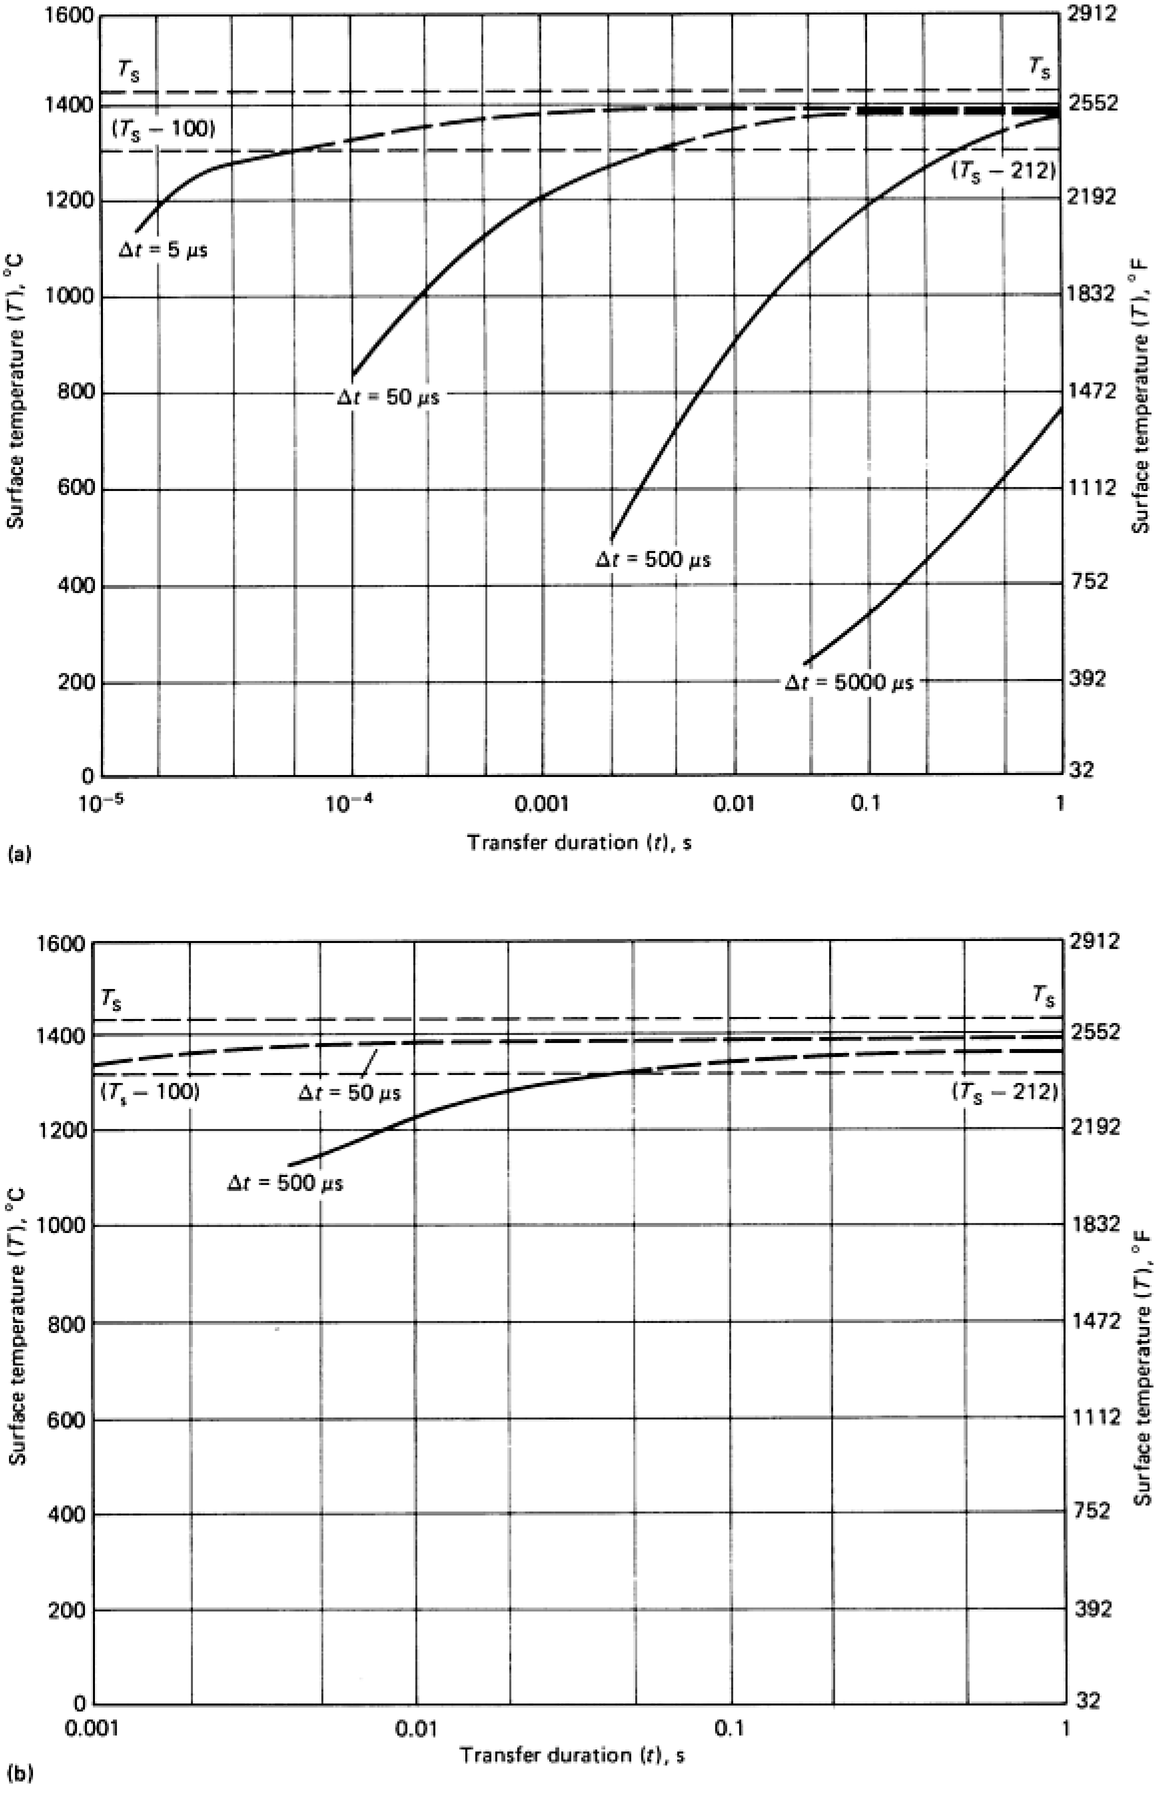

Fig. 3 Plot of surface temperature, T, below the melting point, T_S, versus transfer time, t, for selected pulse spacings, Δt, of 5, 50, 500, and 5000 μs and two selected electron ranges, S, of (a) 10 μm and (b) 50 μm. Data

are for the minimum surface temperature obtained for the pulse energy transfer obtained at the Δ*t* values used.

For the simple experimental determination of the necessary minimum rate of the energy transfer, it is suggested to use a transferred energy density, e_F, as a function of the pulse rate which still prevents the surface from incipient fusing. Figure 4 shows the result obtained for an extreme case of a line-scanned electron beam at a workpiece motion normal to the direction of scan (Ref 4). From the data in Fig. 3 and 4, it is possible to derive coinciding pulse rate requirements for the hardening problem described in Fig. 3.

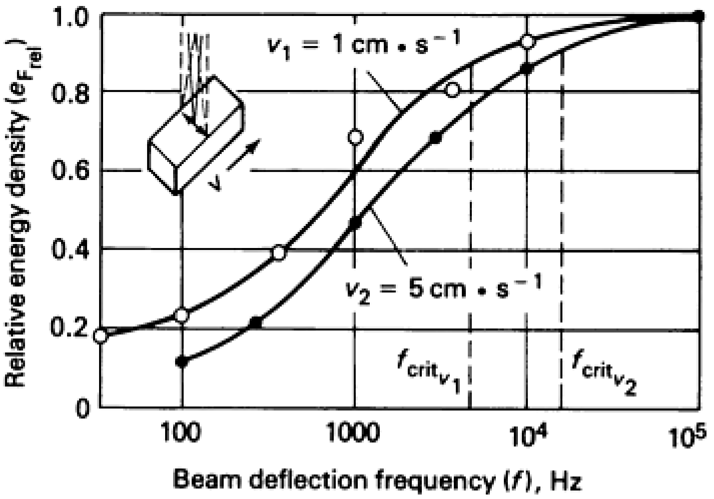

Fig. 4 Relative energy density, eF_{rel} **=** e_F**(f)/**e_F**(100 kHz), transferable without superficial fusing as a function of the beam deflection frequency, *f*, for two different moving rates,** v_1 **and** v_2**, in C 45 steel. Electron energy, 60 keV; beam spot, 0.3 mm (0.01 in.) deflection; triangular function; and critical frequency at selected moving rates,** $fcrit_{v1}$ **and** $fcrit_{v2}$

Thermal Profile of the Workpiece. In the case of electron beam hardening with isothermal energy transfer, the surface temperature is practically constant throughout the energy transfer duration and is chosen such that it lies just below the melting temperature. As the distance to the surface increases, the temperature rise and the maximum temperature obtained will differ as shown in Fig. 5. At a specific distance below the surface, z_o, the austenitizing temperature is attained. At a greater distance, however, such is not the case. Therefore, different austenitizing conditions exist at different distances below the surface of the steel.

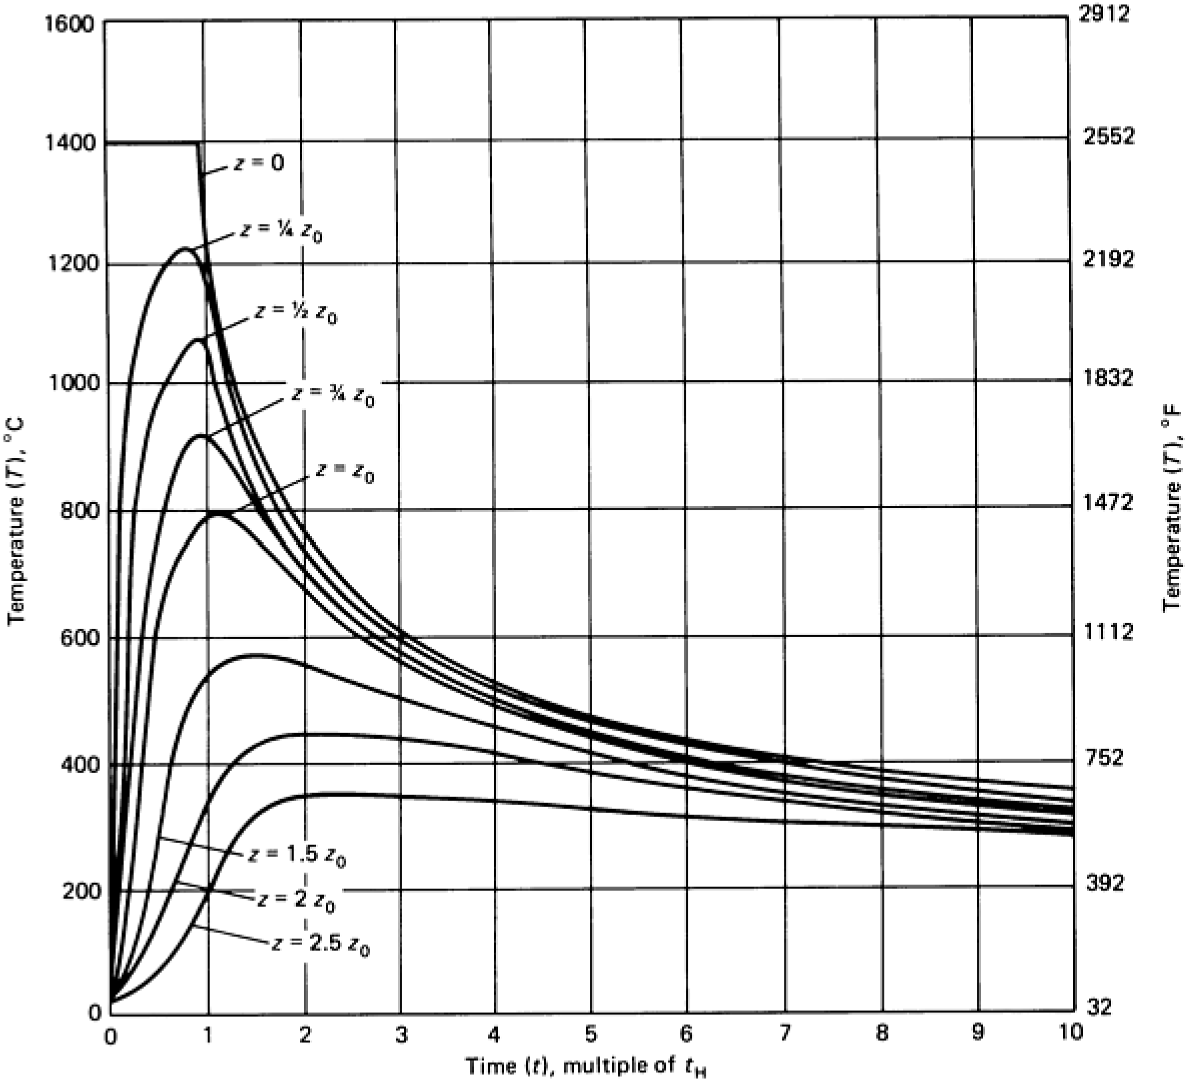

Fig. 5 Plot of temperature versus time, *t*, expressed as a multiple of the energy transfer duration, t_H, as a function of distance from the surface, *z*, for the isothermal energy transfer in steel. Depth is expressed with *z* being a fraction or multiple of the austenitizing depth, z_o.

After the energy transfer duration t_H has elapsed, cooling takes place so that the surface-distant regions of the material are always at a lower temperature level than the near-surface regions. In contrast to hardening techniques that use quenching by an external medium, cooling occurs in the component from the inside core toward the outside surface.

The austenitizing depth determines the thickness of the hardened layer. Heating of the material beyond the austenitizing depth represents an unavoidable internal energy loss that is due to the mechanism of heat conduction. The temperature gradient on the austenitizing boundary obtained at the end of the heat-up duration and the relative share in the internal energy loss are determined by the time behavior of the surface temperature. With an isothermal energy transfer and a surface temperature close to the melting temperature, the maximum austenitizing depth is obtained at a minimized internal energy loss under otherwise given conditions. The slope of the temperature gradient on the austenitizing boundary is reduced with increasing austenitizing depth.

Control of Beam Location and Duration

In the case of an areal energy transfer, electron beam hardening requires energy flow densities on the order of 10^3 to 10^4 W/cm^2 (3×10^6 to 3×10^7 Btu/ft$^2 \cdot$ h). At the focus of the beam, however, the energy flow density ranges from 10^6 to 10^7 W/cm^2 (3×10^9 to 3×10^{10} Btu/ft$^2 \cdot$ h).

Beam Defocusing Method (Ref 5). A simple solution for matching the energy flow density to specific requirements is a technique called beam defocusing. Figure 6 shows computer-controlled deflection used to raster (move) the defocused electron beam over the surface of the workpiece into a shaped pattern of a microenergy dot array. This provides a precise local heating to the austenitizing temperature. When heating ceases, the surface layers rapidly transform into martensite by self-quenching, producing surface hardness values approximately 1 to 2 HRC higher than that obtained in furnace heat treated components.

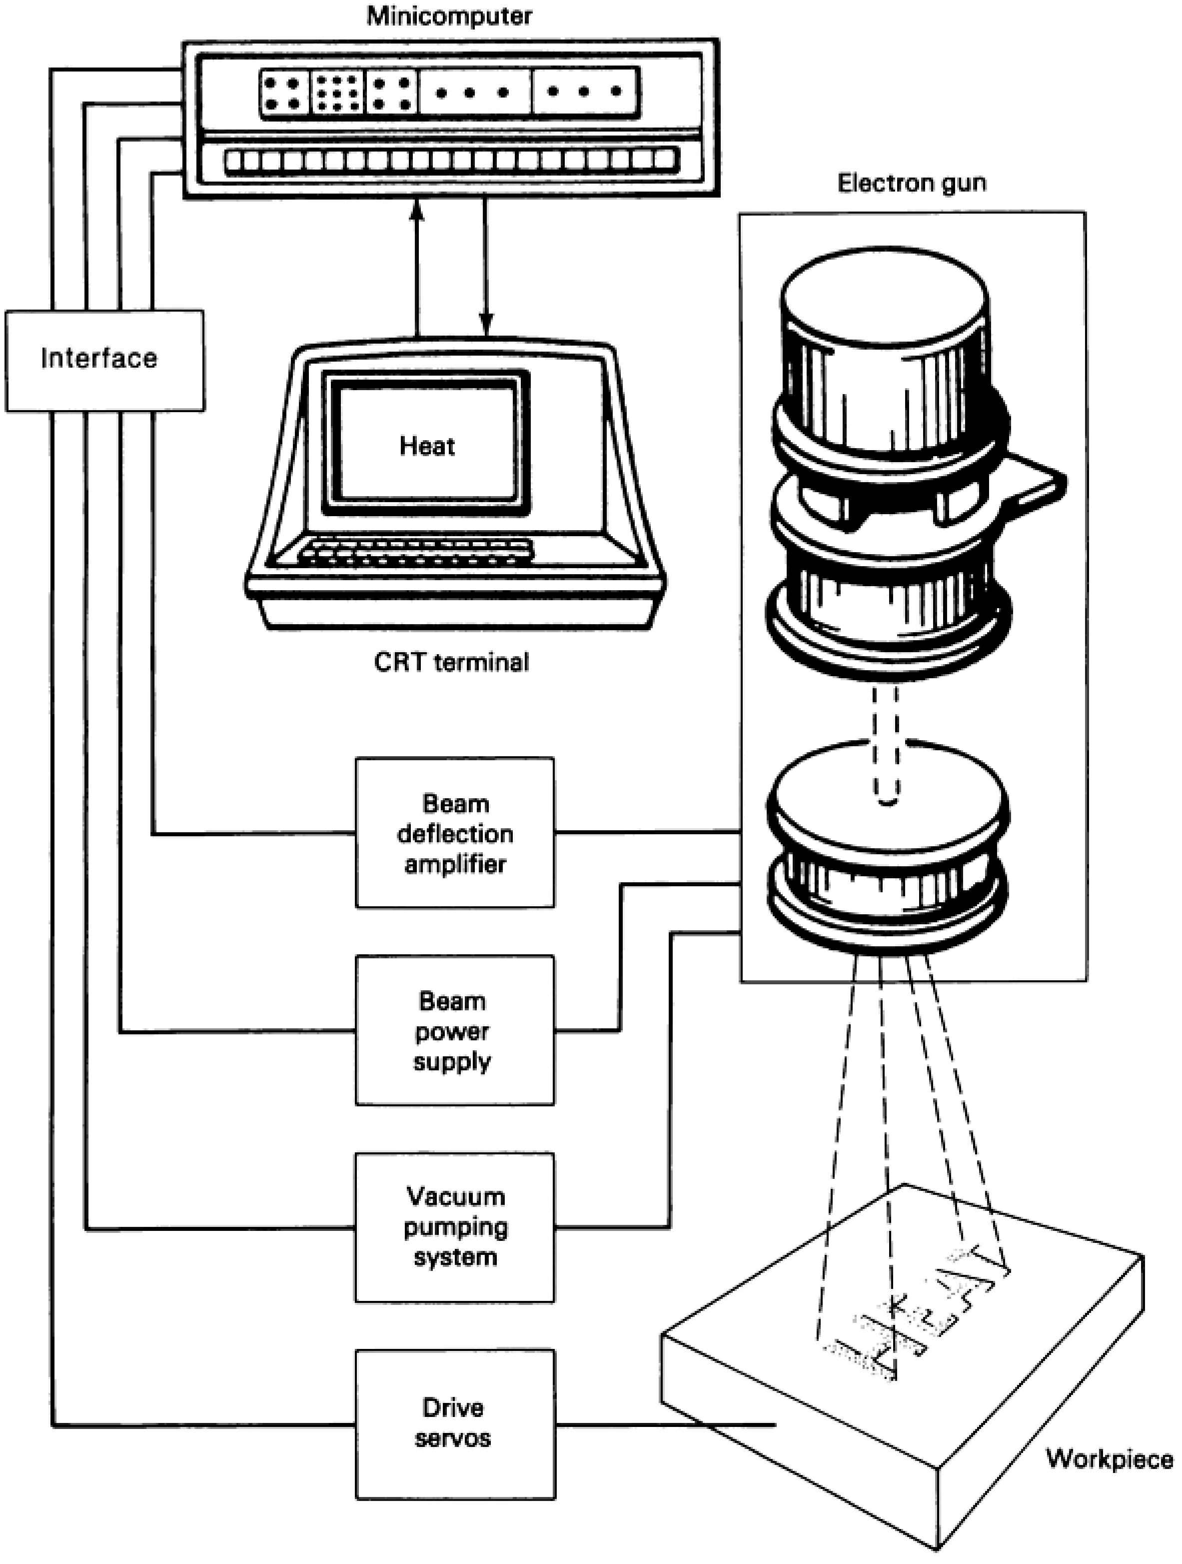

Fig. 6 Schematic of a computer-controlled electron beam hardening installation incorporating the beam defocusing method

Although this method is practical for some applications, it will not be emphasized in this article because it overlooks the principle of very precise energy transfer to a specified location.

In terms of location and time, the most significant beam control is obtained by means of a beam focused onto the component surface (see Fig. 7). Several versions of this technique are used. In variant A (see Fig. 7a), the beam acts on

the neighboring surface locations point-by-point and in a timed sequence. The action time is determined by the austenitizing depth required. Using a time-degressive flow of the beam current, it is possible to obtain an isothermal energy transfer at the center of the corresponding site of the surface. However, the occurrence of temper zones on neighboring sites not heated in a timed sequence is a drawback of this procedure. To avoid the incipient fusing of the surface, the beam power must be limited to approximately several hundred watts. As a result, this procedure is cost-effective only for the hardening of very small surfaces.

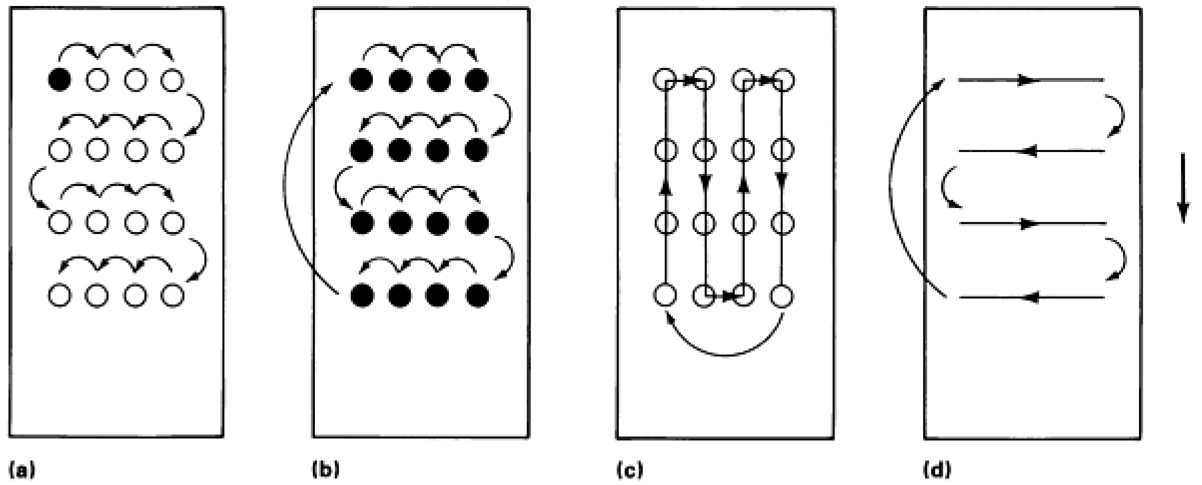

Fig. 7 Beam guidance for surface hardening with respect to location and time. (a) Variant A, point by point in succession. (b) Variant B_1, point by point in repetition. (c) Variant B_2, rate-controlled in line-shaped repetition. (d) Variant C, rf line raster in repetition on a moving workpiece

In variant B_1, the energy transfer also occurs in a dot raster, but the beam is guided in a rapid cyclic sequence from point to point in a jump-like manner (Fig. 7b). Referenced to a given surface location, the energy transfer takes place in a pulsed mode. One decisive advantage of the pulsed mode is that the energy input can be easily matched to the conditions of heat dissipation present at the work site. To this end, the proportional dwell time of the beam within a deflection cycle is chosen so that it is greater at the boundary and corner points of the energy transfer field than on its inner points (Ref 6). Again, a degressive beam current/time dependence is required to obtain an isothermal energy transfer.

Compared to variant B_1, the beam guidance variant B_2 (see Fig. 7c) excels in its ability to guide the electron beam continuously and repeatedly over the energy transfer field. Thus, the risk of overheating at the raster points linked with local surface fusing is notably reduced. The matching of the energy dose to the varying conditions of heat dissipation is achieved by using a site-dependent beam deflection rate.

The beam guidance variants B_1 and B_2 are recommended wherever an energy flow density has to be transferred. This strongly depends on treating site conditions. For example, this holds for cases in which the slope of the surface to the beam axis changes within the energy transfer field. Moreover, curved and limited energy transfer fields can be easily implemented in this way. Hence, the processing variants B_1 and B_2 are recommended for the hardening of surfaces whose accessibility to the beam scan field is limited because of the configuration of the part. Depending on the size of the surface to be hardened, the power consumption of a focused electron beam amounts to several kilowatts. In the beam guidance variant C, the beam is radio frequency (rf) scanned in a line raster (see Fig. 7d). The workpiece is moved normal to the direction of the scan, preferably at a constant speed relative to the energy transfer field that is fixed in space. Thus, the energy transfer duration is determined by the ratio of the raster field extension in the direction of motion to the travel speed of the component surface. Thus, an isothermal energy transfer can be readily implemented by a corresponding choice of the raster line spacings (see Fig. 8). The advantage of this beam guidance version is that the dwell time of the scanned beam on a given surface location is extremely short. With scan rates at 1 to 10 km/s (3000 to 30,000 ft/s), beam dwell times as low as 10 ns can be obtained. Under these conditions, the energy absorption layer acts as a heat accumulator. The oscillations on the component surface temperature become very low. Figure 9 can be used to estimate the temperature oscillation on the surface as a function of several beam parameters and the scan rate. For example, when U_B is 100 kV, dF_x is 0.05 cm, v_y is 4×10^5 cm $\cdot$ s^{-1}, and P is 20 kW, a ΔT value of 53 K is obtained (see Fig. 9). Table 1 lists the composition of C 45 steel and other steels discussed in this article.

Beam guidance version, variant C, uses extremely high beam power consumption in the kilowatt range and provides the highest process productivity in terms of the hardenable surface per unit of time (see Fig. 10). Because each surface location passes the same temperature-time cycle, the lateral homogeneity properties of the hardness layer are very good.

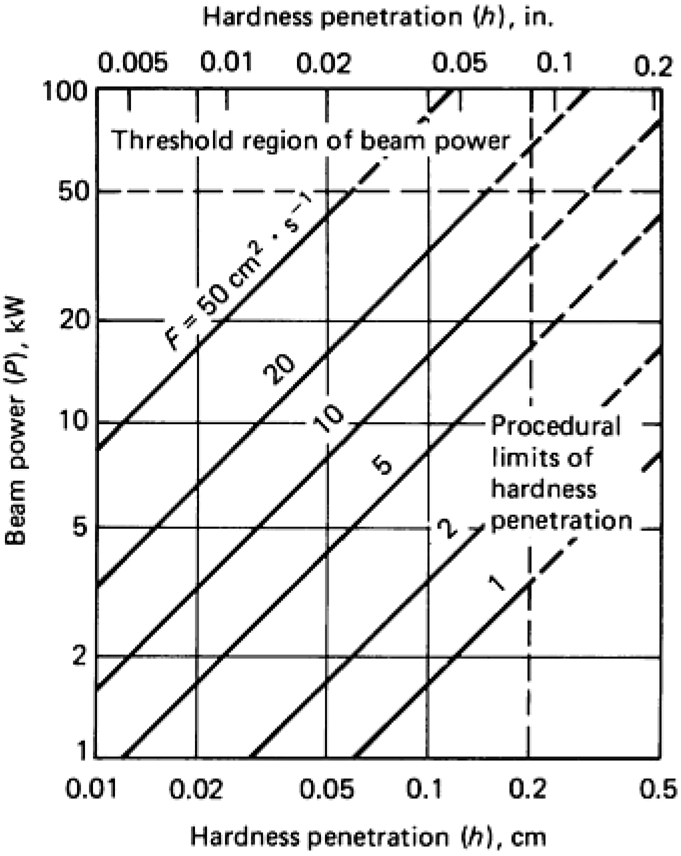

Fig. 10 Plot of beam power, *P*, versus hardness penetration, *h*, for selected values of areal throughput, *F*. Data are for isothermal energy transfer of C 45 steel.

If the reversing points of the beam's deflection are not well defined, tracks of incipient fusing are obtained on the edges of the hardness track. The energy flow density in the raster direction can be selected at random simply by choosing a corresponding raster line spacing. Difficulties are encountered in terms of maintaining the density in the direction of the scan lines without sacrificing the advantage of a high deflection rate.

Beam guidance version C is especially useful for applications such as the hardening of larger surfaces on plane and cylindrical components.

Properties of the Hardened Layer

When a material undergoes austenitizing and self-quenching heat treatments, a hardened surface layer is produced because of heat conduction. The properties of the hardened layer depend on the mode of energy transfer and the composition and microstructure of the material. This section will discuss process-specific properties of the hardened layer in greater detail. The results are based on isothermal energy transfer data obtained using the high-speed scan technique (see Fig. 8) and a surface temperature that is close to the melting temperature of the material being tested.

Hardness Penetration and Energy Density Transfer. Figure 11 shows the effect of different thermal pretreatments on a carbon steel and a low-alloy steel. The scattering of the data points attests to the variation in the material properties of the two steels. The following conclusions can be drawn from the data in Fig. 11:

- At a given temperature, the transfer energy density, e_F, is a representative measure of the hardening depth
- The relation between the energy density, e_F, and the hardening depth is linear
- At a given surface energy, the hardening depth obtained depends on the material composition
- Based on the material composition of both steel types, the thermal pretreatment state has a low to dominant effect on the hardening depth. The latter holds true especially for high alloying contributions, especially chromium

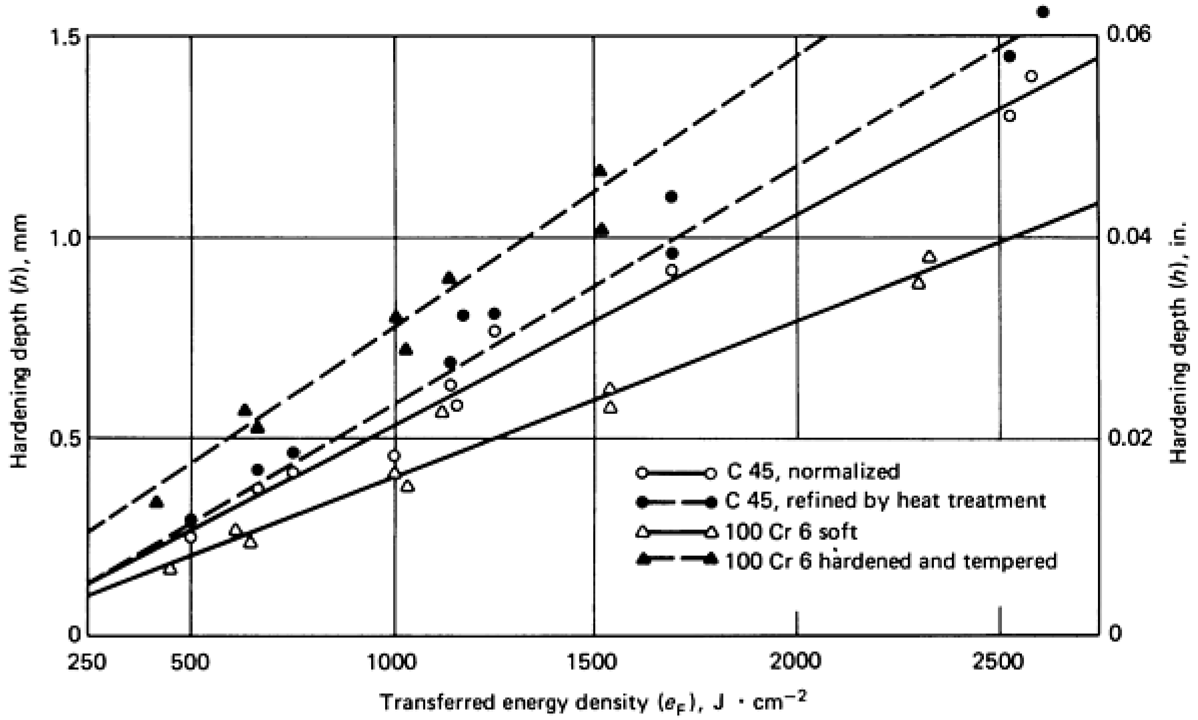

Fig. 11 Plot of hardening depth, *h*, as a function of the surface energy density, e_F, lost via isothermal energy transfer near the melting temperature of C 45 and 100 Cr 6 for selected preheating conditions. Source: Ref 9

Based on these conclusions, it can be assumed that it is possible to mathematically determine the effect of thermal heat treatments on the hardening depth of a material at selected temperatures prior to experimentally determining the conditions required.

Cross-Sectional Profile of the Hardened Layer. A significant feature of the energy transfer principle illustrated in Fig. 8 is that, on each surface location within the hardness track, an equal energy density is applied in the same time regime. However, a constant hardening depth across the hardness track can be expected only for those track regions in which identical conditions of heat dissipation exist (that is, wherever the isotherms run parallel to the surface). This holds true in cases where the width of the energy transfer track either coincides with or exceeds the width of the workpiece.

On the other hand, if the width of the workpiece is greater than the width of the energy transfer track, other heat dissipation variables determine the marginal zones. At the track edge, the isotherms are bent toward the surface. Thus, a constant hardening depth exists at the exact center of the track that, depending on the ratio of the track width to hardening depth, is flanked by marginal zones where the hardening depth continually reduces to zero. As a rule, this effect, although caused by the heat conduction mechanism, cannot be fully eliminated by a higher energy input at the marginal zones of the track. Figure 12 shows the typical cross-sectional profile of a hardness track with a track width-to-hardening depth ratio of 50:1. With its pronounced range of constant hardening depth, it significantly differs from the cross-sectional

profiles obtained with other energy transfer techniques. The drop in hardening depth is limited to a narrow marginal zone of which the width is less than twice the hardening depth.

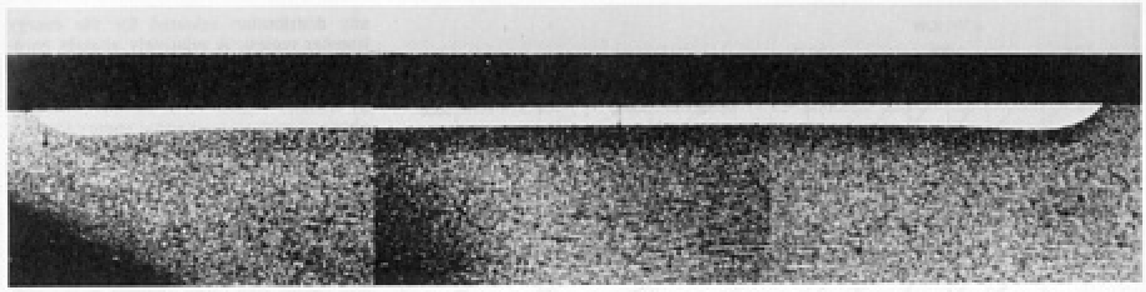

Fig. 12 Cross-sectional profile of a hardness track in Ck 67 steel refined by heat treatment. Hardening depth, 0.4 mm (0.016 in.); width of hardness track, 20 mm (0.8 in.); energy input, 600 J · cm^{-2}

Hardness Gradient in the Hardened Layer. As predicted by the energy transfer principle and as corroborated by other researchers (Ref 10), hardness measurements that are taken on the surface in the direction of the track and transverse to the track resulted in constant hardness values. At the track edges, however, the hardness values drop abruptly to the base material value and then the temper zone value. In accordance with the properties of the material, the surface hardness may also depend on the hardening depth within certain limits. This is attributable to the dwell time increasing with the hardening depth to keep the surface at a higher temperature while simultaneously reducing the quench rate.

The hardness profile measured normal to the workpiece surface is determined by the effect of the rapidly changing temperature cycle with distance to the surface. Depending on the morphology of the material and the kinetics of the austenitizing process, this temperature change has a bearing on the hardness gradient. The finite temperature difference, $TA_{c3} - TA_{c1}$, between the completion and the beginning of austenitizing, which is related to the slope of the temperature gradient in this transformation range, also provides a finite slope of the hardness gradient between the hardened layer and the base material. In the case of a base material that has been quenched and tempered, the inevitable heat-up of the material beyond the austenitizing depth usually produces a tempered boundary layer having a corresponding drop in hardness. Figure 13(a) shows the hardness profile normal to the surface at selected hardening depths for C 45 steel refined through heat treatment. A relatively constant maximum hardness value (800 to 900 HV) over a wide range of layer thickness values to 0.50 mm (0.02 in.) is typically followed by a steep drop in hardness value of the base material that levels off at 350 HV with increasing distances to the surface of the material. The slope of this drop in hardness in the transition region is reduced proportionately with the increasing hardening depth as the transfer energy density is increased. The scatter in the measured values about the plotted curve is negligible. Figure 13(b) shows the corresponding hardness profiles for the same material following normalization. The spread of the measured microhardness values is remarkably wide and can be attributed to the inhomogeneity of the initial state that has both ferritic and pearlitic zones. This scattering of hardness values clearly reflects the known strong effect a thermal pretreatment of the material exerts on the hardness values in the case of a short-time hardening.

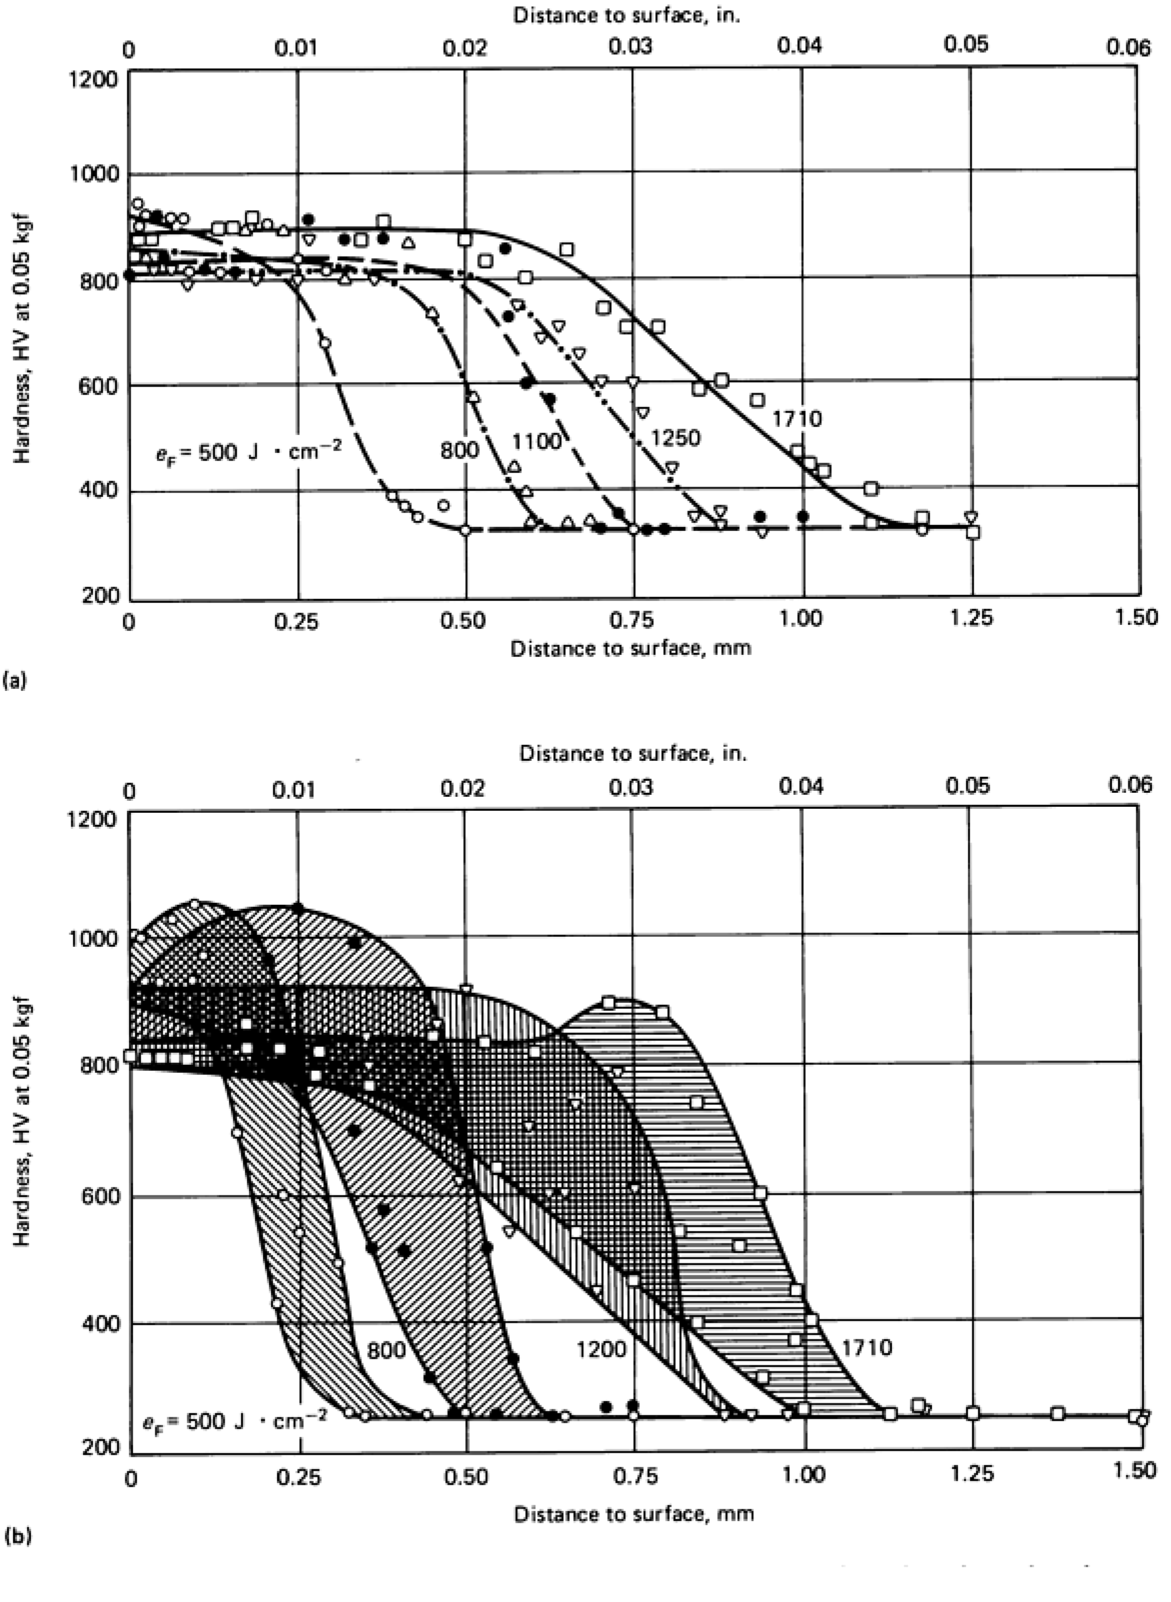

Fig. 13 Effect of preheating state on the hardening depth profile of C 45 steel at selected transferred energy densities, e_F. (a) Refined by heat treatment. (b) Normalized. Source: Ref 11

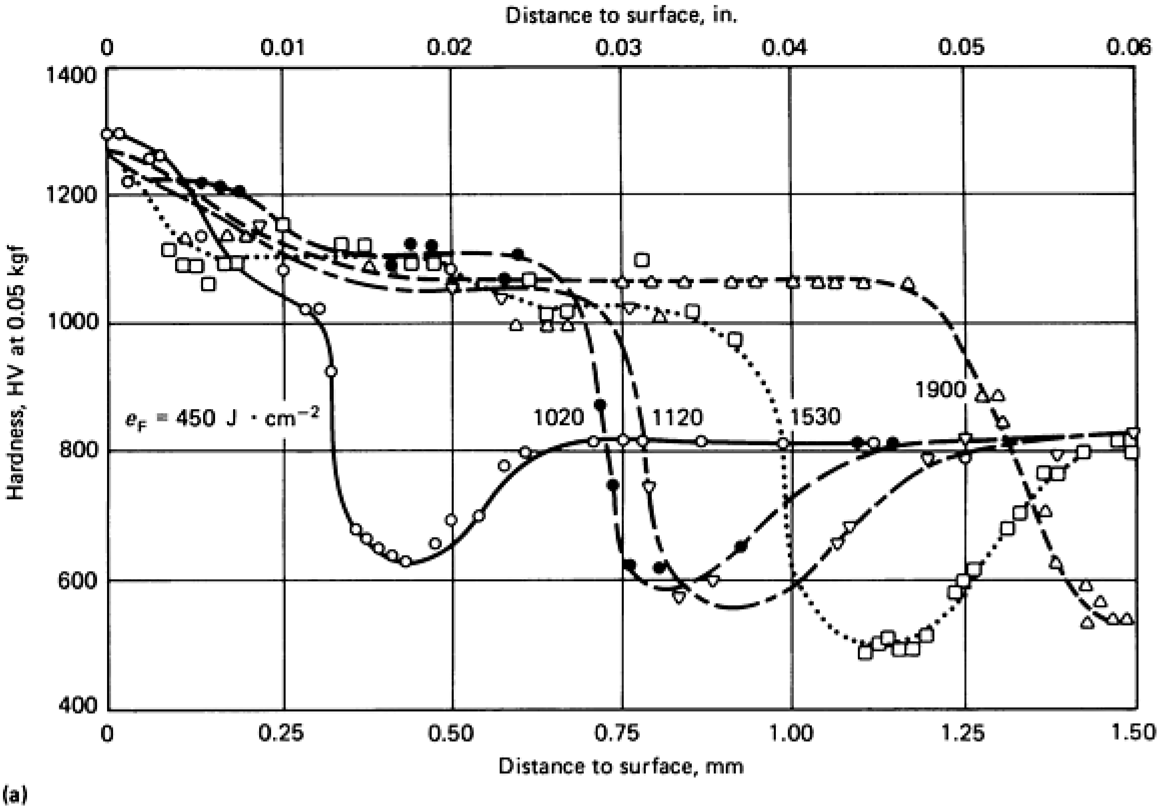
Figure 14 shows the hardening profiles obtained with 100 Cr 6 hypereutectoid steel both in the hardened and tempered state (Fig. 14a) and in the soft initial state (Fig. 14b). Similar to the data in Fig. 13 for C 45 steel, pronounced differences are obtained for the various heat treatment states of 100 Cr 6 material. In addition, the plot in Fig. 14 introduces a distinct hardness minimum in the boundary region between the hardened layer and the base material for the hardened and tempered 100 Cr 6 material. The minimum hardness values become progressively lower as the hardening depth increases.

This is a consequence of the increased dwell times required as the tempering temperature is approached. However, the hardness values in this tempered layer (about 500 to 550 HV at a distance of 0.50 mm, or 0.02 in., below the surface) are much higher than the 250 HV hardness value obtained at a distance of 0.5 mm (0.02 in.) found in the soft-annealed material. Similar tempering zones also occur with quenched and/or tempered hardened materials as well as with the initial tempered states of other materials if the basic hardness exceeds 500 HV at a distance of 0.50 mm (0.02 in.) below the surface. As already evident from Fig. 11, a notably greater hardness penetration is obtained with the hardened and tempered base material compared to the soft-annealed material although the energy input is similar. When compared to normalized C 45 carbon steel, the hardness values measured for soft-annealed 100 Cr 6 steel exhibit much less scatter. Above all, the quenched and tempered or hardened and tempered initial states of both materials differ with respect to the slope of the hardness transition in the base material.



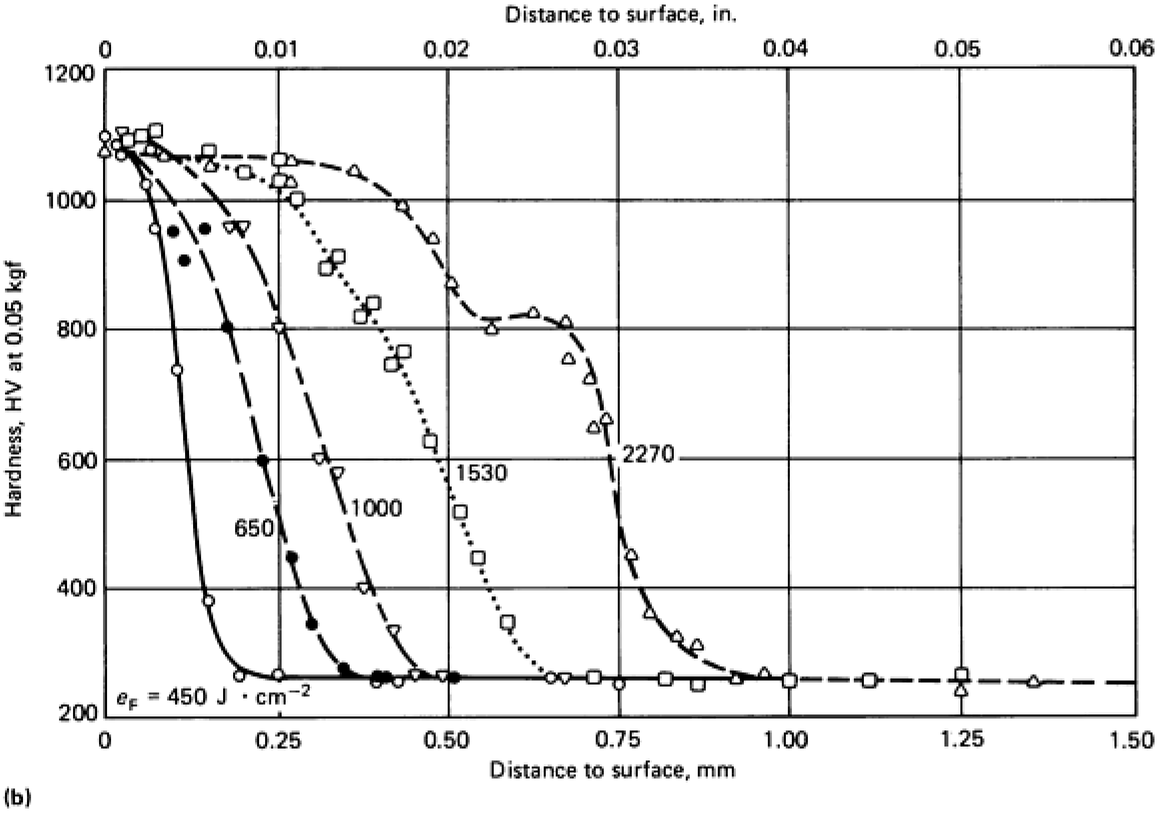


Fig. 14 Effect of preheating state on the hardening depth profile of 100 Cr 6 hypereutectoid steel at selected transferred energy densities, e_F. (a) Hardened and tempered. (b) Soft. Source: Ref 11

In the transition region of the base material, the hardness gradient is determined by the material-dependent transformation kinetics and the temperature gradient in this region. However, the temperature gradient can be directly affected via the power density distribution selected for the energy transfer region. A relatively straight hardness transition curve is obtained at a constant power density distribution in the energy transfer region when compared to that obtained with an isothermal energy transfer (Ref 12). However, it should be noted that such a measure increases the thermal stress imposed on the workpiece if a layer thickness having maximum hardness is to be maintained.

Surface Roughness. The crystalline transformation processes linked to the temperature cycles also cause changes in the geometrical surface structure. For example, surfaces polished to an average surface roughness, *Rz*, of 0.05 μm (2 μin.) had a surface roughness of up to 1.5 μm (60 μin.) after the hardening process (Fig. 15). Depending on the material, the surface roughness increases with the surface temperature and the duration of the energy transfer.

Fig. 15 Surface relief of a normalized C 45 steel sample polished before hardening that had the isothermal energy transfer at approximately the melting temperature. Energy density transferred, 1250 J · cm^{-2}; surface roughness, R_z, is 1.2 μm (48 μin.). Source: Ref 9

Because temperatures close to the melting point provide a greater surface roughness and maximum surface temperatures, a reduction in roughness that is caused by a heat buildup and the incipient fusion of the surface peaks is observed.

Surface Deformation. The various specific volumes of the initial and transformation products cause a surface deformation in the region of the hardness track. The surface of the hardened track becomes elevated compared to its initial level. The graphs in Fig. 16 confirm that the surface deformation is a function of the energy density transferred and the composition of the material. In addition, a slight surface retraction may occur in the marginal zone of the hardened track. With hardening depths of approximately 1.5 mm (0.06 in.), surface elevations as high as 15 μm (600 μin.) were observed. Because no direct correlation has been established between material composition and the temperature cycle used, no general linear relation between hardening depth and surface deformation can be determined. However, it is evident that the surface deformation is more pronounced than the surface roughness.

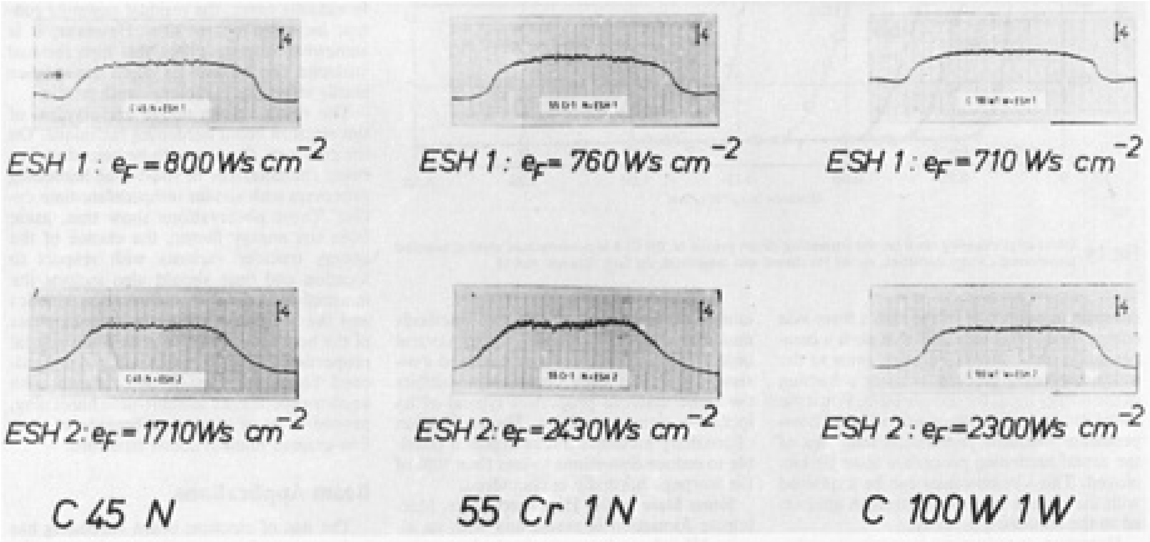

Fig. 16 Surface deformation in the region of the hardness track for C 45, 55 Cr 1, and C 100 W1 steels. N, normalized; W, soft. W · s = watt · second = J. Source: Ref 9

Workpiece Distortion. Although electron beam hardening is generally classified as a method that produces minimal distortion, the degree of distortion encountered cannot be neglected in all cases. Because workpiece distortion depends not only on factors such as component rigidity, hardening depth, location, and extension of the hardened surface but also on the material composition and its pretreatment state, it is difficult to set up general guidelines for workpiece distortion. Parts having a low areal moment of inertia (for example, ledges hardened on one side only) are especially sensitive to warpage.

Sample slabs of 90 Mn V 8 steel measuring 8 mm ($\frac{5}{16}$ in.) thick by 305 mm (12 in.) long have a distortion of more than 1 mm (0.04 in.) after being hardened to a depth of 0.8 mm (0.03 in.) over the total (35 mm, or $1\frac{3}{8}$ in.) width. In this case, the hardened plane developed a concave shape.

There are two possible methods of lowering the distortion during the hardening of the slabs:

- Prestressing in the direction opposite to warpage during the energy transfer
- Applying an ancillary hardness track at the rear side of the slab before the actual hardening process commences

Identical energy transfer conditions are used for front-side hardening as are used for rear-side hardening but at reduced beam current settings. Figure 17 shows the residual warpage following hardening to be a function of the energy input on the rear side of the slab. Note that an optimum compensation of the distortion obtained for the slab's rear-side energy input is approximately 50% of the value obtained for the subsequent hardening of the slab's front-side energy input. This indicates that such a compensation must always be made prior to the actual hardening process by using a fraction of the energy input for this purpose. When the timed sequence is transposed, a higher compensation hardness penetration than that of the actual hardening procedure must be employed. This circumstance can be explained with the change in material strength attributed to the hardening process.

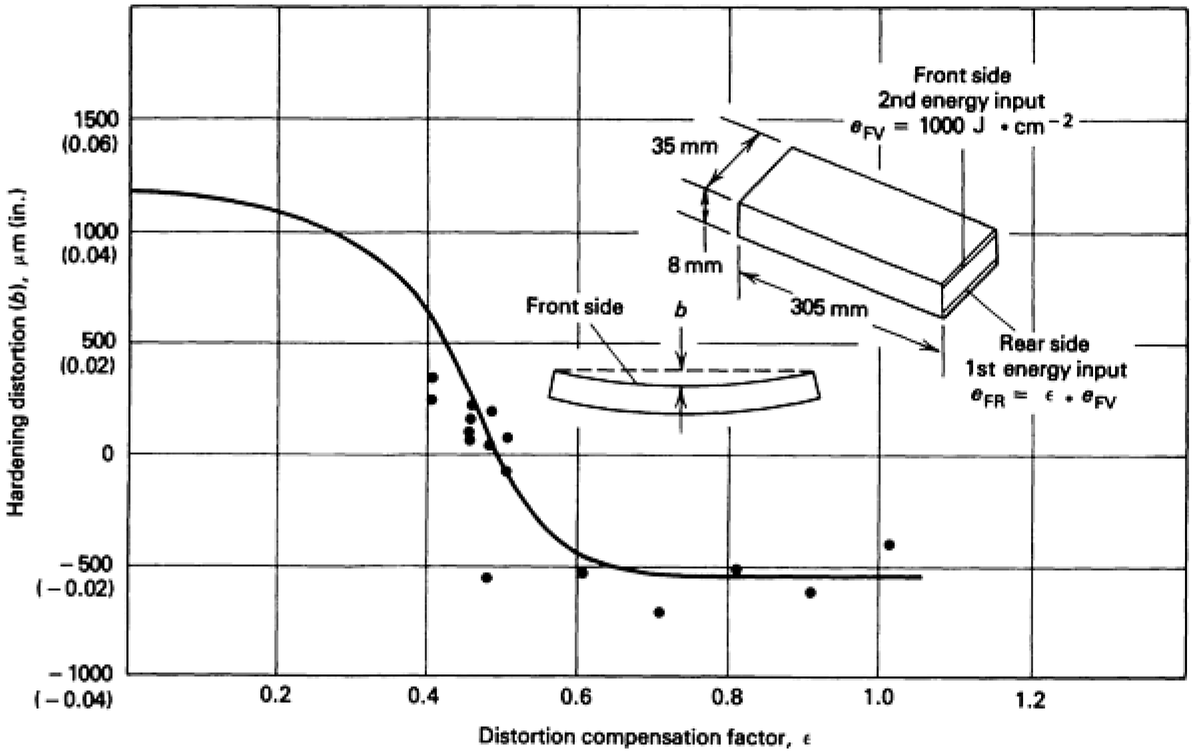

Fig. 17 Hardening distortion, *b*, as a function of the portion of the energy density, ε, transferred to the rear side during the preceding rear-side hardening process. Material is 90 MnV 8 steel having transferred energy density of 1000 J · cm^{-2}.

However, a reduction in workpiece distortion comparable to the reduction obtained through one of the two methods mentioned above (typically up to several orders of magnitude) can be obtained consistently only if each component exhibits the same material properties typical of its locked-in stress condition. The application of auxiliary hardness tracks makes it possible to reduce distortions to less than 10% of the warpage normally encountered.

Stress State in the Hardened Layer. Martensite formation is associated with an almost 1% volume increase. As the increasing cooling action diffuses from the inside core of the component to its surface and the martensite progressively forms in the same direction, residual compressive forces in the hardened layer are typically generated by the electron beam hardening technique. In the subsurface zones of a workpiece track hardened to a depth of 0.8 mm (0.03 in.), residual compressive forces of 300 MPa (45 ksi) were obtained in C 45 steel both in the longitudinal and transverse directions to the track (Ref 4).

Hardened Layer Microstructure. Because the material and crystalline reactions that occur during the hardening process are sensitive to the temperature-time cycle, relevant property gradients must be present in the hardened layer. Generally, the grain size in the hardened layer (especially pronounced in the case of hypoeutectoid steel grades) gradually decreases with increasing depth from the surface into the base material core. At hardening depths greater than 1 mm (0.04 in.), a rather coarse-grained structure is obtained near the surface whereas the deep-seated zones exhibit an extremely fine-grained structure as indicated in Fig. 18. At lower hardness penetrations, however, a fine-grained structure is also found on the surface. An incomplete dissolution structure is present in the transition region to the base material because it is only partially austenitized. As is the case with hypereutectoid steel grades, particularly those grades having a higher chromium content, carbides are dissolved only incompletely toward the surface. It is also typical of these steel grades that, other than martensite, a high residual austenite content is likely to be present in the hardened layer. With increasing hardness penetration, the residual austenite content also increases toward the surface. In extreme cases, the residual austenite content increases up to 30%. However, it is somewhat surprising that this high residual austenite content and its depth dependence hardly affect the hardening depth profile.

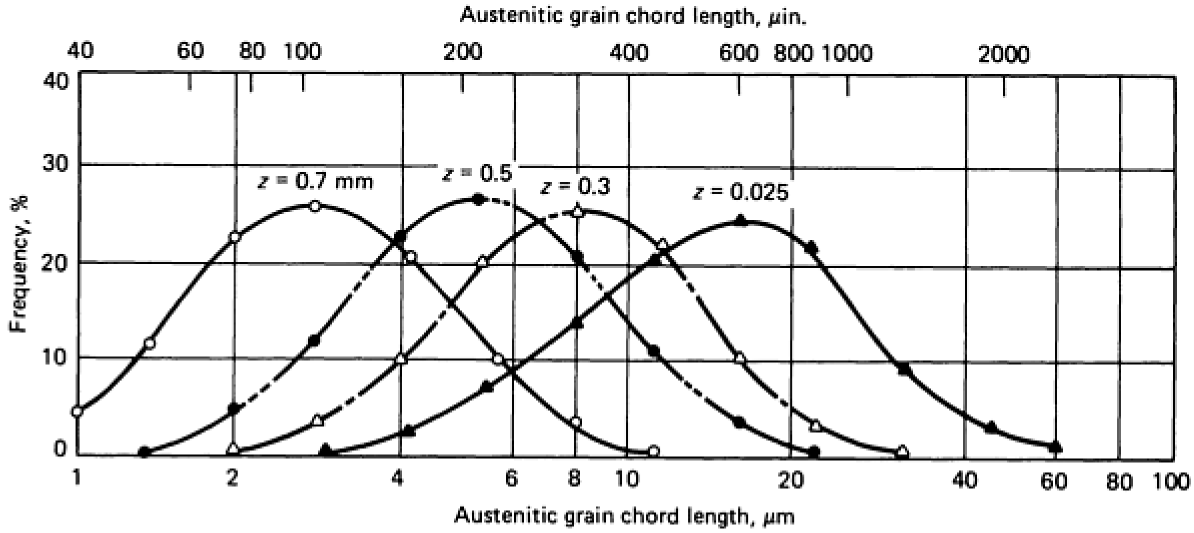

Fig. 18 Frequency distribution of austenitic grain chord lengths for various distances to the surface, *z*, obtained via thermal energy transfer at approximately the melting temperature. Data are for C 45 steel, refined by heat treatment to a hardening depth of 0.86 mm (0.034 in.). Source: Ref 9

The results given above are atypical of the electron beam hardening technique. On the contrary, they have to be considered as being characteristic of short-time hardening processes with similar temperature-time cycles. These observations show that, aside from the energy factor, the choice of the energy transfer variants with respect to location and time should also include the material-dependent transformation kinetics and the structural properties requirements of the hardened layer. In regard to material properties, quenched and tempered or hardened base materials, in accordance with known experiences in short-time hardening, proved to be of advantage because of their fine-grained homogeneous structure.

Beam Applications

The use of electron beam hardening has to be assessed in compliance with material and technological requirements and, above all, economic criteria. The prevailing conditions in an industry may also be of critical importance. In the vast majority of applications, this technique can compete successfully with induction hardening and other conventional hardening techniques such as case hardening.

From an engineering aspect, practically all parts with surfaces that are accessible to the beam and with a thermal capacity that is sufficient for self-quenching can be considered candidates for electron beam surface hardening. In terms of material specifications, the workpiece thickness that is in direct thermal contact with the hardened layer should be at least five to ten times the hardening depth. Another material consideration is the minimum temperature required for martensite formation. A very straightforward process regime is obtained with throughgoing, interrupted plane, or cylindrically hardened surfaces. For example, the circumferential surfaces of bores are hardenable with diameter-to-depth ratios up to unity. The flank-profile hardening of gears and racks generally calls for specialized beam guidance techniques. Occasionally, crucial problems may arise when the hardening of irregular and spherically bent surfaces is attempted.

Technologically, this process is preferred for hardening depths in a range of 0.3 to 1 mm (0.01 to 0.04 in.). Depending on the material being used, however, it can also produce a maximum hardening depth of approximately 2 mm (0.08 in.). In some cases, the maximum hardening depth is also fixed by the coarse-grain growth and the bainite or pearlite formation caused by a low cooling rate. Hardness penetrations below 0.3 mm (0.01 in.) (minimums of 10 μm, or 400 μin., on the order of the electron range are possible) can be implemented without difficulty but are not yet demanded in practice. It is especially these thin hardened layers where the most outstanding materials properties (for example, extreme grain fineness and very high hardness values) can be attained.

Electron beam hardening offers the following technological benefits:

- Precise control and reproducibility of the energy input with respect to location and time
- Constant hardening depth for both areal and laterally patterned hardening up to a track width of 50 to 100 mm (2 to 4 in.)
- Low thermal stress is imposed on the workpiece to minimize warpage
- No scaling or oxidation of component surfaces
- No component-dependent means of energy transfer
- No preparation of surfaces to be hardened or of regions that have to be left untreated
- Computer numerical control (CNC) or computer-controlled processing similar to that used for machine tools, which are CAD/CAM (computer-aided design/computer-aided manufacturing) compatible and easy to integrate into mechanical flow lines
- Plant operation requires only electric power and low quantities of cooling water (usually in closed circulation systems) but neither transport media such as a working gas or an inert gas nor hardening salts or quenching oils are required
- High energy efficiency
- High process productivity with available beam power ranging from 20 to 50 kW
- No waste products generated
- Technological equipment suitable for several processes such as deep welding, hardening, and fusion treatment of surfaces

With an initial outlay of $500,000 to 1,200,000 required, the investment costs of electron beam facilities are relatively high and, therefore, usually limit the profitable use of this technique to high-volume production. As is the case with other machine tools and production equipment, the facility is most cost-effective when it is designed to match the requirements of a given application. In terms of the lot sizes containing identical parts, the programmability of the process makes no particular demands provided they do not arise from such secondary considerations such as the change of component loading and handling devices.

Experience has shown that the quality improvements obtained can be expressed as a direct gain only conditionally. Above all, economic estimates should also be based on the technological benefits of electron beam hardening. In general, substantial sections of component technology must often be altered because of limited materials selection in order to utilize the advantages of the process to the maximum. Frequently, the most important sources of economic gain are time savings gained at final machining or grinding, the omission of production processes, and a reduction in transport and energy expenditures.

Aside from these general economic considerations, it is the presence of equipment already installed in a facility that determines whether or not the addition of an electron beam hardening operation is feasible. An electron beam welding installation can be modified to convert the equipment for electron beam hardening operations. This conversion allows the

gradual introduction of electron beam hardening into the plant, thus providing multiple utilization of the plant equipment while minimizing the financial risks inherent in the introduction of innovative technology.

Example 1: Electron Beam Hardening of a Milling Machine Quill.

Figure 19 shows the quill of a milling machine that has been electron beam hardened. The entire surface of the cylindrical portion of the workpiece is hardened to a depth of 0.7 mm (0.03 in.). Hardening is achieved via isothermal energy transfer using a helical track to provide complete coverage of the surface to be hardened (Ref 4). Because the energy transfer data can be easily programmed into a computer, it is easy to isolate areas not to be hardened (that is, toothing and various plane faces). The hardened surface makes up 76% of the circumferential surface and totals 2100 cm^2 (325 $in.^2$) in area. The processing time required to harden one quill amounts to 8 min. This comparatively long time is fixed solely by the power of the electron beam used and in this case is restricted to 5 kW. The processing time could be lowered to 2 min if the beam generated 20 kW of power. Even for processing times of 8 min, however, electron beam hardening is still a cost-effective method for heat treating quills used in milling machines. Electron beam hardening is cost effective because of reduced expenditures for (Ref 13):

- Grinding operations
- Production steps and auxiliary procedures, including in-plant transport
- Energy used for heat treatment operations when compared to conventional techniques

Processing times, energy consumption data, and grinding allowances for milling machine quills hardened by several methods are compared in Fig. 20. This example is typical of the economic advantages that result partly by a mere substitution of one hardening process by another. The most significant savings, however, result from an overall streamlined flow of engineering processes. In addition to electron beam hardening of the quill, the same firm now heat treats approximately 60 other components having plane and cylindrical surfaces.

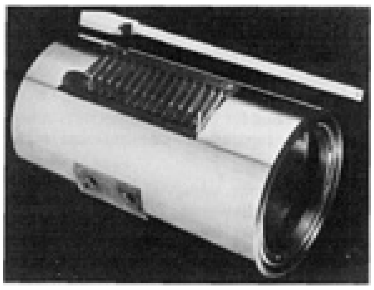

Fig. 19 Milling machine quill that was surface-hardened to a depth of 0.7 mm (0.03 in.) by electron beam hardening. Toothed region and plane surfaces of the quill were not hardened.

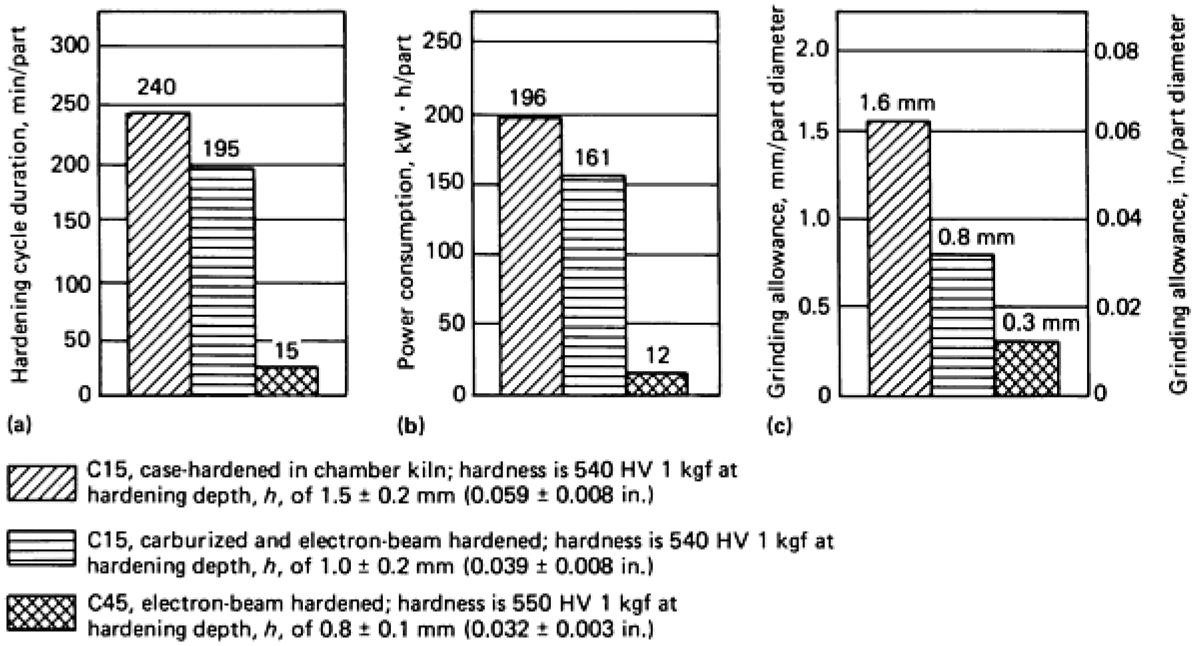

Fig. 20 Comparison of electron beam hardened and conventional case hardened milling machine quills shown in Fig. 19 to show electron beam hardening is a cost-effective option when heat treating C 15 and C 45 steels when the following factors are considered: (a) processing times, (b) electrical energy consumption, and (c) grinding allowance

Example 2: Partial Electron Beam Hardening of Shaft to a Depth of 0.3 to 0.7 mm (0.012 to 0.028 in.).

A variety of low-volume production components can be partially surface hardened with an electron beam (Ref 3). Shafts made of quenched and tempered steel (for example, 50 CrV 4, C 45, 42 Cr Mo 4, and 42 Mn V 7) can be hardened on the bearing and running surfaces of seal rings in order to reduce wear and tear (Fig. 21). The hardness penetration ranges from 0.3 to 0.7 mm (0.012 to 0.028 in.). Electron beam hardening had to prove it could be competitive against conventional methods such as flame or induction hardening and case- or nitrogen-hardening. In this application, electron beam hardening has the following economic advantages over conventional hardening techniques:

- Lower reject rates (for example, avoidance of quench cracks sometimes found with flame hardening)
- Reduced grinding expenditure because of almost warpage-free hardening
- Streamlining of the process flow, including a reduction in transportation steps

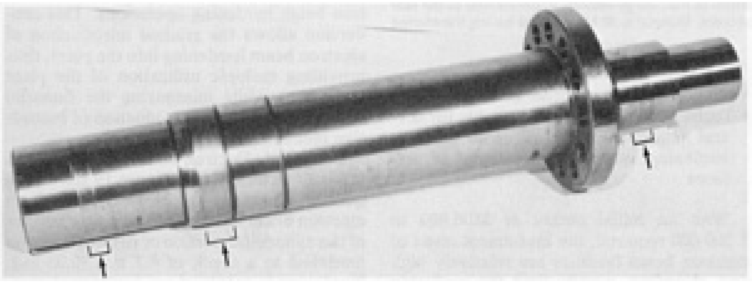

Fig. 21 Partially surface-hardened shaft that was hardened to reduce wear on bearing surfaces (indicated by arrows)

Narrow Tempering Zone Anomaly. An anomaly from Examples 1 and 2 and similar applications is the existence of a narrow tempering zone in the boundary region of the applied helical or ring-shaped hardness tracks. This tempering zone whose hardness ranges from 500 to 550 HV is approximately one to two times the hardening depth. In many cases, these temper zones can be avoided by extending the energy transfer field over an adequately large contact angle of 20 to 90° depending on the material composition. Thus, the boundary line between the previously heated track and the energy transfer field will be passed prior to martensite precipitation.

Example 3: Cutting Edges of a Ck 67 Steel Harvester Mower Blade Hardened in a Line-Shaped Pattern.

Figure 22 shows a typical component having preferred wear-resistant properties imparted via the use of an electron beam hardened layer. The cutting region of the harvester mower blade can be electron beam hardened either in the areal mode or, as shown in Fig. 22, in a line-shaped pattern. Compared to conventionally hardened blades; these electron beam hardened mower blades provide a much longer service life. The blade hardening time is about 0.6 s.

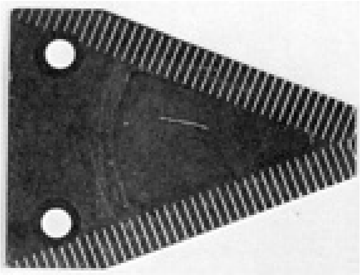

Fig. 22 Austempered Ck 67 steel harvester mower blade with cutting edges hardened in a line-shaped pattern

Additional Electron Beam Hardened Components. Other examples of typical components that can be electron beam hardened on a cost-effective basis are shown in Fig. 23.

Electron Guns and Auxiliary Equipment Required for EB Hardening

One significant additional component in the beam guidance system of an electron beam hardening system distinguishes this device from a typical electron beam welding system. Figure 24 is a schematic of the electron-optical setup of an electron gun used for hardening operations. A three-electrode system, with a tungsten bolt cathode that is heated by electron bombardment, is used to generate the beam. The rotationally symmetrical accelerated stream of electrons enters the beam guidance system via the anode bore as a beam that is focused onto the work plane by means of a magnetic focusing lens. The electron gun used for welding lacks the additional complex electron-optical package that is present in the magnetic field lens system of the electron gun used for hardening applications. This lens system consists of a dedicated deflection unit, a dynamic lens, and a magnetic octupole. The nearly distortion-free deflection unit is, with the exception of its field winding, of a nonmetallic composition that has low inductance properties. When connected with a matching power supply unit, it allows for linear time beam deflections at frequencies exceeding 100 kHz. When used in conjunction with the dynamic focusing lens, the magnetic octupole is suitable for elliptic focal spot shaping at an axial ratio of 10:1.

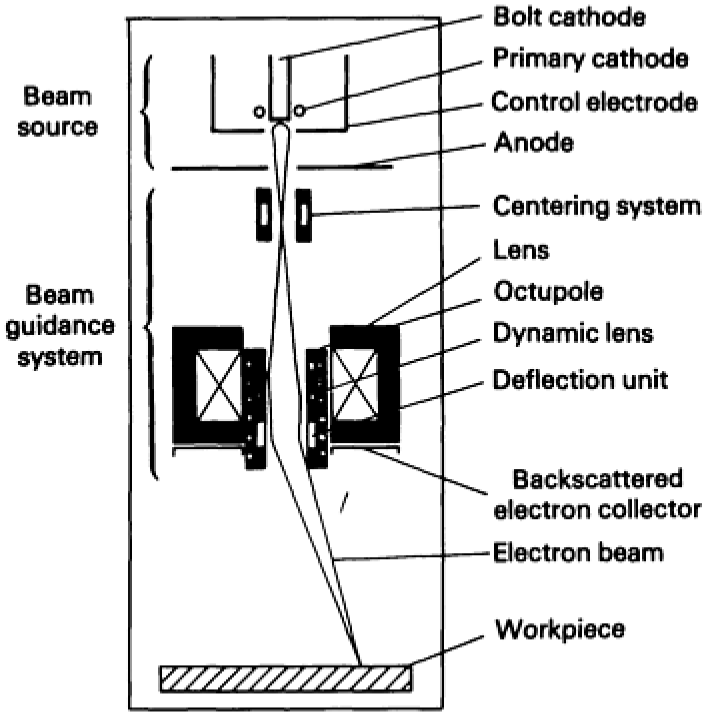

Fig. 24 Schematic of the beam generating system and the optical focusing system of a cutting, treatment, and welding (CTW) electron gun

Figure 25 is a photograph of a typical electron gun. The exit side of the beam contains an electron collector to provide process control for the hardening operations (Ref 10). The gun operates with an acceleration voltage of 60 kV and generates a beam power of up to 5, 10, or 20 kW, depending on the specific version used. In addition to welding and

hardening applications, the electron gun can be used for other thermal surface modifications. The electron gun can easily be programmed to function in numerous applications without any modification or dismantling of the setup shown in Fig. 24.

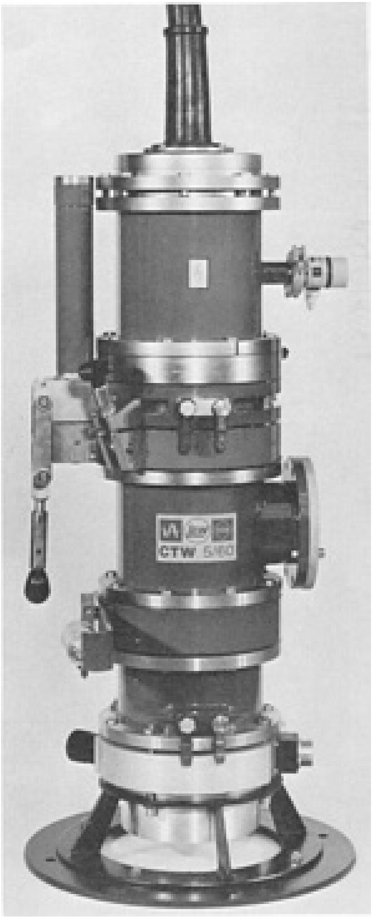

Fig. 25 An electron gun with acceleration voltage, U_B, of 60 kV and beam power, *P,* of 10 kW

Electron beam hardening facilities can be designed either as part of a flexible manufacturing (FMS) system (see the article "Multiple-Operation Machining" in Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*) or as stand-alone installations.

Figure 26 shows a system solution used to manufacture suppport elements for roller bearings. The flexible manufacturing system consists of two CNC-controlled milling machines for the complete machining of the workpieces (see Fig. 26) that are subsequently heat treated in the CNC-controlled electron beam hardening machine (see Fig. 27). The raceway for the guiding rollers is hardened similar to the slot flanks shown in Fig. 23(a). The electron beam hardening machine is equipped with a vertically adjustable electron gun that emits a horizontal beam at the rear of the process chamber.

The integration of the hardening process with the machining process made possible by heat efficient operations such as electron beam hardening has resulted in increased productivity and a more cost-effective product. In general, electron beam hardening facilities require pumps capable of providing a vacuum in the work chamber of the machine that ranges from 0.01 to 1 Pa (75 μtorr to 7.5 mtorr).

Electron Beam Hardening versus Laser Beam Hardening. In recent years, heat-treating engineers have focused their efforts on pinpointing the properties that differentiate electron beam hardening from laser beam hardening. The qualitative results of both hardening techniques are almost identical. However, differences do arise from the varying properties of both beam types and the entirely different methods that generate the beams. Comparing electron beam hardening and laser beam hardening to each other and to conventional hardening methods is the most accurate gage of their performance. Both techniques have common advantages and drawbacks compared to conventional hardening techniques as well as specific positive and negative qualities with respect to each other.

Both beam techniques overshadow conventional hardening methods because of the following primary factors:

- Locally well-defined and reproducible energy transfer to the workpiece regions
- Low thermal stress imposed on the component

Secondary benefits include the capability to adapt to a CNC-control process similar to that used in mechanical processing lines and the omission of cooling media for quenching. However, the rather high capital investment costs of high-energy beam hardening facilities may be prohibitive to some customers.

Laser beam hardening has the advantage over electron beam hardening whenever the following factors are significant:

- Relatively large distance between beam source (laser oscillator) and process site
- Beam guidance aided by mirrors (that is, in robot levers and multistation machining)
- Comparatively low costs with low beam power setting (2 to 3 kW) sufficient for hardening
- Parts whose bulk and configuration prevent them from being placed in a vacuum and therefore processing at atmospheric pressure

The following factors favor electron beam hardening as a viable option:

- Inert environment characteristic of a low-or high-vacuum atmosphere is required
- No working or protective gases are required
- Energy absorption properties of the component surface are independent of the optical surface properties (no application of absorption layers for energy coupling)
- High overall energy efficiency of the installation increases with the beam power
- Easy generation of limited energy transfer fields to a maximum of >10 cm^2 (>1.6 $in.^2$) and of any desired power density distribution via cyclic rf beam deflection programs (usability of the energy absorption layer as heat accumulator)
- High-volume productivity at beam powers of 10 kW and above

This discussion indicates that the variables that favor either electron beam hardening or laser beam hardening are clearly delineated. Conditions that must exist for the advantages provided by both hardening methods to overlap and actually compete against each other are very narrow and limited. Therefore, electron beam hardening and laser beam hardening cannot be classified as true competitors within the heat-treating industry.

Gas Carburizing of Steels

C.A. Stickels, Ford Motor Company, Manufacturing Development Center

Introduction

CARBURIZING is a case-hardening process in which carbon is dissolved in the surface layers of a low-carbon steel part at a temperature sufficient to render the steel austenitic, followed by quenching and tempering to form a martensitic microstructure. The resulting gradient in carbon content below the surface of the part causes a gradient in hardness, producing a strong, wear-resistant surface layer on a material, usually low-carbon steel, which is readily fabricated into parts. In gas carburizing, commercially the most important variant of carburizing, the source of carbon is a carbon-rich furnace atmosphere produced either from gaseous hydrocarbons, for example, methane (CH_4), propane (C_3H_3), and butane (C_4H_{10}), or from vaporized hydro-carbon liquids.

Acknowledgements

Preparation of this article benefited from the suggestions and criticisms of Gary D. Keil, Caterpillar, Inc. and Gregory A. Fuller and his colleagues at the Timken Company.

Carbon Sources

Low-carbon steel parts exposed to carbon-rich atmospheres derived from a wide variety of sources will carburize at temperatures of 850 °C (1560 °F) and above. In the most primitive form of this process, the carbon source is so rich that the solubility limit of carbon in austenite is reached at the surface of the steel and some carbides may form at the surface. (In earlier editions of *Metals Handbook,* the carbon gradient produced by maintaining saturated austenite at the surface of the steel is referred to as the normal carbon gradient.) Such atmospheres will also deposit soot on surfaces within the furnace, including the parts. While this mode of carburizing is still practiced in parts of the world in which resources are limited, the goal of current practice in modern manufacturing plants is to control the carbon content of furnace atmospheres so that:

- The final carbon concentration at the surface of the parts is below the solubility limit in austenite
- Sooting of the furnace atmosphere is minimized

Controlled carburizing atmospheres are produced by blending a carrier gas with an enriching gas, which serves as the source of carbon. The usual carrier, endothermic gas, is not merely a diluent, but plays a role, described below, in accelerating the carburizing reaction at the surface of the parts. The amount of enriching gas required by the process depends primarily on the carbon demand, that is, the rate at which carbon is absorbed by the work load.

Endothermic gas (Endogas) is a blend of carbon monoxide, hydrogen, and nitrogen (with smaller amounts of carbon dioxide, water vapor, and methane) produced by reacting a hydrocarbon gas such as natural gas (primarily methane), propane, or butane with air. Endogas is usually produced in a separately fired retort furnace (Endogas generator) using an air-to-hydrocarbon feed ratio that will produce an oxygen-to-carbon atom ratio of about 1.05 in the Endogas. For Endogas produced from pure methane, the air-to-methane ratio is about 2.5; for Endogas produced from pure propane, the air-to-propane ratio is about 7.5. These ratios will change depending on the composition of the hydrocarbon feed gases and the water vapor content of the ambient air. Table 1 lists typical compositions of natural gas. Propane for atmosphere generation should contain less than 5% propylene ($CH_3CH{=}CH_2$) and less than 2.5% butane or heavier hydrocarbons, satisfying the requirements in ASTM D 1835 for so-called special-duty propane or the Gas Producers Association specification 2140, grade HD 5.

CH_4, methane; CH_3CH_3, ethane: N_2, nitrogen.

Source: American Gas Association

A carrier gas similar in composition to Endogas produced from methane can be formed from a nitrogen-methanol blend. The proportions of nitrogen and methanol (CH_3OH) are usually chosen to give the same nitrogen-to-oxygen ratio as that of air, that is, about 1.9 volumes of nitrogen for each volume of gaseous methanol. Upon entering the furnace, each volume of gaseous methanol cracks to form approximately one volume of carbon monoxide and two volumes of hydrogen.

A carrier gas can be generated *in situ* by the direct addition of air and a hydrocarbon gas to the carburizing furnace (Ref 1). Special precautions (low flow rates, high temperatures, and good mixing) must be taken in setting up and controlling such a process to ensure a thorough reaction of the feed gases and uniformity of carburizing. Similar precautions are needed if carrier gases high in either carbon dioxide or water vapor content (such as exothermic gas) are used.

Carburizing Equipment

Gas carburizing furnaces vary widely in physical construction, but they can be divided into two major categories, batch and continuous furnaces. In a batch-type furnace, the work load is charged and discharged as a single unit or batch. In a continuous furnace, the work enters and leaves the furnace in a continuous stream. Continuous furnaces are favored for the high-volume production of similar parts with total case depth requirements of less than 2 mm (0.08 in.).

Batch Furnaces. The most common types of batch furnaces are pit furnaces and horizontal batch furnaces. Pit furnaces are usually placed in a pit with the cover or lid located just above floor level and are often loaded and unloaded with the aid of an overhead crane (Fig. 1). Pit furnaces are frequently used for large parts requiring long processing times. If the work is to be direct quenched, the load must be moved through air before quenching. As a result, parts will be covered by an adherent black scale, which, depending on the needs of the application, may have to be removed by shot blasting or acid pickling.

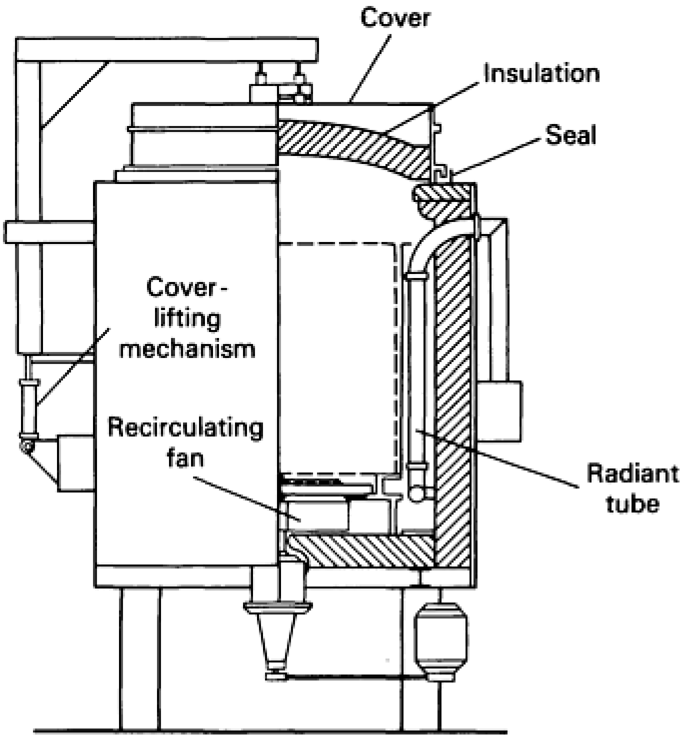

Fig. 1 A pit batch carburizing furnace. Dashed lines location of workload.

Horizontal batch furnaces are frequently used for carburizing and direct quenching. Many of these furnaces are so-called sealed quench, or integral quench, furnaces; that is, parts are discharged from the furnace into a vestibule that covers an oil quench tank (Fig. 2). Because the furnace atmosphere also flows through the vestibule, parts can be kept free of oxidation prior to quenching. Sealed-quench batch furnaces are capable of processing many different types of loads with widely varying case depth requirements. Like pit furnaces, they can be made quite gas tight, with the result that positive furnace pressures are easily achieved.

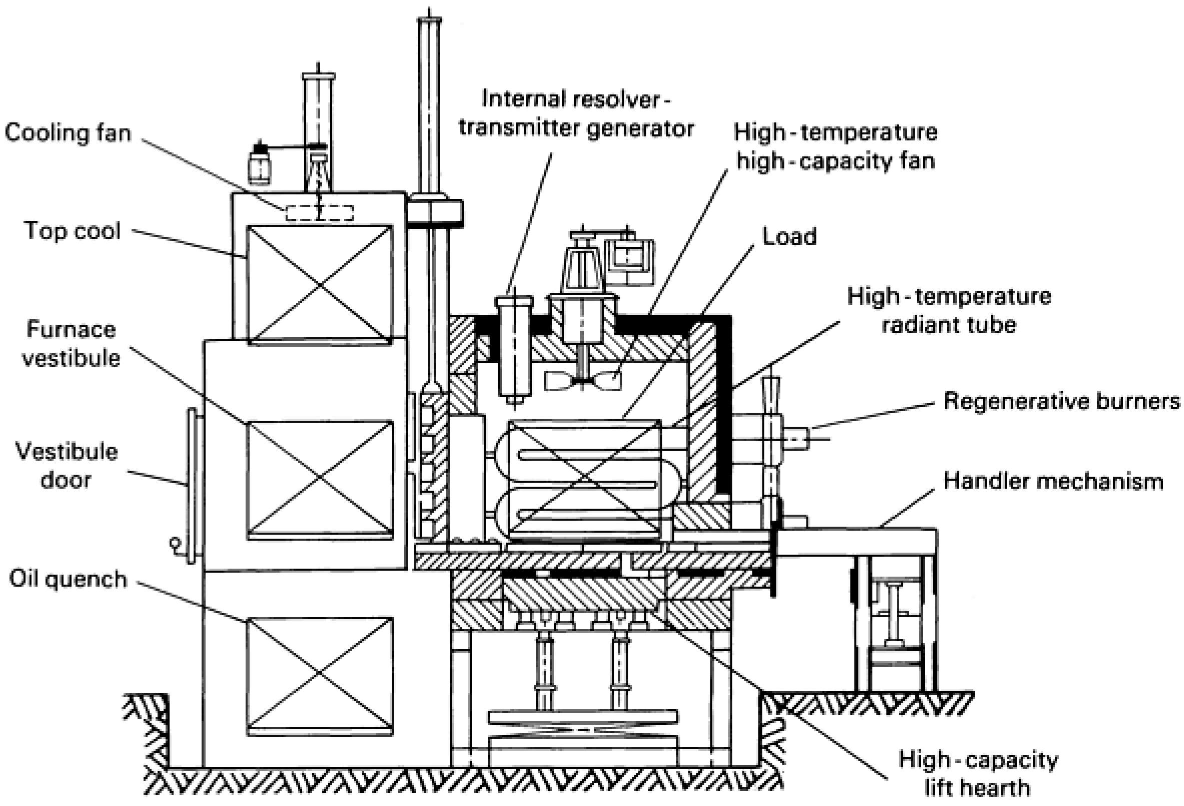

Fig. 2 **A high-productivity gas-fired integral quench furnace**

Continuous Furnaces. Types of continuous furnaces used for carburizing include mesh belt, shaker hearth, rotary retort, rotary hearth, roller hearth, and pusher designs. Many of these furnaces can be built with sealed oil quenching so that oxide-free parts can be produced. Most of these furnaces can be sealed well enough that positive furnace pressures can be maintained. Some continuous mesh belt furnaces, on the other hand, are open to the air at either end. Because air cannot be positively excluded, carburizing in these furnaces is often difficult to control.

Furnace Atmosphere Parameters. Certain principles of operation apply to all controlled-atmosphere furnaces regardless of design. First, in order to ensure the uniformity of carburizing, the furnaces must be equipped with internal fans so that the atmosphere is well circulated through the work load. In addition, the individual parts within the work load must be well spaced to allow the atmosphere to penetrate the load. Critical parts, such as gears, are usually placed on fixtures to control not only their spacing, but also their orientation entering the quenchant. At times the weight of trays and fixtures in pusher furnaces is two to three times the weight of the parts processed.

Second, the furnace should be operated at a positive pressure so that if the furnace has small leaks, air does not enter the furnace. Pressures of 12 to 37 Pa (0.09 to 0.28 torr, or 0.05 to 0.15 in. water column) are usually satisfactory for carburizing furnaces. The furnace pressure can be controlled by adjusting the orifice size in atmosphere vent lines and the carrier gas flow rate.

Because the hot gases inside a furnace are low in density, the pressure differential (furnace pressure minus ambient pressure, measured at the same height) will have its smallest value at the lowest point in the furnace. The minimum furnace pressure needed (at any height) to maintain a positive differential at all heights (P_{min}) can be computed from the relation:

$$P_{min} = H(D_A - D_F) \quad \textbf{(Eq 1)}$$

where H is the internal height of the furnace chamber, D_A is the density of ambient air outside the furnace, and D_F is the density of the atmosphere inside the furnace. Because $D_A >> D_F$, a suitable minimum value for the furnace pressure in pascals is:

$$P_{min} = H(0.117) \quad \textbf{(Eq 2)}$$

where H is in centimeters and it is assumed that the ambient air is at 1 kPa (1 atm) pressure and 20 °C (70 °F). Even though the furnace pressure is nominally positive, air can still enter the furnace through small openings if there are local fluctuations in the ambient pressure. A large cooling fan blowing at the furnace might raise the ambient pressure locally by as much as 25 Pa (0.19 torr, or 0.1 in. water column).

Third, the rate at which the furnace atmosphere responds to changes in inlet gas composition depends on the mean residence time of the atmosphere gases in the furnace. The mean residence time (t_{res}) is approximately:

$$t_{res} = \frac{(V.T_A)}{F.T_F} \quad \textbf{(Eq 3)}$$

where V is the furnace volume; F is the carrier gas flow rate measured at T_A, the absolute ambient temperature; and T_F is the absolute furnace temperature. Residence times in carburizing furnaces vary from about 2 to 15 min. If the inlet gas composition is changed, it takes about three residence times for 95% of the effect of the change to be felt in the furnace. Therefore, batch furnaces, in which the atmosphere composition must be changed during the course of a processing cycle, are usually operated with shorter residence times than are continuous furnaces. It is often considered an advantage to use high flow rates of carrier gas to speed the purging of air that enters the furnace when parts are charged. However, the same result can usually be achieved more economically by using an automatic control system to regulate the flow of the hydrocarbon enriching gas.

Preparation of Parts for Carburizing

Parts, trays, and fixtures should be thoroughly cleaned before they are charged into a carburizing furnace. Often they are washed in a hot alkaline solution. Some users heat washed parts, trays, and fixtures in an oxidizing atmosphere at 400 °C (750 °F) before carburizing to remove traces of organic contaminants (Ref 2).

Very thin oxide layers on parts (such as those produced by oxidation below 500 °C, or 900 °F) are reduced by the carburizing atmosphere. Heavy oxide layers, such as forging scale, will be reduced to iron flakes, which are not adherent to the part.

Residues from alkaline washer solutions deposited on parts, particularly those with silicates, can cause spotty carburizing, as well as give the parts a blotchy appearance. In addition, alkaline residues can adversely affect the life of heat-resistant furnace alloys. Quenching salts remaining on trays and fixtures can also damage furnace hardware (for example, silicon carbide rails in pusher furnaces). Chlorine- or sulfur-containing residues on parts will release gases that can react with brickwork, the protective oxide films on heat-resistant alloy fixtures, or the work load.

Carburizing Process Variables

The successful operation of the gas carburizing process depends on the control of three principal variables:

- Temperature
- Time

- Atmosphere composition

Other variables that affect the amount of carbon transferred to parts include the degree of atmosphere circulation and the alloy content of the parts.

Temperature. The maximum rate at which carbon can be added to steel is limited by the rate of diffusion of carbon in austenite. This diffusion rate increases greatly with increasing temperature; the rate of carbon addition at 925 °C (1700 °F) is about 40% greater than at 870 °C (1600 °F).

The temperature most commonly used for carburizing is 925 °C (1700 °F). This temperature permits a reasonably rapid carburizing rate without excessively rapid deterioration of furnace equipment, particularly the alloy trays and fixtures. The carburizing temperature is sometimes raised to 955 °C (1750 °F) or 980 °C (1800 °F) to shorten the time of carburizing for parts requiring deep cases. Conversely, shallow case carburizing is frequently done at lower temperatures because case depth can be controlled more accurately with the slower rate of carburizing obtained at lower temperatures.

For consistent results in carburizing, the temperature must be uniform throughout the work load. Temperature gradients through the work load will persist for a substantial period of time while the work is being heated to the carburizing temperature. Because parts at the exterior of the load reach the furnace temperature first, they will begin carburizing well before parts at the interior of the load. The consequence is variability in case depth from part to part and within a single part. In addition, soot can be deposited on cold parts exposed to a carburizing atmosphere. Therefore, for best results, the work load should be heated to the carburizing temperature in a near-neutral furnace atmosphere. In batch furnaces, parts can be heated in Endogas until they reach the furnace temperature; then carburizing can commence with the addition of the enriching gas. Many new continuous furnaces are being built with separate preheat chambers to ensure that the load is at a uniform temperature before entering the carburizing zone. In continuous furnaces that lack positive separation between heating and carburizing stages, the best that can be done is to:

- Add only Endogas to the front of the furnace
- Establish a front-to-back internal flow of atmosphere gases by adjusting flow rates and orifice size in the effluent lines at either end of the furnace

In batch furnaces, the thermocouple used for temperature control is usually positioned so that it reaches the set-point temperature before the work load does. In continuous furnaces that are not positively separated into zones, the thermocouple in the first zone (used for heating) should be placed near the end of that zone. This prevents overheating of the work load. The control thermocouple is usually positioned near the center of the carburizing zone. If the last zone is at a lower temperature than the carburizing zone, the control thermocouple is usually placed near the discharge end of the zone. However, the features of individual furnaces, such as the location of radiant tubes, must be considered when positioning control thermocouples.

Time. The effect of time and temperature on total case depth is shown in Fig. 3. The data given, originally published by Harris (Ref 3) in 1944, are computed assuming saturated austenite at the surface of the workpieces. When the surface carbon content is controlled so that it is less than the saturation value, case depths will be less than they otherwise would be. Figure 4 shows how the carburizing time decreases with increasing carburizing temperature for a case depth of 1.5 mm (0.06 in.). In addition to the time at the carburizing temperature, several hours may be required to bring large workpieces or heavy loads of smaller parts to operating temperature. For work quenched directly from the carburizing furnace, the cycle may be lengthened further by allowing time for the work to cool from the carburizing temperature to about 843 °C (1550 °F) prior to quenching. If the workload is exposed to the carburizing atmosphere during heating, some carburizing will occur before the nominal start of carburizing. Similarly, additional diffusion and interchange of carbon with the atmosphere will occur during cooling prior to quenching. Thus, the actual case depth achieved may differ significantly from the values listed in the table in Fig. 3. More complex mathematical models that allow for variations in temperature and atmosphere carbon potential with time can be constructed to allow a better prediction of case depth.

Carbon Potential. The carbon potential of a furnace atmosphere at a specified temperature is defined as the carbon content of pure iron that is in thermodynamic equilibrium with the atmosphere. The carbon potential of the furnace atmosphere must be greater than the carbon potential of the surface of the workpieces in order for carburizing to occur. It is the difference in carbon potential that provides the driving force for carbon transfer to the parts.

Carbon Diffusion. The combined effects of time, temperature, and carbon concentration on the diffusion of carbon in austenite can be expressed by Fick's laws of diffusion. Fick's first law states that the flux of the diffusing substance perpendicular to a plane of unit cross-sectional area is proportional to the local carbon gradient perpendicular to the plane. The constant of proportionality is the diffusion coefficient *D,* which has the units $(\text{distance})^2/\text{time}$. Fick's second law is a material balance within an elemental volume of the system; the flux of carbon into an elemental volume of iron minus the flux of carbon out of the elemental volume equals the rate of accumulation of carbon within the volume. Combining the two laws leads to a partial differential equation that describes the diffusion process. Reference 5 provides solutions to the diffusion equation for a variety of boundary conditions and part configurations, for example, plate, rod, sphere, and so on. With these solutions and values of the diffusion coefficient, it is possible to predict the carbon gradient and depth of penetration occurring for any combination of time, temperature, and surface carbon concentration.

The diffusion coefficient for carbon in austenite is a function of carbon content and temperature. The following expression, proposed by Tibbetts (Ref 6) summarizes the experimental data:

$$D = 0.47 \exp[-1.6\,C - (37000 - 6600\,C)/RT] \qquad \textbf{(Eq 4)}$$

where D is in cm^2/s, C is the weight percent carbon, T is temperature in degrees Kelvin, and R is the gas constant. Exact solutions to the diffusion equation when the diffusion coefficient depends on composition are available for steady-state diffusion (Ref 5), but for time-dependent solutions, numerical methods must be used. Figure 5 lists a BASIC computer program for finding the carbon concentration gradient below a flat surface using the expression above for the diffusion coefficient. In this program, the surface boundary condition is:

$$\text{Carbon flux} = \beta\sigma(CP - C_0) \qquad \textbf{(Eq 5)}$$

where carbon flux is in g/s · cm^2, β is an effective reaction rate constant in s^{-1}, σ, is the density in g/cm^3, *CP* is the atmosphere carbon potential, and C_0 is the surface carbon content. The value of β may vary depending on the degree of atmosphere circulation within the furnace. Taking β equal to 0.00002 s^{-1} seems to produce results that are in reasonable agreement with experience. However, values of β that are as much as a factor of two larger or smaller may be needed to model carburizing behavior in specific furnaces.

Fig. 5 Finite-difference computation of the diffusion of carbon in austenite using BASIC computer program

Alloy Effects. The various alloying elements found in carburizing steels have an influence on the activity of carbon dissolved in austenite. A definition of carbon activity (a_C) is:

$$a_C = (\text{wt\% } C)\ \Gamma \qquad \textbf{(Eq 6)}$$

where Γ, the activity coefficient, is chosen so that a_C = 1 for an amount of carbon in solution that is in equilibrium with graphite. Chromium tends to decrease the activity coefficient, and nickel tends to raise it. As a consequence, foils of a chromium-bearing steel equilibrated with a specific furnace atmosphere will take on more carbon than pure iron, and nickel-bearing steels will take on less carbon. It is also true that carbides are produced at lower carbon potentials in chromium-bearing steels than in carbon steels. The primary effect of alloying elements on the diffusion of carbon is due to their effect on the driving force for the surface reaction (Eq 5). To obtain the true driving force, the surface carbon content in an alloy must be converted into the equivalent carbon content in pure iron. Methods of correcting the activity coefficient of carbon for alloy content are available (Ref 7). However, the quantity of experimental data upon which such

correlations are based is rather limited. Therefore, predictions should be verified by experiments, particularly when an alloy contains substantial amounts of more than one alloying element.

Gas Carburizing Atmospheres

In the discussion of carburizing atmospheres in this section, it will be assumed that the atmosphere consists of an endothermic carrier gas (produced from methane) that is enriched by a methane addition, which serves as the source of the carbon being transported to the work load. The main constituents of the atmosphere are CO, N_2, H_2, CO_2, H_2O, and CH_4. Of these constituents, N_2 is inert, acting only as a diluent. The amounts of CO, CO_2, H_2, and H_2O present are very nearly the proportions expected at equilibrium from the reversible reaction:

$$CO + H_2O \leftrightarrow CO_2 + H_2 \qquad \textbf{(Eq 7)}$$

given the particular ratios of carbon, oxygen, and hydrogen in the atmosphere. Methane is invariably present in amounts well in excess of the amount that would be expected if all the gaseous constituents were in equilibrium.

Although the sequence of reactions involved in carburizing is not known in detail, it is known that carbon can be added or removed rapidly from steel by the overall reversible reactions:

$$2CO \leftrightarrow C \text{ (in Fe)} + CO_2 \qquad \textbf{(Eq 8)}$$

and

$$CO + H_2 \leftrightarrow C \text{ (in Fe)} + H_2O \qquad \textbf{(Eq 9)}$$

A carburization process based solely on the decomposition of CO would require large flow rates of atmosphere gas to produce appreciable carburizing. As an example, the loss of just 0.47 g C from a cubic meter of endothermic gas at 927 °C (1700 °F) is sufficient to reduce the CO-to-CO_2 ratio from 249 to 132 and the carbon potential from 1.25 to 0.8%. The loss of 0.47 g C represents about the same amount present in a steel part of 100 cm^2 (15.5 $in.^2$) surface area carburized to a depth of 1 mm (0.040 in.).

The methane enrichment of endothermic gas provides carbon for the process by slow reactions such as:

$$CH_4 + CO_2 \rightarrow 2CO + 2H_2 \qquad \textbf{(Eq 10)}$$

and

$$CH_4 + H_2O \rightarrow CO + 3H_2 \qquad \textbf{(Eq 11)}$$

which reduce the concentrations of CO_2 and H_2O, respectively. These reactions regenerate CO and H_2, thereby directing the reactions of Eq 8 and 9 to the right. Because the methane content of carburizing atmospheres is usually far above the

content that is expected at equilibrium, given the CO_2 and H_2O contents present, it is evident that the reactions in Eq 10 and 11 do not approach equilibrium. The sum of the reactions in Eq 8 and 10 and in Eq 9 and 11 is reduced to:

$$CH_4 \rightarrow C \text{ (in Fe)} + 2H_2 \qquad \textbf{(Eq 12)}$$

Thus, with constant CO_2 content and constant dew point, the net atmosphere composition change during carburizing is a reduction in methane content and an increase in the hydrogen content. In most commercial operations, atmosphere flow rates are high enough and the rate of methane decomposition is low enough to prevent a large buildup of hydrogen during a carburizing cycle. However, with carburizing loads having high surface area, there is a drop in the CO content of 1 to 3% at the beginning of the cycle when the carbon demand is greatest. This is caused by the dilution of the furnace atmosphere with hydrogen.

Carbon potential control during carburizing is achieved by varying the flow rate of the hydrocarbon-enriching gas, while maintaining a steady flow of endothermic carrier gas. As a basis for regulating the enrichment gas flow, the concentration of some constituent of the furnace atmosphere is monitored:

- Water vapor content by dew point measurement
- Carbon dioxide content by infrared gas analysis
- Oxygen potential using a zirconia oxygen sensor

The first two quantities provide measures of carbon potential according to the reactions of Eq 8 and 9. Oxygen potential is related to carbon potential by the reaction:

$$C \text{ (in Fe)} + \tfrac{1}{2}O_2 \leftrightarrow CO \qquad \textbf{(Eq 13)}$$

When the carbon monoxide content of the atmosphere remains relatively constant, both the carbon dioxide and the oxygen potential provide good measures of the carbon potential. For the dew point to be a valid measure of carbon potential, the product of the hydrogen and carbon monoxide contents must be stable. If the hydrogen content of the furnace atmosphere rises, as a result of either carburizing or sooting, the relationships between CO_2 content, oxygen potential, dew point, and the carbon potential will be altered. For this reason, some process control systems include infrared analysis of CO and the measurement of CO_2 or oxygen potential so that a true carbon potential may be computed for all operating conditions.

Calculation of Equilibrium Compositions. Gas carburizing is a nonequilibrium process; that is, the gaseous constituents of the atmosphere are not fully in equilibrium with one another, and the atmosphere is not in equilibrium with the steel being carburized. Nevertheless, several important reactions, for example, reactions in Eq 7, 8, and 9, approach equilibrium rapidly enough to permit predictions of the rate of carburizing from the atmosphere composition. Thus, the same case carbon gradient can be expected from different furnaces with different atmosphere gas flow rates when certain factors are held constant:

- Carbon potential, as inferred from CO_2, H_2O, or oxygen potential measurements
- Carburizing time
- Carburizing temperature

To compute the equilibrium gas composition resulting from the reaction of a blend of a hydrocarbon gas and air:

- Six gaseous species are assumed to be present in the reacted gas: CO, CO_2, H_2, H_2O, CH_4, and N_2. The partial pressures of five of these are unknowns to be determined; the sixth can be found by computing the difference after the others are known
- The carbon-to-hydrogen and oxygen-to-nitrogen ratios are fixed by the nature of the hydrocarbon and the composition of air. With the air-to-hydrocarbon ratio fixed, three equations can be found that relate the five unknown partial pressures

- Two equilibrium relationships, for example, the reactions in Eq 7 and 10, provide two additional equations; thus, all the partial pressures are determined

Because explicit expressions for the unknowns cannot be written, trial-and-error computation methods must be used with the aid of a computer (Ref 8). After the equilibrium composition of the gas is known, its carbon potential is found by writing the equilibrium relationship for Eq 8:

$$K_8 = (a_C \cdot P_{CO_2})/(P_{CO})^2 \qquad \textbf{(Eq 14)}$$

where P_{CO} and P_{CO_2} are partial pressures of CO and CO_2, respectively; a_C is the activity of carbon (a_C = 1 when the atmosphere is in equilibrium with graphite); and K_8 is the equilibrium constant for the reaction in Eq 8.

The constant K_8 can be computed from the Gibbs free energy of formation of CO and CO_2 at the temperature of interest (free energy values are tabulated in Ref 9):

$$\Delta F^\circ_{CO_2} - 2\Delta F^\circ_{CO} = -R\,T \cdot \ln K_8 \qquad \textbf{(Eq 15)}$$

where ΔF°_{CO} and $\Delta F^\circ_{CO_2}$ are free energies of CO and CO_2, respectively; T is the absolute temperature; and R is the gas constant.

The carbon activity is related to the carbon content of austenite by the expression (Ref 10):

$$\ln a_C = \ln y_C + (9167\, y_C + 5093)/T - 1.867 \qquad \textbf{(Eq 16)}$$
$$\text{where } y_C = (4.65\, w)/(100 - w)$$

where T is the temperature in degrees Kelvin, w is the weight percent carbon in austenite, and y_C is the atom ratio of carbon to iron. Combining Eq 14 and 16 gives a relation between carbon potential (that is, the equilibrium carbon content in austenite) and the carbon dioxide and carbon monoxide contents. As long as the assumptions of the calculation are satisfied, measuring just the CO_2 content suffices to define the carbon potential. However, when carbon is removed from the atmosphere by carburizing, there is a reduction in the carbon-to-hydrogen ratio characterizing the atmosphere. When the carbon-to-hydrogen ratio may vary, it is necessary to measure two constituents of the atmosphere, CO and CO_2 content, to define the carbon potential accurately. However, unless the changes in the atmosphere are large, it is seldom worth measuring both CO and CO_2 because of the effect of the added measuring error on the uncertainty of the computed carbon potential.

Endothermic gas derived from propane has a carbon monoxide content of about 23%, whereas that derived from methane has a carbon monoxide content of about 20%. Therefore, the carbon dioxide contents corresponding to a given carbon potential are higher for atmospheres derived from propane than for those derived from methane. Figures 6 and 7 show the relationship between carbon dioxide content and carbon potential for endothermic gas atmospheres derived from methane and propane, respectively.

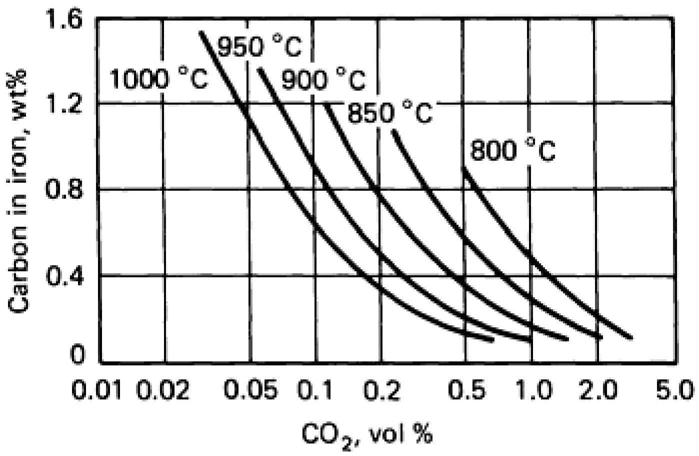

Fig. 6 Relationship between CO_2 content and carbon potential for endothermic gas from methane

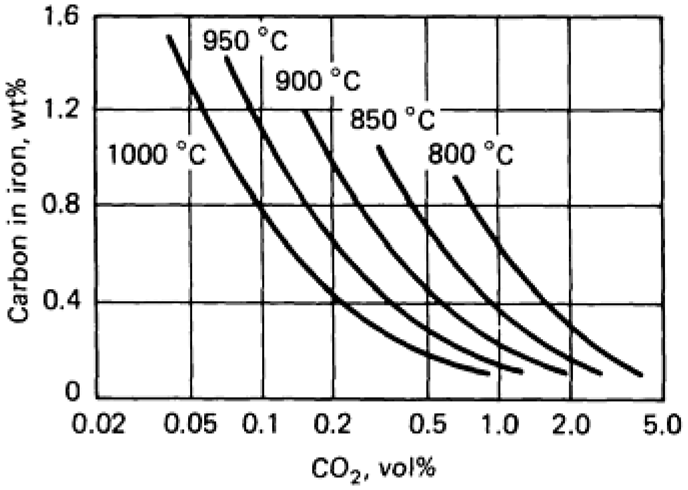

Fig. 7 Relationship between CO_2 content and carbon potential for endothermic gas from propane

The oxygen potential (or oxygen partial pressure), as measured by a zirconia oxygen sensor, is related to the carbon activity by the equilibrium equation for the reaction given in Eq 13:

$$a_c = \frac{P_{CO}}{K_{13} P_{O_2}} \quad \textbf{(Eq 17)}$$

where $P\ O_2$ is the oxygen partial pressure and K_{13} is the equilibrium constant. In carburizing atmospheres, the oxygen partial pressure is approximately 10^{-14} to 10^{-20} Pa (10^{-19} to 10^{-25} atm).

The voltage output of a zirconia oxygen sensor, with air as a reference gas, is a function of the absolute temperature (T) and the oxygen partial pressure ($P\ O_2$) according to the expression:

$$emf = 0.000049593 T \log_{10}\left(\frac{P_{O_2}}{0.209}\right) \quad \textbf{(Eq 18)}$$

where emf is in volts. Combining Eq 16, 17, and 18 yields a relation between carbon potential and emf. Because this relation also depends on the carbon monoxide content of the atmosphere (Eq 18), emf measurements corresponding to a

certain carbon potential for endothermic gas atmospheres derived from methane (Fig. 8) differ from those for atmospheres derived from propane (Fig. 9).

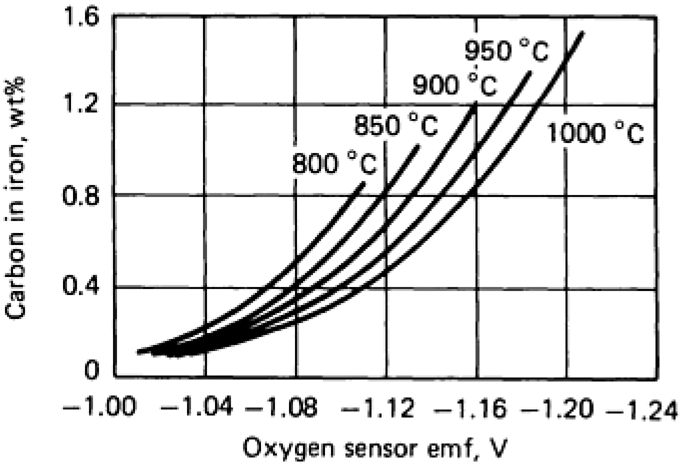

Fig. 8 Measurements of the emf of endothermic gas from methane

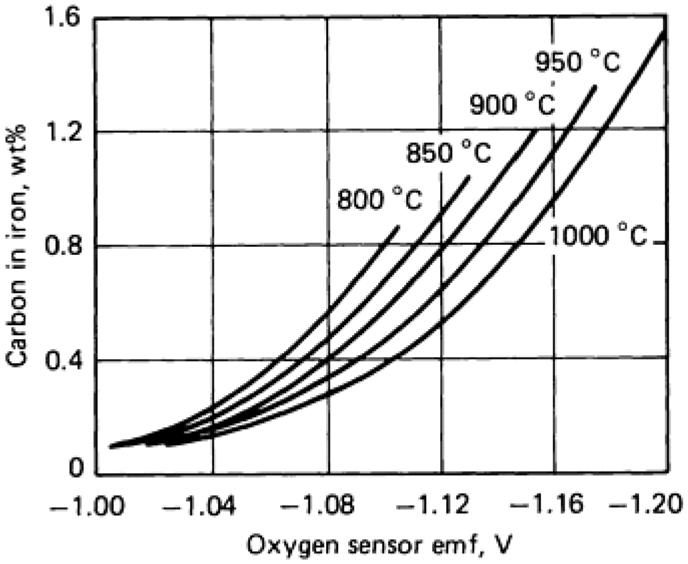

Fig. 9 Measurements of the emf of endothermic gas from propane

The water vapor content of the atmosphere is related to the carbon potential by the reaction in Eq 11. The equilibrium relation is:

$$a_c = \frac{K_{11} P_{CO} P_{H_2}}{P_{H_2O}} \qquad \textbf{(Eq 19)}$$

where K_{11} is the equilibrium constant.

For atmospheres derived from a particular hydrocarbon, the product of the carbon monoxide and hydrogen contents varies little for large changes in water vapor content. The water vapor content of the atmosphere is usually measured by determining its dew point. An equation relating dew point in degrees Celsius and P_{H_2O} in atmospheres is:

$$Dew\ \text{point} = \frac{5422.18}{14.73316 - \ln P_{H_2O}} - 273.16 \quad \textbf{(Eq 20)}$$

Equations 16, 19, and 20 can be combined to produce the relations between dew point and carbon potential plotted in Fig. 10 and 11 for endothermic gas atmospheres derived from methane and propane, respectively.

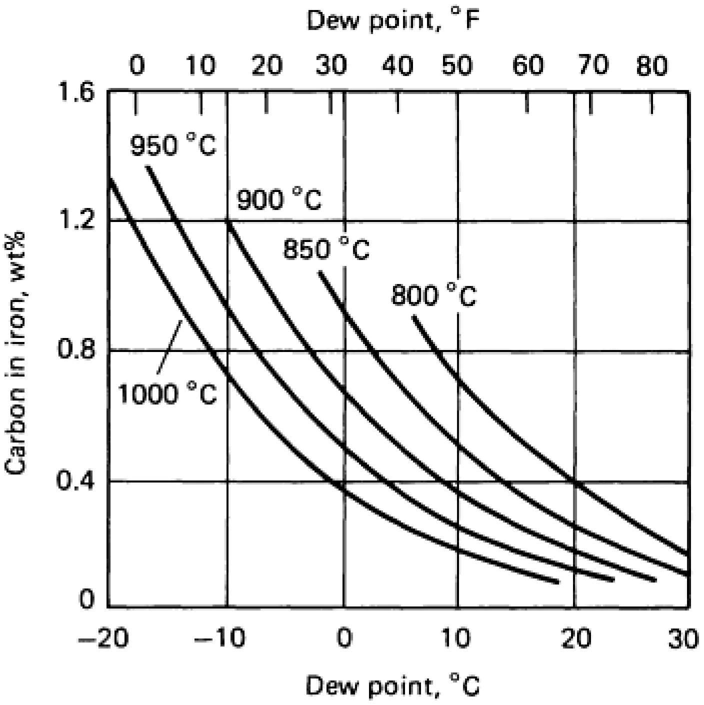

Fig. 10 Relationship between dew point and carbon potential for endothermic gas derived from methane

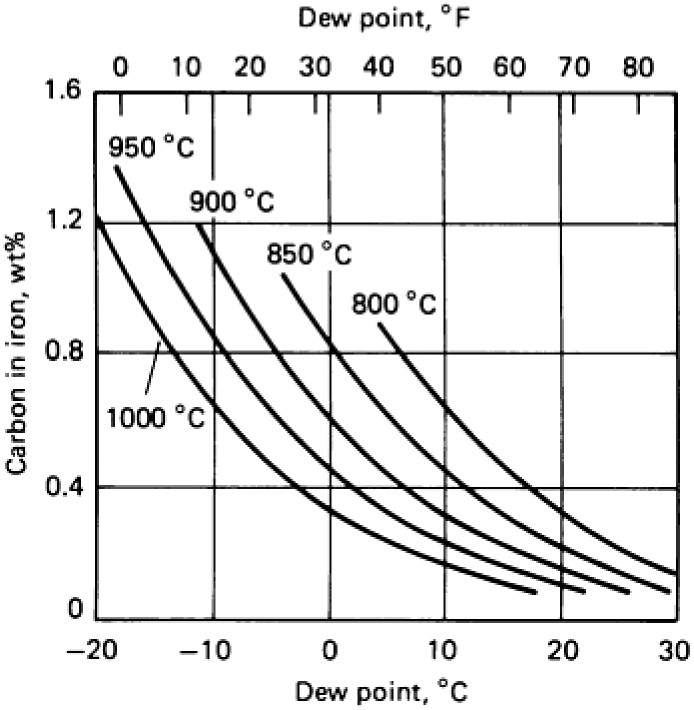

Fig. 11 Relationship between dew point and carbon potential for endothermic gas derived from propane

Sooting. If the carbon potential of a furnace atmosphere is allowed to become very high, sooting will occur. As carbon is lost from the atmosphere, hydrogen is produced. One symptom of a sooting condition is a pronounced drop in the CO content due to hydrogen dilution. When a furnace becomes sooted, it is found that the carbon potential of the furnace atmosphere is no longer controllable; that is, changes to the flow of enriching gas no longer produce the expected changes in atmosphere composition and carbon potential. The only practical solution is to empty the furnace of parts, introduce air, and burn out the soot.

Some care is necessary in burning out accumulated soot to prevent local overheating in the furnace. Typically, the furnace temperature will be set at about 815 °C (1500 °F) for burnout, and air will be admitted to the furnace, by either opening doors or introducing a flow of air. The rise in temperature due to the combustion of soot should be monitored. The air supply can be reduced if the temperature rise is excessive.

Modern automatic atmosphere control systems minimize sooting by maintaining a constant atmosphere composition, thereby matching carbon supply to carbon demand. However, even with the best system, a furnace can be sooted up if the control carbon potential is set too high.

Furnace Conditioning. When a carburizing atmosphere is introduced into an empty furnace that has been idle for some time or that has just been burned out to remove soot, it is found that the amount of enriching gas needed to maintain a given carbon potential is much higher than would be expected. As time passes (typically, 12 to 24 h), the amount of enriching gas needed to maintain the carbon potential decreases to a steady-state value. This process is called conditioning a furnace.

During the time in which conditioning is occurring, carbon is deposited in the crevices of the brickwork and at other locations where the temperature is low. This occurs because the carbon potential of a carburizing atmosphere increases as the temperature falls. An atmosphere with a carbon potential of 1% at 927 °C (1700 °F) is capable, thermodynamically, of depositing soot at or below 843 °C (1550 °F). Eventually, the crevices will be filled with carbon, and the exposed carbon will be at a high enough temperature that further carbon deposition cannot occur. However, there will be some locations, such as sight ports and gas sample lines, where soot will continue to be deposited as the furnace is used. Soot may also form in unheated furnace vestibules as the furnace atmosphere gas cools upon entering the vestibule.

Process Controllers. A process controller compares the output of a sensor with a set point and generates a control signal intended to reduce the difference between these two values. The sensor can be a thermocouple, if the temperature is to be controlled, or an oxygen sensor or infrared gas analyzer, if the atmosphere composition is to be controlled. In the case of atmosphere control, the device being controlled is usually a valve on the enriching gas line. Valves are of two types:

- Those in which the flow through the valve is proportional to the motion, linear or angular, of the valve stem
- Those simply used to switch the flow on and off

In the first case, the control signal is translated into the position of the valve stem. In the second case, time proportioning is used: The fraction of the time that the valve is open is proportional to the control signal.

Most controllers used with furnaces employ proportional, integral, and derivative (PID) modes of feedback control (Ref 11). The controller converts an error signal (E) (the difference between the actual output of the sensor and the desired output) into a control signal (M) using the logic:

$$M = K\left(E + \frac{1}{T_1}\int E.dt + T_d.dE/dt\right) \qquad \textbf{(Eq 21)}$$

where K is the proportional gain, T_I is the integral time constant, and T_d is the derivative time constant. M can be thought of as the fraction of maximum possible flow through the valve. The quantity $100/K$ is often called the percent proportional band. The quantity $1/T_I$ is often called the reset rate. Derivative control is often called rate control. A process can be controlled using only proportional control (the control signal directly proportional to the error signal), but it will always stabilize at a nonzero value of E. For the process to stabilize at $E = 0$, both integral control and proportional

control are needed. The integral portion of the logic effectively generates an offset signal that allows the process to stabilize at E = 0. When the set point on the controller is changed, the integral logic must generate a new offset signal for the process to stabilize at E = 0. If T_I is too large, the rate of approach to E = 0 will be very sluggish; if T_I is too small, the process will overshoot the set point. Finding proper values for K, T_I, and T_d can be quite time consuming, but it is necessary to ensure a controlled process. Fortunately, controller manufacturers have recently introduced self-tuning controllers capable of sensing the response of the system and choosing appropriate values of K, T_I, and T_d.

Nitrogen-Methanol Atmospheres. The *in situ* generation of a carrier gas from a blend of nitrogen and methanol has become more common in recent years. The primary advantage of this approach is that separately fired endothermic gas generators are no longer required. The primary disadvantage is that operating costs are often higher, although this obviously depends on the local cost and availability of natural gas and propane.

Upon entering a heat-treating furnace, methanol cracks to form CO and H_2. The nitrogen-to-methanol ratio is usually chosen so that the nitrogen-to-oxygen ratio is the same as that for air.

$$CH_3OH + 1.89N_2 \rightarrow CO + 2H_2 + 1.89N_2 + CH_4 + 2.39\,(0,2095O_2 \overset{Air}{+} 0.7905N_2) \rightarrow CO + 2H_2 + 1.89N_2 \quad \textbf{(Eq 22)}$$

The material balances above show that when the nitrogen-to-methanol mole ratio is 1.89, the atom ratios of oxygen, hydrogen, carbon, and nitrogen will be the same as those produced from air-to-methane mole ratio of 2.39. Because Endogas is usually produced with an air-to-methane ratio of about 2.5, it is clear that a nitrogen-methanol carrier gas is richer than conventional Endogas. This poses no special problems when carburizing, but may lead to sooting if the nitrogen-methanol blend is run into an empty furnace for long periods of time. Air is often added to nitrogen-methanol to reduce its carbon potential for neutral hardening applications.

Heat is required to vaporize methanol and the cracking of methanol to CO and hydrogen is quite endothermic. Therefore, successful cracking is favored by higher furnace temperatures and lower rates of carrier gas usage. The presence of lower than expected CO contents in furnace atmospheres is symptomatic of incomplete cracking. However, low CO contents can also arise if the proportions of nitrogen and methanol change with changes in the carrier gas flow.

Because of the similarity in atmosphere composition, a 1.89 mole ratio nitrogen-methanol carrier gas enriched with methane can be controlled using the same control points (Fig. 6, 8, and 10) as an Endogas atmosphere produced from methane. The only additional complication is the need for maintaining a constant mole ratio for the carrier gas, particularly when changing the carrier gas flow rate. Rather than invest in sophisticated flow metering, some users have chosen to control their processes by measuring two atmospheric constituents (CO and oxygen potential, for example), rather than just one, to determine carbon potential.

Nitrogen of high purity (about 10 ppm residual CO_2 and water vapor) is produced by liquifying air and then using the differences in boiling points of the various constituents to effect the separation of nitrogen. In most instances, liquid nitrogen is shipped from an air separation plant to the heat-treating plant and stored in vacuum-insulated vessels. Nitrogen of lesser purity can be produced on site by a variety of means:

- *Combustion processes.* Air is burned with natural gas, and the CO_2 and H_2O are stripped from the gas by absorption and condensation
- *Pressure swing absorption, vacuum swing absorption.* Air separation using zeolite molecular sieves
- *Membrane air separation.* Differences in molecular diffusion rates through thin-walled fibrous tubes are used to separate oxygen and nitrogen

Low-purity less expensive nitrogen can be used with methanol to form satisfactory furnace atmospheres. However, because the oxygen content of the nitrogen should be kept relatively constant, the nitrogen generation process must be designed with this requirement in mind.

Process Planning

Designers usually specify the case hardness, case depth, and core hardness required to meet the service loads they anticipate for a particular part. It is the task of the process engineer to develop the carburizing treatment that will produce the properties desired. Some of the considerations involved in setting up processes include:

- Case microstructure
- Residual stress
- Alloy selection
- Operating schedules
- Quenchants
- Reheating for quenching
- Tempering
- Selective carburizing

Case Microstructure. A carburized case is usually a mixture of tempered martensite and retained austenite. Other microconstituents, such as primary carbides, bainite, and pearlite, are generally avoided. For a particular alloy, the amount of retained austenite in the case increases as the case carbon content increases. An appreciable decrease in case hardness is usually found when the amount of retained austenite exceeds about 15%, but for applications involving contact loading, such as rolling element bearings, the best service life is found when the retained austenite content is quite high, for example, 30 to 40%. In other applications, especially when dimensional stability is critical, the retained austenite content should be low.

Figure 12 shows the dependence of retained austenite content on carbon content for iron-carbon alloys (Ref 12). For a given carbon content, more retained austenite is usually present in alloy steels. Therefore, by controlling the case carbon content, the amount of retained austenite can be regulated. Tempering above 260 °C (500 °F) will also eliminate retained austenite, but at the expense of case hardness.

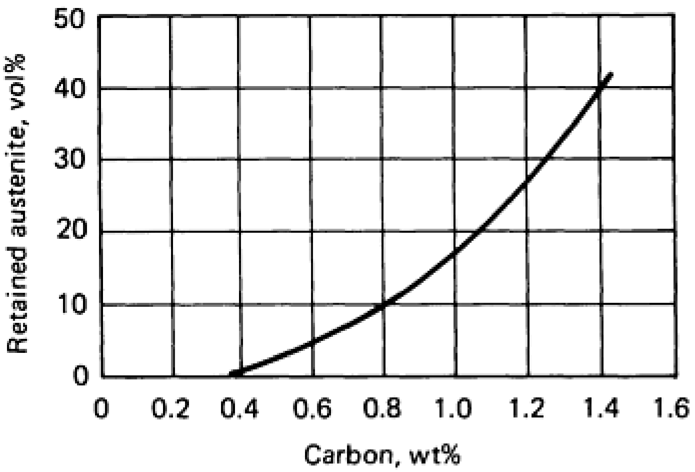

Fig. 12 Effect of retained austenite content on carbon content for iron-carbon alloys

Residual Stress. Carburized parts have a compressive residual stress in the case that is balanced by a tensile residual stress in the core. The presence of this stress distribution is an advantage for applications in which maximum tensile

stresses are experienced at the surface of the part, for example, bending or torsional loading. When other factors are the same, the magnitude of the compressive residual stress at the surface depends on the ratio of case and core thicknesses. When the core is much thicker than the case, compressive stresses at the surface will be high. When the reverse is true, surface compressive stress will be low and core tensile residual stress will be high. Because retained austenite is more dense than is martensite, the former will tend to reduce the magnitude of the compressive residual stress in the surface.

Alloy Selection. Frequently used carburizing steels are listed in Table 2. Carburizing steels are usually selected on the basis of case and core hardenability; comparative hardenability data for these alloys can be found in the SAE specifications J1268 and J1868 (*SAE Handbook,* Volume 1 or the article "Hardenability Curves" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). As a rule, carburized plain carbon steels with less than 1% Mn must be water quenched to form a martensitic case. If an oil quench must be used, adequate case hardenability can usually be obtained by carbonitriding a coarse-grained steel.

Alloy steels are used for most heavily loaded parts, not only because of their increased hardenability, but also because the standards of steel cleanliness are more restrictive. Many of the alloy steels are similar in hardenability but differ in other important respects. For example, nickel-molybdenum alloys provide the most trouble-free processing because the principal alloying elements are neither strong oxide nor strong carbide formers. However, economic considerations often dictate the use of less expensive steels, such as chromium-manganese alloys, which are prone to alloy depletion (and loss of hardenability) because of the formation of grain-boundary oxides near the surface during carburizing. Chromium-nickel-molybdenum steels, such as SAE 8620 and 8720, provide a balance between cost, hardenability, and ease of processing that leads to their being specified for many parts. More expensive steels, such as SAE 9310 and 3310, are used for critical gearing applications. Some special carburizing alloys, CBS 1000M, for example, have secondary hardening characteristics that provide resistance to softening for temperatures up to about 550 °C (1025 °F).

Operating Schedules. To minimize the total amount of time required for carburizing to a given case depth, most processes are set up in a boost-diffuse mode. The boost step is at a relatively high temperature and high carbon potential to facilitate the rapid development of a deep case; the diffuse step is at a lower carbon potential, allowing the case carbon content to decrease to the level desired. Mathematical models for diffusion, described above, are very helpful in choosing the times and temperatures required for each step.

In practical situations, many considerations, in addition to minimizing processing time, enter into the choice of processing parameters. In continuous furnaces that cannot be separated into distinct zones by means of internal doors, there is a limit to the magnitude of the differences in temperature and carbon potential that can be sustained over the length of the furnace. Similarly, in batch furnaces, the rate at which the temperature can be lowered depends on the thermal inertia of the furnace and load and the magnitude of the heat losses; the rate at which the atmosphere gas composition can be changed depends on the mean residence time of the gas in the furnace. In the absence of a detailed mathematical model incorporating furnace operating characteristics, some trial-and-error experimentation may be required to find the operating set points that produce the desired results. The maximum operating temperature can be limited by the accelerated degradation of fixtures experienced at higher temperatures. Lower processing temperatures are generally favored when the distortion of parts must be minimized.

Thin-cased parts (0.5 mm, or 0.02 in., effective case or less) tend to be processed at 870 °C (1600 °F) or below simply because the processing time at higher temperatures is so short that it is difficult to control the results. For the same reason, thin-cased parts are carburized using a constant carbon potential rather than a boost-diffuse process. Sometimes the available equipment, for example, a continuous pusher furnace, is larger than the process requires. In this situation the furnace may be run at a lower-than-customary temperature to avoid the frequent door openings, which tend to upset the furnace atmosphere, that would be necessary at higher temperatures.

Quenchants. Carburized parts can be quenched in brine or caustic solutions, water-based polymer quenchants, oils, or molten salt. The more rapid the quench, the lower the requirements for hardenability, but the greater the likelihood of distortion. If a part is used as-heat treated (no finishing operations to control dimensions), marquenching into molten salt or hot oil may be used. Rings and shafts are often press quenched, that is, clamped in a fixture while hot and sprayed with oil, to reduce distortion. The choice of alloy and quenchant and the manufacturing-process design are interrelated and must be compatible.

Reheating for Quenching. It has been the practice in some industries to carburize parts at a relatively high temperature (927 °C, or 1700 °F, or above), cool slowly to ambient temperature, then reheat to a lower temperature (843 °C, or 1550 °F, for example), and quench. The advantages of this approach are:

- The final austenite grain size, which controls the size of the martensite plates and laths, is smaller, and therefore the microstructure is more refined
- The low reheat temperature places an upper limit on the amount of carbon dissolved in austenite, thereby limiting the amount of retained austenite present in the case

The main disadvantage of this processing, aside from added cost, is increased distortion of the parts. As better controls have become available for regulating furnace atmospheres and as the use of fine-grain steels has become the norm, the need for this practice has diminished.

Tempering. As high-carbon martensite is tempered, carbides precipitate, increasing the density and reducing the hardness of this constituent. The retained austenite, which accompanies the high-carbon martensite, transforms in the temperature range of 220 to 260 °C (425 to 500 °F), reducing the density and increasing the hardness of this constituent. Thus, the response of case hardness to tempering can be complex, affected by the fraction of retained austenite present initially.

Density changes during tempering affect the relief of residual stresses produced by carburizing. Figure 13 (Ref 13) shows the effect on stress relief of tempering for 1 h at various temperatures. Stress relief occurs at lower tempering temperatures, as the amount of carbon dissolved in austenite increases. The dependence of stress relief on tempering temperature in carburized parts is qualitatively similar to these results, although more complex behavior can be expected in steels with high levels of retained austenite.

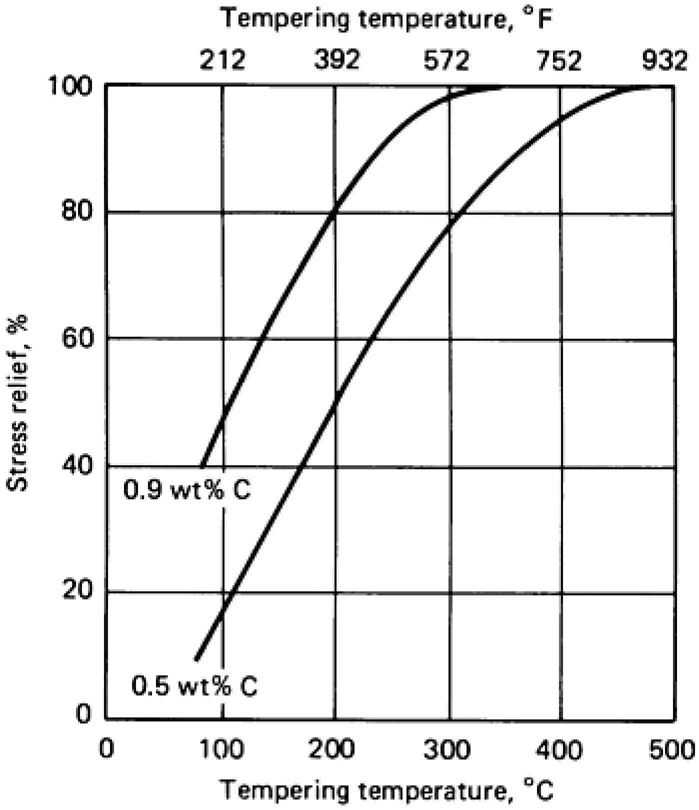

Fig. 13 Plot of stress relief versus tempering temperatures held for 1 h for two carbon concentrations in austenite. Source: Ref 13

The decrease in hardness with tempering is shown in Fig. 14 for four carburized steels. The HRC hardness values shown were converted from Rockwell A for surface hardness and from Vickers microhardness for the subsurface values. It should be noted that the hardness changes very little for tempering temperatures up to 205 °C (400 °F). However, a substantial degree of stress relief will have been experienced as indicated in Fig. 13.

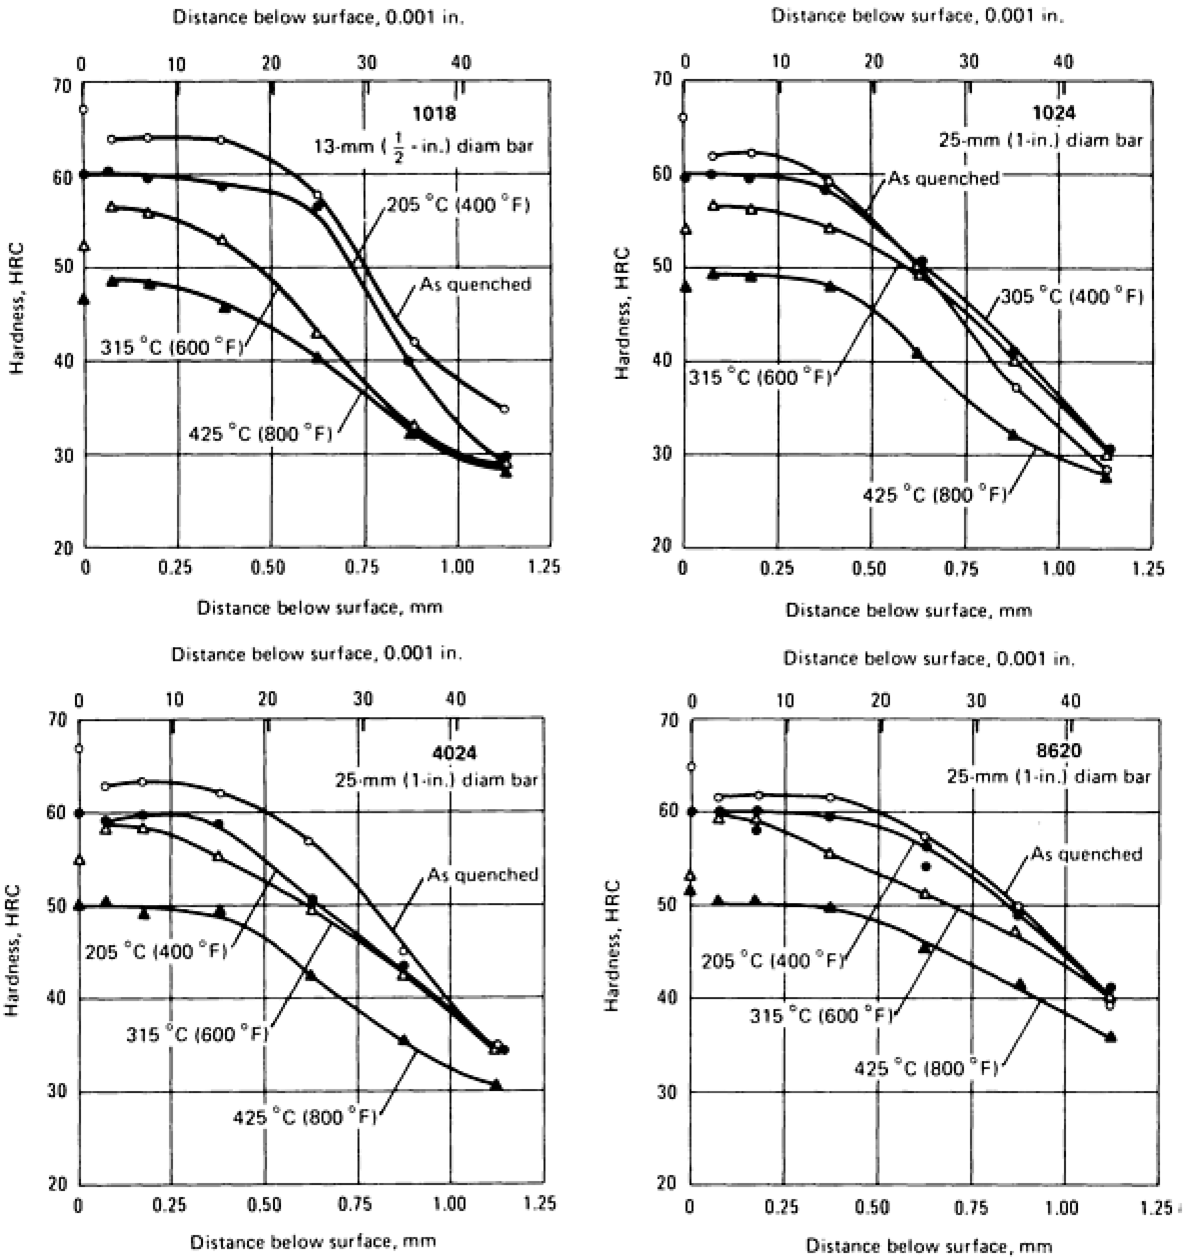

Fig. 14 Effect of tempering on hardness in carburized cases for selected steels. Samples were carburized at 925 °C (1700 °F) for 4.5 h, then oil quenched and tempered.

Parts that are to be ground after heat treatment should always be tempered. The tempering temperature should be greater than the surface temperature experienced during grinding. If it is not, grinding will produce surface tensile residual stresses. Tempering in the range of 150 to 205 °C (300 to 400 °F) improves subsequent dimensional stability. If the best possible stability is required, as in some instrument bearings, the treatment should also be designed to eliminate retained austenite. On the other hand, because tempering reduces the compressive residual surface stresses, resistance to bending and torsional fatigue may be best if the parts are not tempered at all. Tempering is omitted on many thin-cased parts (0.5 mm, or 0.02 in., case depth or less) that are not finished after heat treatment.

Selective Carburizing. To function properly, some parts must be selectively carburized, that is, carburized only on certain surfaces. Some gears are carburized only on teeth, splines, and bearing surfaces. In addition to satisfying the performance requirements of a part, selective carburizing may facilitate the machining or welding of noncarburized surfaces in the hardened condition.

Surfaces that are not to be carburized must be protected by a coating or shield that is impervious to the carburizing atmosphere. Various means are employed to protect or stop off selected surfaces from the atmosphere.

Copper plating to a minimum thickness of 13 μm (0.5 mil) is widely used for this purpose because it is relatively easy to apply, is machinable, and does not contaminate furnace atmospheres. Prior to carburizing a large, 915 mm (36 in.) diam, 4620 steel ring gear, for example, the gear is copper plated on the inside diameter flange area only to permit finish machining, after hardening, of the bore and bolt holes located in the flange. Surfaces that are not to be copper plated can be coated with a chemical-resistant lacquer, which is removed prior to carburizing. Alter carburizing, the copper can be chemically stripped from the part or removed in subsequent machining operations.

Ceramic coatings in the form of paint can also protect selected surfaces from carburizing. Surfaces must be thoroughly cleaned before ceramic paint is applied, and the first coat is allowed to dry before a second coat is applied. Ceramic paint coatings must adhere tightly in order to be impervious to the carburizing atmosphere. The application of ceramic paint to the bushing and button recesses of a rock bit cutter, for example, has been used in production.

Stopoffs. Blind holes can be stopped off by inserting copper plugs or by filling them with clay. If air is entrapped by the plug, a means of venting must be provided to relieve the pressure buildup during heating. Through holes may be plugged at either end to limit access by the atmosphere, thereby minimizing carburization. Internal threads can be protected by the insertion of a copper screw; external threads by capping with a copper nut. If a steel screw or nut is used, the threads should be coated with a stopoff material to facilitate removal. The success of all stopoff methods depends largely on the care used in their applications. Seldom are mechanical stopoffs completely effective in production.

If parts are cooled slowly after carburizing, they will be soft enough to permit the removal of the case in selected areas by machining. After subsequent reheating and quenching, these areas will remain lower in carbon and relatively soft. Operations can also be planned so that the case on a hardened part can be removed selectively by grinding. This practice is usually confined to small areas and generally to cases less than 1.3 mm (0.05 in.) in depth.

A part that has been carburized may be locally softened by induction heating. The heat may just temper the part, or, for steels with low hardenability, may actually normalize the area to be softened. This practice is used to soften threads on carburized shafts in the automotive industry.

Dimensional Control

Parts should be as near to final dimensions as possible before carburization so that heat treating times may be kept short. Nevertheless, some growth and distortion will be encountered in all carburized parts. Part size and shape strongly influence distortion, but a host of other factors can play a role as well, such as:

- Residual stresses existing in parts prior to heat treatment
- Shape changes induced by heating too rapidly
- Method of stacking or fixturing parts during carburizing and quenching
- Increasing growth as the case depth increases
- Severity of quenching (including variations caused by changing quench temperatures)
- Hardenability, as influenced by variations in steel composition

A variety of methods, to be described, are used to minimize distortion. All of them add to heat treating cost, but they may be cost effective when total production costs are considered.

In the high-volume production of precision components, such as automotive transmission gears, a general objective is to hold constant all of the processing variables affecting growth and distortion and then to compensate for the changes that do take place by adjusting the shape of the green machined (unhardened) part. For example, the lead angle of a helical

gear becomes smaller after it has been carburized because the gear becomes longer. Once the change has been documented, the machining operation prior to heat treatment can be adjusted to compensate for the growth. Trial lots of parts are processed using the intended production process and then measured to determine shape changes. After production has begun, parts may be checked periodically to ensure that processing conditions that affect distortion have not changed.

Fixturing can be used to separate parts, allowing more uniform heating and access to the carburizing atmosphere, and to orient parts so that each part enters the quench bath the same way. Fixturing adds labor cost (fixtures are often loaded and unloaded by hand) and adds operating cost because the fixtures may weigh as much as, or more than, the work load. However, proper fixturing is often effective in reducing variations in growth and lessening distortion, thereby allowing compensation for the changes in the shape of the green part.

Marquenching, or martempering, involves quenching in molten salt or in hot oil; the quenchant temperature is above the M_s temperature (the temperature at which martensite starts to form from austenite upon cooling) of the case, but below the M_s temperature of the core. Consequently, the core transforms, while parts are in the quenchant, to a mixed microstructure of martensite, bainite, and ferrite. The case transforms to martensite while the parts are cooling in air after leaving the quenchant. Distortion is reduced because the transformation strains in the core are reduced, and because thermal gradients are much lower during transformation in the case and core.

Press quenching and other means of quenching in fixtures, such as plug or cold die, are effective for reducing distortion. While quench presses may have automated loading systems, they are often loaded manually, one part at a time. Quenching in fixtures adds significantly to the cost of heat treating, but there may be no practical alternative for limiting distortion of certain parts, for example, thin-walled rings and slender shafts.

Straightening is employed to reduce the distortion of heat-treated shafts. Most straightening is done by flexing the part. There is always a risk of cracking the case when straightening carburized parts, so it is the usual practice to straighten after tempering. Some manufacturers find it best to straighten while parts are still hot from the tempering furnace. In one instance, shafts which cracked upon straightening after tempering could be straightened without cracking immediately after quenching. Many straighteners are equipped with acoustic emission sensors to detect cracking. Selective peening has also been used as a method for straightening parts.

Case Depth Measurement

Case depth is usually specified as the depth below the surface at which a defined value of some property occurs. A case depth to a hardness of 50 HRC and a case depth to a carbon content of 0.4 wt% are examples of specifications for an effective case depth. Also used is the term total case depth, which is too vague for general use as a specification because of the gradual transition between case and core properties in most carburized parts. However, some carbonitrided parts and induction case hardened parts will have a sharp transition in microstructure clearly separating case and core. Only in these instances is total case depth defined well enough to be useful as a specification. Methods of measuring case depth are described in detail in SAE Recommended Practice J423.

Many parts, such as gears, consist of some surfaces that are convex, some that are relatively flat, and some that are concave. It is usually found that the case depth will be least at the concave surface (the root) and greatest at the convex surface (the tooth tip). The effect of surface curvature on effective case depth is shown in Fig. 15. These data are computed for a particular case:

- Surface carbon, 1%
- Core carbon, 0.2%
- Diffusion time/temperature sufficient to produce a case depth to 0.4% of 1 mm (0.04 in.) beneath the flat surface of a slab of infinite thickness

From Fig. 15, the same treatment that will produce a case depth of 1 mm (0.04 in.) in a plane slab of 3 mm (0.12 in.) half-thickness will produce a case depth of 1.13 mm (0.0445 in.) in a rod of 3 mm (0.12 in.) radius, a case depth of 1.28 mm (0.0504 in.) in a sphere of 3 mm (0.12 in.) radius, and a case depth of 0.93 mm (0.037 in.) in a circular hole of 3 mm (0.12 in.) radius. The effect of surface curvature is quite pronounced if the radius of curvature of the surface is less than about five times the effective case depth beneath a flat surface. The effect of curvature is small when the radius of curvature of

the surface is more than ten times the effective case depth. Surface curvature also affects cooling so that in parts with marginal hardenability there may be a greater difference between convex and concave surfaces when effective case depth is defined in terms of depth to a specified hardness than when it is defined as depth to a specified carbon content. These facts must be kept in mind when comparing case depth at various locations on a part and when comparing case depths on parts with case depths on testpieces.

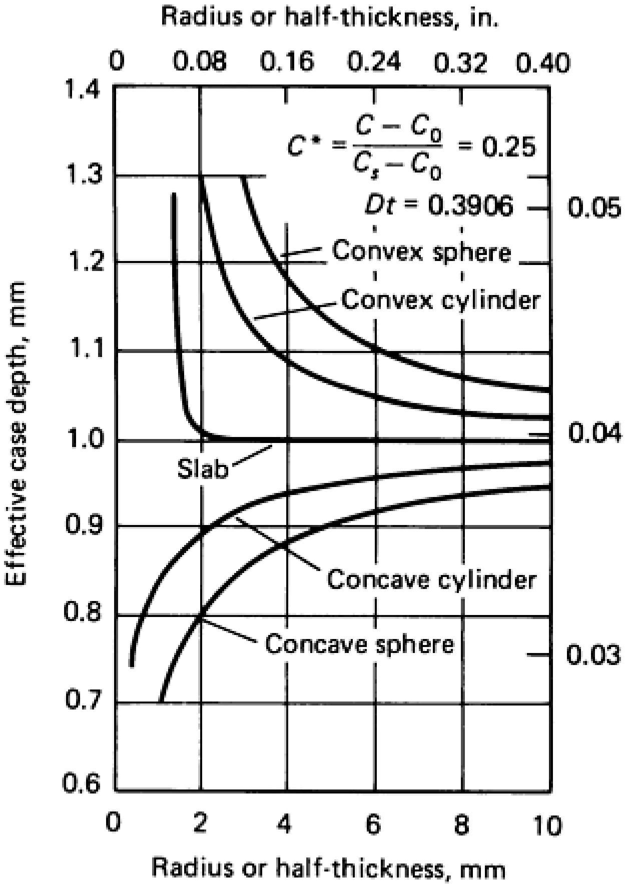

Fig. 15 Influence of surface curvature on case depth. *C**, **normalized carbon content; *C*, concentration of diffusing substance; C_0, base carbon content of the alloy; C_s, surface carbon content (often taken to be the maximum dissolved carbon content in austenite at the carburizing temperature); *D*, diffusion constant, having units (distance)^2/time; *t*, time**

Effective case depth to a specified hardness value is best measured by means of a microhardness traverse on a polished metallographic section cut normal to the surface. Vickers (diamond pyramid hardness) or Knoop or Rockwell microficial indenters may be used with loads of 0.5 to 2 kg. Specifications can be written in terms of a microhardness value or in terms of HRC hardness, where it is understood that microhardness (HV, HK, or HRMF) is converted to HRC using standard tables (50 HRC = 513 HV = 542 HK = 870 HRMF). Surface hardness, which is often a part of carburizing specifications, can be obtained by extrapolating subsurface microhardness values to the surface. Alternatively, the microhardness at a depth of 0.1 mm (0.004 in.) beneath the surface can be defined as the surface hardness. It is difficult to get reliable microhardness readings closer than 0.1 mm (0.004 in.) to the edge of a polished section because of edge rounding, which occurs during polishing.

Effective case depth to a specified carbon content is most frequently measured on testpieces of the same alloy and shape as the workpieces and processed simultaneously with the work load. Typically, a ground bar about 25 mm (1 in.) in diameter is used. If it is quenched with the work load, it must be tempered at about 650 to 700 °C (1200 to 1300 °F) prior to machining. Bars are cut dry, at very slow speeds to avoid burning, and washed between cuts with Freon. Turnings are collected on clean paper, rewashed, and analyzed for carbon. To detect the effect of the final atmosphere exposure on the near surface carbon gradient, three or four initial cuts of 0.025 mm (0.001 in.) thickness should be made. Thereafter, cuts of 0.075 to 0.125 mm (0.003 to 0.005 in.) thickness can be made through the case. The accuracy of the method depends

on good machining practice in addition to well-standardized analytical procedures. One user reports repeatability of 0 to 0.03% C at depths greater than 0.075 mm (0.003 in.) and 0 to 0.05% C for samples taken closer to the surface.

As a plant floor test, test bars about 10 to 12.5 mm (0.4 to 0.5 in.) can be processed with the work load, quenched, and fractured. The depth of the case, evident on the fracture surface, can be read with a 10× Brinell glass. Even workpieces can be fractured if their shape (and cost) allow easy fracture. A variant of this test involves reheating a test bar to 780 °C (1440 °F) and then quenching and fracturing. In plain carbon steels, only material with a carbon content of 0.4 wt% or greater will become austenitic at this temperature. Therefore, the line of demarcation between case and core on the fracture surface should occur at a carbon content of 0.4 wt%.

Another test for case depth makes use of the principle that the M_s temperature depends primarily on the dissolved carbon content of austenite. A carburized testpiece or part is austenitized, quenched in a bath at precisely controlled temperature, held for a few minutes to allow tempering of the martensite formed, and then quenched to room temperature. A polished, etched section will show a line of demarcation between the martensite tempered in the salt bath (dark) and the untempered martensite formed during the final quench (white). The location of the line of demarcation corresponds to a specific carbon content. The appropriate quenching bath temperature can be found from a correlation between M_s temperature (in degrees Fahrenheit) and composition (Ref 14):

$$M_s = 930 - 600(\%C) - 60(\%Mn) - 50(\%Cr) - 30(\%Ni) - 20(\%Si + \%Mo + \%W) \quad \textbf{(Eq 23)}$$

If the quenching bath temperature is chosen to be the M_s temperature for 0.4 wt% C in a given alloy, then the austenitizing temperature must be high enough to dissolve at least this much carbon in austenite, typically 830 °C (1525 °F).

Surface hardness is often measured on the plant floor on workpieces using a superficial hardness test, Rockwell 15N, for example. Because of the rather light load, the necessity for supporting pieces well, and the importance of a smooth surface, values tend to be unreliable. However, such checks of surface hardness is often necessary to detect the presence of a shallow, decarburized layer such as might occur if parts experience a delay when transferred from the carburizing furnace to the quench bath.

Safety Precautions

Gas carburizing atmospheres are highly toxic and highly inflammable and form explosive gas mixtures when mixed with air. A safety program emphasizing furnace operator training and preventative maintenance should be established and adhered to for all heat-treating operations using controlled atmospheres. The installation of alarms and other safety devices cannot substitute for a properly trained operator.

Recommended procedures for safe furnace operation are provided by furnace manufacturers; this information should form the basis for operator training. Safety standards for furnaces and related equipment are also published by the National Fire Prevention Association. Because procedures differ somewhat for furnaces of different design, the discussion in this section focuses on the principles of safe operation, that is, the goal of operating procedures. The three factors of prime consideration are discussed below.

First, all atmosphere gas discharged from the furnace to the operating environment must be burned to ensure that poisonous carbon monoxide is converted to carbon dioxide. Pilot flames should be maintained on atmosphere vent lines at all times, and there must be a flame curtain that ignites automatically whenever a furnace door opens. There should be a thermocouple inserted into each pilot flame and connected to an alarm system to verify that each pilot is ignited. Air-Endogas mixtures that are too lean to support combustion can still contain enough carbon monoxide to be hazardous. The threshold limit value for long-term exposure to carbon monoxide, set by the American Conference of Governmental Industrial Hygienists, is 50 ppm. The short-term exposure limit is 400 ppm. A concentration of 50,000 ppm CO is quickly fatal.

Second, air and Endogas will self-ignite if mixed at a temperature of 760 °C (1400 °F) or above. That is, Endogas may be introduced into an air-filled furnace heated to 760 °C (1400 °F) or above without risk of explosion; the Endogas will simply burn until the oxygen in the furnace is consumed. At temperatures below 760 °C (1400 °F) there is the risk that Endogas will not ignite spontaneously upon entering an air-filled furnace and that the furnace will then fill with an air-Endogas mixture, which may then ignite explosively. Table 3 lists autoignition temperatures and composition limits within which combustion can occur for mixtures of several gases and air.

Table 3 Properties of air-combustible gas mixtures

Gas	**Autoignition temperature**		**Flammable limits in air, vol %**
	°C	**°F**	
Methane	540	1005	5.4-15
Propane	466	870	2.4-9.5
Hydrogen	400	750	4.0-75
Carbon monoxide	609	1130	12.5-74
Methanol	385	725	6.7-36

Third, it is very convenient to have available at each furnace a source of inert gas, such as nitrogen, that is available for purging the furnace in the event of power failure or other emergencies. Many operations use cylinders of compressed nitrogen to provide automatic purging whenever the furnace temperature falls below 760 °C (1400 °F) or whenever the pressure in the Endogas line falls below a critical value. Purging with nitrogen can also be used routinely prior to introducing Endogas into a furnace or when removing the atmosphere from a furnace prior to shutdown. As a rule of thumb, the volume of gas required for effective purging is at least five times the volume of the furnace chamber.

Special precautions are needed to introduce combustible atmospheres safely into furnaces equipped with unheated vestibules. The usual procedure is to raise the furnace temperature above 760 °C (1400 °F), close the furnace door, open the vestibule door, and introduce the atmosphere gas into the furnace while maintaining a pilot flame at the furnace door to ignite gas entering the vestibule. Once a gas flame has been established at the furnace door (one that will continue burning after the pilot flame has been removed), the vestibule door can be closed and pilot flames ignited at the point that gas exits the vestibule. The flame burning at the furnace door will consume oxygen in the vestibule, reducing it to the point at which combustion can no longer be supported. Vestibule explosions can occur during start-up if the flame at the furnace door blows out before sufficient oxygen is consumed in the vestibule. Start-up is simplified if nitrogen is available; thorough purging of the furnace and the vestibule with nitrogen prior to the introduction of the atmosphere gas will eliminate any risk of explosion.

Whenever a furnace must be operated with a flammable atmosphere below 760 °C (1400 °F), the usual practice is to raise the furnace temperature above 760 °C (1400 °F), introduce the furnace atmosphere, and decrease to the operating temperature. Other safe practices have been developed that make use of nitrogen gas for purging air from the furnace before combustible gases are introduced.

Pack Carburizing of Steels

Revised by Robert W. Foreman, Consultant

Introduction

PACK CARBURIZING is a process in which carbon monoxide derived from a solid compound decomposes at the metal surface into nascent carbon and carbon dioxide. The nascent carbon is absorbed into the metal, and the carbon dioxide immediately reacts with carbonaceous material present in the solid carburizing compound to produce fresh carbon monoxide. The formation of carbon monoxide is enhanced by energizers or catalysts, such as barium carbonate ($BaCO_3$), calcium carbonate ($CaCO_3$), potassium carbonate (K_2CO_3), and sodium carbonate (Na_2CO_3), that are present in the carburizing compound. These energizers facilitate the reduction of carbon dioxide with carbon to form carbon monoxide. Thus, in a closed system, the amount of energizer does not change. Carburizing continues as long as enough carbon is present to react with the excess carbon dioxide.

Pack carburizing is no longer a major commercial process. This has been mainly due to replacement by more controllable and less labor-intensive gas and liquid carburizing processes. However, any labor cost advantage gas carburizing or liquid carburizing may have over pack carburizing can be negated should workpieces require additional steps such as cleaning and the application of protective coatings in carburizing stopoff operations. Environmental concerns have also led to reduced use of pack carburizing. It still has application to some specialized uses, however.

Advantages. Among the principal advantages of pack carburizing are:

- It can make use of a wide variety of furnaces because it produces its own contained environment
- It is ideally suited for slow cooling of work from the carburizing temperature, a procedure that may be advantageous for parts that are to be finish machined after carburizing and before hardening
- Compared to gas carburizing, it offers a wider selection of stop-off techniques for selective carburizing

Disadvantages. By its nature, pack carburizing is less clean and less convenient than other carburizing processes. Other disadvantages generally associated with pack carburizing include:

- It is not well suited to production of shallow case depths where strict case-depth tolerances are required
- It cannot provide the degree of flexibility and accuracy of control over surface carbon content and carbon gradient that can be obtained in gas carburizing
- It is not well suited for direct quenching or quenching in dies; thus, extra handling and processing are required for the hardening operation
- More processing time is required for pack carburizing than for gas or liquid carburizing because of the necessity of heating and cooling the extra thermal mass associated with the compound and the container
- It is labor intensive

Carburizing Compounds

The common commercial carburizing compounds are reusable and contain 10 to 20% alkali or alkaline earth metal carbonates bound to hardwood charcoal or to coke by oil, tar, or molasses. Barium carbonate is the principal energizer, usually comprising about 50 to 70% of the total carbonate content. The remainder of the energizer usually is made up of calcium carbonate, although sodium carbonate and potassium carbonate also may be used. It should be noted that barium carbonate, now designated by government regulations as a health hazard due to its toxicity and the disposal problems it presents, is gradually being phased out by U.S. manufacturers as a catalyst in pack-carburizing operations.

Hardwood charcoal is more reactive than coke as a source of carbon for pack carburizing Nevertheless, coke offers certain advantages, such as minimum shrinkage, good hot strength, and good thermal conductivity. More active carburizing compounds therefore contain both charcoal and coke, with typical compounds containing a greater percentage of coke.

Addition Rate. Because of losses associated with the use of pack-carburizing compounds, new compound usually is added to the used compound before it is returned to service. The loss in energizer normally is somewhat higher than loss of the rest of the compound. Therefore, somewhat larger percentages of new compound are used to ensure that the energizer level does not drop below approximately 5 to 8%. When direct quenching or severe mechanical handling methods are used, the addition rate may be as high as one part new compound to two parts used compound. When furnace cooling and careful handling methods are used, the addition rate may be one part new compound to three to five parts used compound.

Used compound often is screened to remove fines. The compound is then thoroughly mixed with the make-up material. Because many compounds, particularly those of the coated-charcoal type, are extremely friable, they require careful handling to minimize losses due to formation of dust or fines.

Process Control

In pack carburizing, as in other carburization processes, the carbon-concentration gradient obtained is a function of carbon potential, carburizing temperature and time, and the chemical composition of the steel. Two process-control attributes peculiar to pack carburizing are:

- There may be a variation in case depth within a given furnace load due to dissimilar thermal histories within the carburizing containers
- Distortion of parts during carburizing may be reduced because the compound can be used to support the parts

Carbon Potential. The carbon potential of the atmosphere generated by the carburizing compound, as well as the carbon content obtained at the surface of the work, increases directly with an increase in the ratio of carbon monoxide to carbon dioxide. Thus, more carbon is made available at the work surface by the use of energizers and carburizing materials that promote formation of carbon monoxide.

In pack carburizing, the rate of evolution of carbonaceous gas is fixed and is almost always in excess of the rate required to supply the necessary carbon for a saturated surface layer.

Temperature. Pack carburizing normally is performed at temperatures from 815 to 955 °C (1500 to 1750 °F). In recent years, the upper limits have been steadily raised, and carburizing temperatures as high as 1095 °C (2000 °F) have been used. Steelmaking processes have improved to the extent that fine grain size is maintained at temperatures approaching or exceeding 1040 °C (1900 °F). Above this temperature, the coarsening effect occurs only after prolonged periods of time, allowing high-temperature treatment without excessive grain coarsening.

The rate at which the carburized case is formed increases rapidly with temperature. If a factor of 1.0 is representative of 815 °C (1500 °F), the factor increases to 1.5 at 870 °C (1600 °F) and to more than 2.0 at 925 °C (1700 °F). Improved containers, fine-grain steels, and other improvements now permit the use of a wide variety of temperatures.

The surface carbon content is approximately that of the saturation limit for carbon in austenite. At operating temperature, the desired average carbon level throughout the case is directly dependent upon the carburizing temperature. When eutectoid cases are desired, the carburizing temperature is normally about 815 °C (1500 °F). AS more carbon is required in the case, the temperature is increased.

Time. The rate of change in case depth at a particular carburizing temperature is proportional to the square root of time. The rate of carburization is thus highest at the beginning of the cycle and gradually diminishes as the cycle is extended (see Fig. 1).

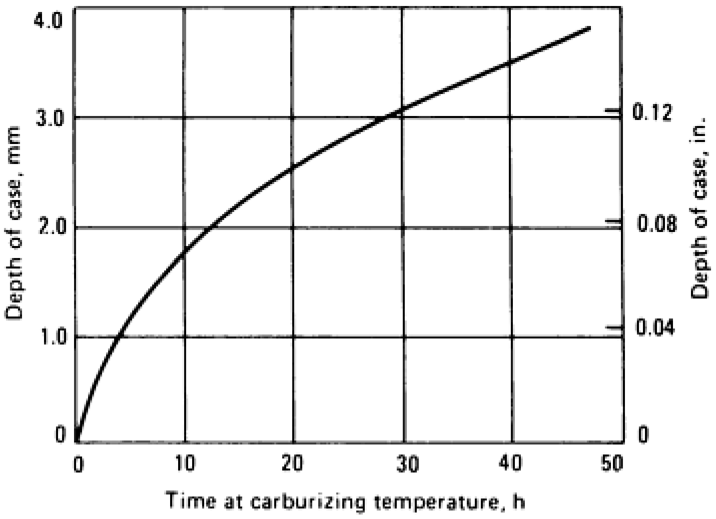

Fig. 1 Effect of time on case depth at 925 °C (1700 °F)

Steel Composition. Any carburizing grade of carbon or alloy steel is suitable for pack carburizing. It is generally agreed that the diffusion rate of carbon in steel is not markedly influenced by the chemical composition of the steel. Chemical composition does have an effect on the activity of carbon and thus can affect the carbon level at saturation for a particular temperature.

Depth of Case. Even with good process control, it is difficult to obtain parts with total case-depth variation of less than 0.25 mm (0.010 in.) from maximum to minimum in a given furnace load, assuming a carburizing temperature of 925 °C (1700 °F). Commercial tolerances for case depths obtained in pack carburizing begin at ±0.25 mm (±0.010 in.), and, for deeper case depths, increase to ±0.8 mm (±0.03 in.). Lower carburizing temperatures provide some reduction in case-depth variation because variation in the time required for all parts of the load to reach carburizing temperature becomes a smaller percentage of total furnace time. Because of the inherent variation in case depth and the cost of packing materials, pack carburizing normally is not used on work requiring a case depth of less than 0.8 mm (0.03 in.). Typical pack-carburizing temperatures selected to produce different case depths on a variety of production parts are given in Table 1.

Table 1 Typical applications of pack carburizing

Part	Dimensions[a]				Weight		Steel	Carburizing			
	OD		OA					Case depth to 50 HRC		Temperature	
	mm	in.	mm	in.	kg	lb		mm	in.	°C	°F
Mine-loader bevel gear	102	4.0	76	3.0	1.4	3.1	2317	0.6	0.024	925	1700

Distortion normally becomes more pronounced as processing temperature is increased. In some instances, carburizing temperature is selected on the basis of the maximum amount of distortion that can be tolerated. In any case, following proper container packing procedures will help minimize distortion.

Furnaces for Pack Carburizing

The suitability of a furnace for pack carburizing depends on its ability, at reasonable cost, to: provide adequate thermal capacity and temperature uniformity (furnaces must be controllable to within ±5 °C, or ±9 °F, and must be capable of uniform through heating to within ±8 to ±14 °C, or ±14 to ±25 °F); and provide adequate support for containers and workpieces at the required temperatures.

Modern heating systems and furnace construction provide ample heating capacity and temperature uniformity over a wide range of temperatures. A variation of ±8 °C (± 14 °F) throughout the entire working section of a large furnace can be easily maintained. Many furnaces incorporate automatic compensation for heat losses at doors or other connection points. Combustion systems that maintain constant pressure or constant flow permit close temperature control on variable loads. Zoning is also a major contributor to control. To maintain good uniformity, it is necessary to load the furnace as uniformly as possible and to allow adequate space between containers--50 to 100 mm (2 to 4 in.) or more--to permit circulation of the heating gases.

The three types of furnaces most commonly used for pack carburizing are the box, car-bottom, and pit types. Box furnaces are loaded by mechanical devices or by in-plant transportation equipment. Car-bottom furnaces provide for convenient loading of heavy units. A car-bottom furnace with a car at each end allows a second car to be loaded while the furnace is in use, which minimizes the heat loss and downtime between batches. Pit furnaces are general-purpose furnaces that may be used for carburizing and other heat-treating operations that require minimum floor space.

Adequate support of containers and workpieces does much to minimize distortion. It also helps maintain the shape and extend the life of carburizing containers. Three or more points of support should be used in car-bottom furnaces. The container should be blocked above the hearth to allow circulation around, and proper shimming of, the container. In box-type furnaces, silicon carbide and certain other hearth materials, provide excellent wear resistance to maintain the shape of the hearth. Their high thermal conductivity helps promote temperature uniformity.

Furnaces for pack carburizing have a minimum number of parts that are subject to high wear or that require frequent maintenance. Very few alloy parts inside the furnace are subjected to thermal fatigue, and a minimum of auxiliary equipment is needed. The personnel who operate these furnaces do not need extensive technical training. (For more information on equipment, see the next Section, "Heat-Treating Equipment," in this Volume.)

Carburizing Containers

Materials. Carburizing containers are made of carbon steel, of aluminum-coated carbon steel, or of iron-nickel-chromium heat-resisting alloys. Although uncoated carbon steel boxes scale severely during carburizing and have short lives, they often are the most economical for processing odd lots and unusual shapes.

Aluminum coating can significantly extend the life of a carbon steel container, making this material potentially the lowest in cost per hour per unit weight carburized.

In the long run, heat-resisting alloys are the most economical container materials for carburizing large numbers of moderate-size parts. However, because heat-resisting alloys are considerably higher in initial cost than plain or aluminum-coated carbon steel, they must be used continuously if they are to approach the lowest possible prorated cost.

Design and Construction. For containers of all three materials, the trend has been toward lighter construction from sheet or plate, rather than the heavier cast construction. These lighter containers require ribbing, corrugating, or other bracing methods to make them rigid enough to withstand long periods at high temperature. Containers often are equipped with braced lifting eyes or hooks, special lid-receiving sections, and test-pin openings.

A carburizing container should be no larger than necessary. If possible, it should be narrow in at least one dimension to promote uniform heating of the contents. A properly designed box will provide a cooling rate high enough to minimize formation of a carbide network in the case, but low enough to avoid distortion or excessive hardening.

Lid Construction. Lids for carburizing containers vary from simple sheet-metal plates to built-up lids of metal and refractory material. The lid may add rigidity to the container. It must be tight enough to prevent air from entering and burning the compound, yet not so tight as to prevent easy expulsion of excess gas generated within the container. Lids must be capable of venting the container, and the venting means must be able to withstand the intense heat liberated by combustion of flammable gas. Lids that fit too loosely can be partly sealed with clay-base cements.

Conditioning. Before new alloy carburizing containers are placed in service, they may be conditioned by "precarburizing" without a work load. This pretreatment eliminates the possibility of the container, rather than the work load, being carburized during the first production carburizing cycle.

Packing

Intimate contact between compound and workpiece is not necessary; however, when properly packed, the compound will provide good support for the workpiece. The layer of compound surrounding the work must be heavy enough to allow for shrinkage and to maintain a high carbon potential during the entire cycle, but not so heavy as to unduly retard heating of the workpiece to carburizing temperature. If the container can be designed to conform to the shape of the workpiece, the compound will be of both uniform and minimum thickness.

Work-load density --that is, net weight (piece weight) divided by gross weight (weight of the carburizing container, compound, and workpieces)--is an important factor in the efficiency of pack carburizing, because it affects heating and cooling time. The smaller this percentage, the lower the relative efficiency of the process. Table 2 shows work-load densities for three different carburized parts.

Table 2 Work-load densities in pack carburizing

Part	Dimensions[(a)]				Weight per piece				Net weight, % of gross weight
	OD		OA		Net		Total[(b)]		
	mm	in.	mm	in.	kg	lb	kg	lb	
Roll	75	3	1220	48	37	82	72	159	51
Crane wheel	560	22	125	5	130	287	150	331	87
Gear	660	26	205	8	285	628	440	970	65

(a) OD, outside diameter; OA, overall (axial) dimension.

(b) Total weight of work plus packing material plus container, divided by number of pieces in pack

Procedure. Packing of the workpieces in a compound is a dusty and disagreeable operation (one of the reasons this process is losing favor in industry). For this reason, grouping of boxes, workpieces, and compound should be carefully planned so as to minimize handling of the compound. If possible, workpieces should come to the packer already stacked and sorted, preferably on open trays or in pans.

First, a layer of compound from 13 to 50 mm ($\frac{1}{2}$ to 2 in.) deep is placed in the empty box. The part or parts are then stacked in the container, and, if necessary, metal or ceramic supports or spacers are applied and internal container supports are inserted.

Whenever possible, workpieces should be packed with the longest dimension vertical to the base of the container. This is extremely important in processing long parts such as shafts and rolls because it minimizes the tendency of these parts to sag. Suspension of the work within the container or within the furnace is useful in minimizing distortion in relatively thin or delicate parts. For applications where small teeth or small holes are to be uniformly carburized, a 6- or 8-mesh material should be used to ensure good filling.

After the compound is sufficiently tamped, a final layer is placed on top of the parts. The thickness of the top layer varies according to the type of work, depth of case, type of container, and shrinkage rate of the compound, but it should be adequate to ensure that the work will be covered after shrinkage and other movements have occurred. A minimum depth of 50 mm (2 in.) is recommended. In the final step, the lid is put in place.

Process-Control Specimens. In order to control and evaluate the carburizing process, test pins or shims normally are included in the charge. To provide valid results, section sizes and locations of test specimens must closely approximate those of the workpieces. Placing a test pin close to a workpiece often will produce a thermal history identical to that of the workpiece.

For control purposes, many containers are equipped with a test-pin section that can be removed from the load during the carburizing cycle. After the pins have been quenched and fractured, case-depth readings made on them aid in evaluating whether satisfactory carburizing results are being obtained and in determining when the prescribed case depth has been attained.

Selective Carburizing

Stop-off techniques described in the article on gas carburizing in this Volume apply to selective carburization by pack carburizing. In addition, it may be possible to permit any portion of a part that is not to be carburized to protrude from the carburizing container. Alternatively, an inert or lightly oxidizing material may be packed around those areas of a part that are not to be carburized.

Liquid Carburizing and Cyaniding of Steels

Revised by Arthur D. Godding, Heatbath Corporation

Introduction

LIQUID CARBURIZING is a process used for case hardening steel or iron parts. The parts are held at a temperature above Ac_1 in a molten salt that will introduce carbon and nitrogen, or carbon alone, into the metal. Diffusion of the carbon from the surface toward the interior produces a case that can be hardened, usually by fast quenching from the bath. Carbon diffuses from the bath into the metal and produces a case comparable with one resulting from gas carburizing in an atmosphere containing some ammonia. However, because liquid carburizing involves faster heat-up (due to the superior heat-transfer characteristics of salt bath solutions), cycle times for liquid carburizing are shorter than those for gas carburizing.

Most liquid carburizing baths contain cyanide, which introduces both carbon and nitrogen into the case. One type of liquid carburizing bath, however, uses a special grade of carbon, rather than cyanide, as the source of carbon. This bath produces a case that contains only carbon as the hardening agent.

Liquid carburizing may be distinguished from cyaniding (which is performed in a bath containing a higher percentage of cyanide) by the character and composition of the case produced. Cases produced by liquid carburizing are lower in nitrogen and higher in carbon than cases produced by cyaniding. Cyanide cases are seldom applied to depths greater than 0.25 mm (0.010 in.); liquid carburizing can produce cases as deep as 6.35 mm (0.250 in.). For very thin cases, liquid carburizing in low-temperature baths may be employed in place of cyaniding.

Cyanide-Containing Liquid Carburizing Baths

Light case and deep case are arbitrary terms that have been associated with liquid carburizing in baths containing cyanide. There is necessarily some overlapping of bath compositions for the two types of case. In general, the two types are distinguished more by operating temperature or by cycle times than by bath composition. Therefore, the terms low temperature and high temperature are preferred.

Both low-temperature and high-temperature baths are supplied in different cyanide contents to satisfy individual requirements of carburizing activity (carbon potential) within the limitations of normal dragout and replenishment. In many instances, compatible companion compositions are available for starting the bath or for bath make-up, and for regeneration or maintenance of carburizing potential.

Low-temperature cyanide-type baths (light-case baths) are those usually operated in the temperature range from 845 to 900 °C (1550 to 1650 °F), although for certain specific effects this range is sometimes extended to 790 to 925 °C (1450 to 1700 °F). Low-temperature baths are best suited to formation of shallower cases. Low-temperature baths are generally of the accelerated cyanogen type containing various combinations and amounts of the constituents listed in Table 1 and differ from cyaniding baths in that the case produced by a low-temperature bath consists predominantly of carbon. Low-temperature baths are usually operated with a protective carbon cover; however, when the carbon cover on a low-temperature bath is thin, the nitrogen content of the carburized case will be relatively high. Cyaniding baths produce cases that are about 0.13 to 0.25 mm (0.005 to 0.010 in.) deep and that contain appreciable amounts of nitrogen.

Table 1 Operating compositions of liquid carburizing baths

Constituent	Composition of bath, %	
	Light case, low temperature	Deep case, high temperature

	845-900 °C (1550-1650 °F)	900-955 °C (1650-1750 °F)
Sodium cyanide	10-23	6-16
Barium chloride	. . .	30-55[(a)]
Salts of other alkaline earth metals[(b)]	0-10	0-10
Potassium chloride	0-25	0-20
Sodium chloride	20-40	0-20
Sodium carbonate	30 max	30 max
Accelerators other than those involving compounds of alkaline earth metals[(c)]	0-5	0-2
Sodium cyanate	1.0 max	0.5 max
Density of molten salt	1.76 g/cm^3 at 900 °C (0.0636 lb/in.^{3} at 1650 °F)	2.00 g/cm^3 at 925 °C (0.0723 lb/in.^{3} at 1700 °F)

(a) Proprietary barium chloride-free deep-case baths are available.

(b) Calcium and strontium chlorides have been employed. Calcium chloride is more effective, but its hygroscopic nature has limited its use.

(c) Among these accelerators are manganese dioxide, boron oxide, sodium fluoride, and sodium pyrophosphate.

In a low-temperature cyanide-type bath, several reactions occur simultaneously, depending on bath composition, to produce various end products and intermediates. These reaction products include the following: carbon (C), alkali carbonate (Na_2CO_3 or K_2CO_3), nitrogen (N_2 or 2N), carbon monoxide (CO), carbon dioxide (CO_2), cyanamide (Na_2CN_2 or $BaCN_2$), and cyanate (NaNCO).

Two of the major reactions believed to occur in the operating bath are the cyanamide shift and the formation of cyanate:

$$2NaCN \leftrightarrow Na_2CN_2 + C \qquad \textbf{(Eq 1)}$$

and either

$$2NaCN + O_2 \rightarrow 2NaNCO \qquad \textbf{(Eq 2)}$$

or

$$NaCN + CO_2 \leftrightarrow NaNCO + CO \quad \textbf{(Eq 3)}$$

Reactions that influence cyanate content proceed as follows:

$$NaNCO + C \rightarrow NaCN + CO \quad \textbf{(Eq 4)}$$

and either

$$4NaNCO + 2O_2 \rightarrow 2Na_2CO_3 + 2CO + 4N \quad \textbf{(Eq 5)}$$

or

$$4NaNCO + 4CO_2 \rightarrow 2Na_2CO_3 + 6CO + 4N \quad \textbf{(Eq 6)}$$

Equations 5 and 6 deplete the activity of the bath and lead to an eventual loss of carburizing effectiveness unless suitable replenishment practice is followed. Equations 1 and 3 are at least partly reversible. Reactions that produce either carbon monoxide or carbon are beneficial in producing the desired carburized case, as for example:

$$Fe + 2CO \rightarrow Fe[C] + CO_2 \quad \textbf{(Eq 7)}$$

and

$$Fe + C \rightarrow Fe[C] \quad \textbf{(Eq 8)}$$

Low-temperature (light-case) baths are usually operated at higher cyanide contents than high-temperature (deep-case baths). The preferred operating cyanide contents shown in Table 2 provide a case that is essentially eutectoidal (>0.80% C). If a hypoeutectoid (<0.80% C) case is desired, the bath is operated at the lower end of the temperature/cyanide range. Conversely, operation at the higher end of the suggested range favors formation of a hypereutectoid surface carbon content.

Table 2 Relation of operating temperature to sodium cyanide content in barium-activated liquid carburizing baths

Temperature		**NaCN, %**		
°C	**°F**	**min**	**Preferred**	**max[(a)]**
815	1500	14	18	23
845	1550	12	16	20
870	1600	11	14	18
900	1650	10	12	16

925	1700	8	10	14
955	1750	6	8	12

(a) The maximum limits are based on economy. If 30% NaCN is exceeded, there is danger that NaCN will break down, with production of carbon scum and attendant frothing. To correct such a condition, the bath temperature should be lowered and the NaCN content should be adjusted to the preferred value.

High-temperature cyanide-type baths (deep-case baths) are usually operated in the temperature range from 900 to 955 °C (1650 to 1750 °F). This range may be extended somewhat, but at lower temperatures the rate of carbon penetration decreases, and at temperatures higher than about 955 °C (1750 °F), deterioration of the bath and equipment is markedly accelerated. However, rapid carbon penetration can be obtained by operating at temperatures between 980 and 1040 °C (1800 and 1900 °F).

High-temperature baths are used for producing cases 0.5 to 3.0 mm (0.020 to 0.120 in.) deep. In some instances, even deeper cases are produced (up to about 6.35 mm, or 0.250 in.), but the most important use of these baths is for the rapid development of cases 1 to 2 mm (0.040 to 0.080 in.) deep. These baths consist of cyanide and a major proportion of barium chloride (Table 1), with or without supplemental acceleration from other salts of alkaline earth metals. Although the reactions shown for low-temperature liquid carburizing salts apply in some degree, the principal reaction is the so-called cyanamide shift. This reaction is reversible:

$$Ba(CN)_2 \leftrightarrow BaCN_2 + C \qquad \textbf{(Eq 9)}$$

In the presence of iron, the reaction is:

$$Ba(CN)_2 + Fe \rightarrow BaCN_2 + Fe[C] \qquad \textbf{(Eq 10)}$$

Cases produced in high-temperature liquid carburizing baths consist essentially of carbon dissolved in iron. However, sufficient nascent nitrogen is available to produce a superficial nitride-containing skin, which aids in resisting wear and which also resists softening during tempering and other heat treatments requiring higher than normal operating temperatures.

Combination Treatment. It is not uncommon for the carburizing cycle to be initiated in a high-temperature bath and then for the work load to be transferred to a low-temperature carburizing bath. Not only does this practice provide a maximum rate of carburizing, but quenching the work from the low-temperature bath reduces distortion and minimizes retained austenite.

Cyaniding (Liquid Carbonitriding)

Cyaniding, or salt-bath carbonitriding, is a heat-treating process that produces a file-hard, wear-resistant surface on ferrous parts. When steel is heated above Ac_1 in a suitable bath containing alkali cyanides and cyanates, the surface of the steel absorbs both carbon and nitrogen from the molten bath. When quenched in mineral oil, paraffin-base oil, water, or brine, the steel develops a hard surface layer, or case, that contains less carbon and more nitrogen than the case developed in activated liquid carburizing baths.

Because of greater efficiency and lower cost, sodium cyanide is used instead of the more expensive potassium cyanide. The active hardening agents of cyaniding baths--carbon monoxide and nitrogen--are not produced directly from sodium cyanide. Molten cyanide decomposes in the presence of air at the surface of the bath to produce sodium cyanate, which in turn decomposes in accordance with the following chemical reactions:

$$2NaCN + O_2 \rightarrow 2NaNCO \qquad \textbf{(Eq 11)}$$

$$4NaNCO \rightarrow Na_2CO_3 + 2NaCN + CO + 2N \quad \textbf{(Eq 12)}$$

$$2CO \rightarrow CO_2 + C \quad \textbf{(Eq 13)}$$

$$NaCN + CO_2 \rightarrow NaNCO + CO \quad \textbf{(Eq 14)}$$

The rate at which cyanate is formed and decomposes, liberating carbon and nitrogen at the surface of the steel, determines the carbonitriding activity of the bath. At operating temperatures, the higher the concentration of cyanate, the faster the rate of its decomposition. Because the rate of cyanate decomposition also increases with temperature, bath activity is greater at higher operating temperatures. A fresh cyaniding bath must be aged for about 12 h at a temperature above its melting point to provide a sufficient concentration of cyanate for efficient carbonitriding activity. For the aging cycle to be effective, any carbon scum formed on the surface must be removed. To eliminate scum, the cyanide content of the bath must be reduced to the 25 to 30% range by addition of inert salts (sodium chloride and sodium carbonate). At the bath aging temperature--usually about 700 °C (1290 °F)--the rate of its decomposition is low.

Bath Composition. A sodium cyanide mixture such as grade 30 in Table 3, containing 30% NaCN, 40% Na_2CO_3, and 30% NaCl, is generally used for cyaniding on a production basis. This mixture is preferable to any of the other compositions given in Table 3. The inert salts sodium chloride and sodium carbonate are added to cyanide to provide fluidity and to control the melting points of all mixtures. The 30% NaCN mixture, as well as the mixtures containing 45, 75, and 97% NaCN, may be added to the operating bath to maintain a desired cyanide concentration for a specific application.

Table 3 Compositions and properties of sodium cyanide mixtures

Mixture grade designation	Composition, wt%			Melting point		Specific gravity	
	NaCN	$NaCO_3$	NaCl	°C	°F	25 °C (75 °F)	860 °C (1580 °F)
96-98[(a)]	97	2.3	Trace	560	1040	1.50	1.10
75[(b)]	75	3.5	21.5	590	1095	1.60	1.25
45[(b)]	45.3	37.0	17.7	570	1060	1.80	1.40
30[(b)]	30.0	40.0	30.0	625	1155	2.09	1.54

(a) Appearance: white crystalline solid. This grade also contains 0.5% sodium cyanate (NaNCO) and 0.2% sodium hydroxide (NaOH); sodium sulfide (Na_2S) content, nil.

(b) Appearance: white granular mixture

The carbon content of the case developed in cyanide baths increases with an increase in the cyanide concentration of the bath, thus providing considerable versatility. A bath operating at 815 to 850 °C (1500 to 1560 °F) and containing 2 to 4% cyanide may be used to restore carbon to decarburized steels with a core carbon content of 0.30 to 0.40% C, while a 30% cyanide bath at the same temperature will yield a 0.13 mm (0.005 in.) case containing 0.65% C at the surface in 45 min. Sodium cyanide concentration also has some effect on case depth, as shown for 1020 steel in Table 4.

Table 4 Effect of sodium cyanide concentration on case depth in 1020 steel bars

Samples are 25.4 mm diam (1.0 in. diam) bars that were cyanided 30 min at 815 °C (1500 °F).

NaCN in bath, %	Depth of case	
	mm	in.
94.3	0.15	0.0060
76.0	0.18	0.0070
50.8	0.15	0.0060
43.0	0.15	0.0060
30.2	0.15	0.0060
20.8	0.14	0.0055
15.1	0.13	0.0050
10.8	0.10	0.0040

Noncyanide Liquid Carburizing

Liquid carburizing can be accomplished in a bath containing a special grade of carbon instead of cyanide as the source of carbon. In this bath, carbon particles are dispersed in the molten salt by mechanical agitation, which is achieved by means of one or more simple propeller stirrers that occupy a small fraction of the total volume of the bath. Agitation is also believed to introduce greater exposure and absorption of oxygen in the air.

The chemical reaction involved is not fully understood, but is thought to involve adsorption of carbon monoxide on carbon particles. The carbon monoxide is generated by reaction between the carbon and carbonates, which are major ingredients of the molten salt. The adsorbed carbon monoxide is presumed to react with steel surfaces much as in gas or pack carburizing.

Operating temperatures for this type of bath are generally higher than those for cyanide-type baths. A range of about 900 to 955 °C (1650 to 1750 °F) is most commonly employed. Temperatures below about 870 °C (1600 °F) are not recommended and may even lead to decarburization of the steel. The case depths and carbon gradients produced are in the same range as for high-temperature cyanide-type baths (see Fig. 1, 2, 3 for data on carbon and low-alloy steels), but there is no nitrogen in the case. The carbon content is slightly lower than that of standard carburizing baths that contain cyanide.

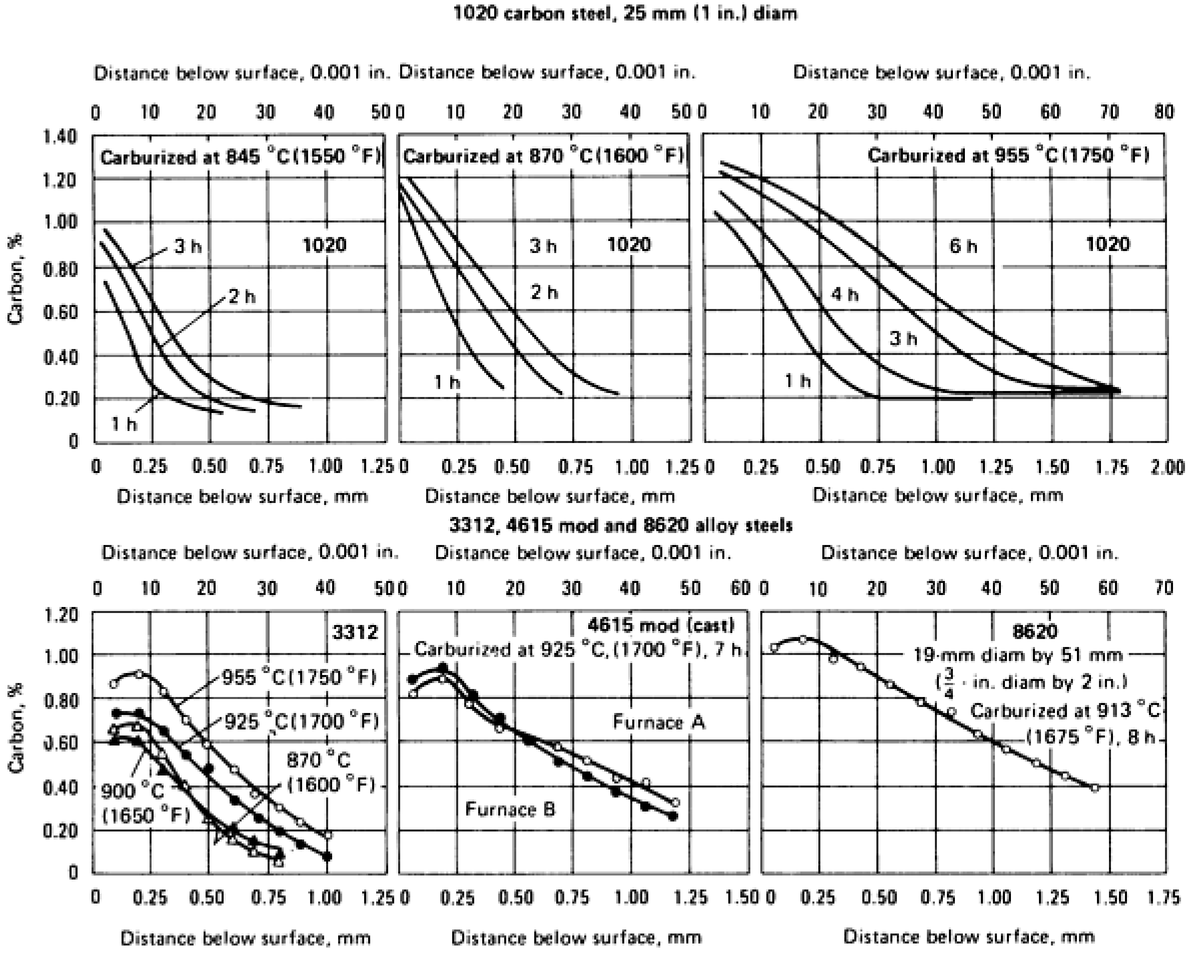

Fig. 1 Carbon gradients produced by liquid carburizing of carbon and alloy steels. Carbon gradients produced by liquid carburizing carbon and alloy steels in low-temperature and high-temperature baths. The 1020 carbon steel bars were carburized at 845, 870, and 955 °C (1550, 1600, and 1750 °F) for the periods shown. The data on 3312 alloy steel show the effect of four different carburizing temperatures on carbon gradient (time constant at 2 h). The data on modified 4615 steel castings indicate the slight differences in gradients obtained in two furnaces employing the same carburizing conditions (7 h at 925 °C, or 1700 °F). These data and the data on 8620 steel parts show a decrease in carbon content near the surface caused by diffusion of carbon during reheating to austenitizing temperature.

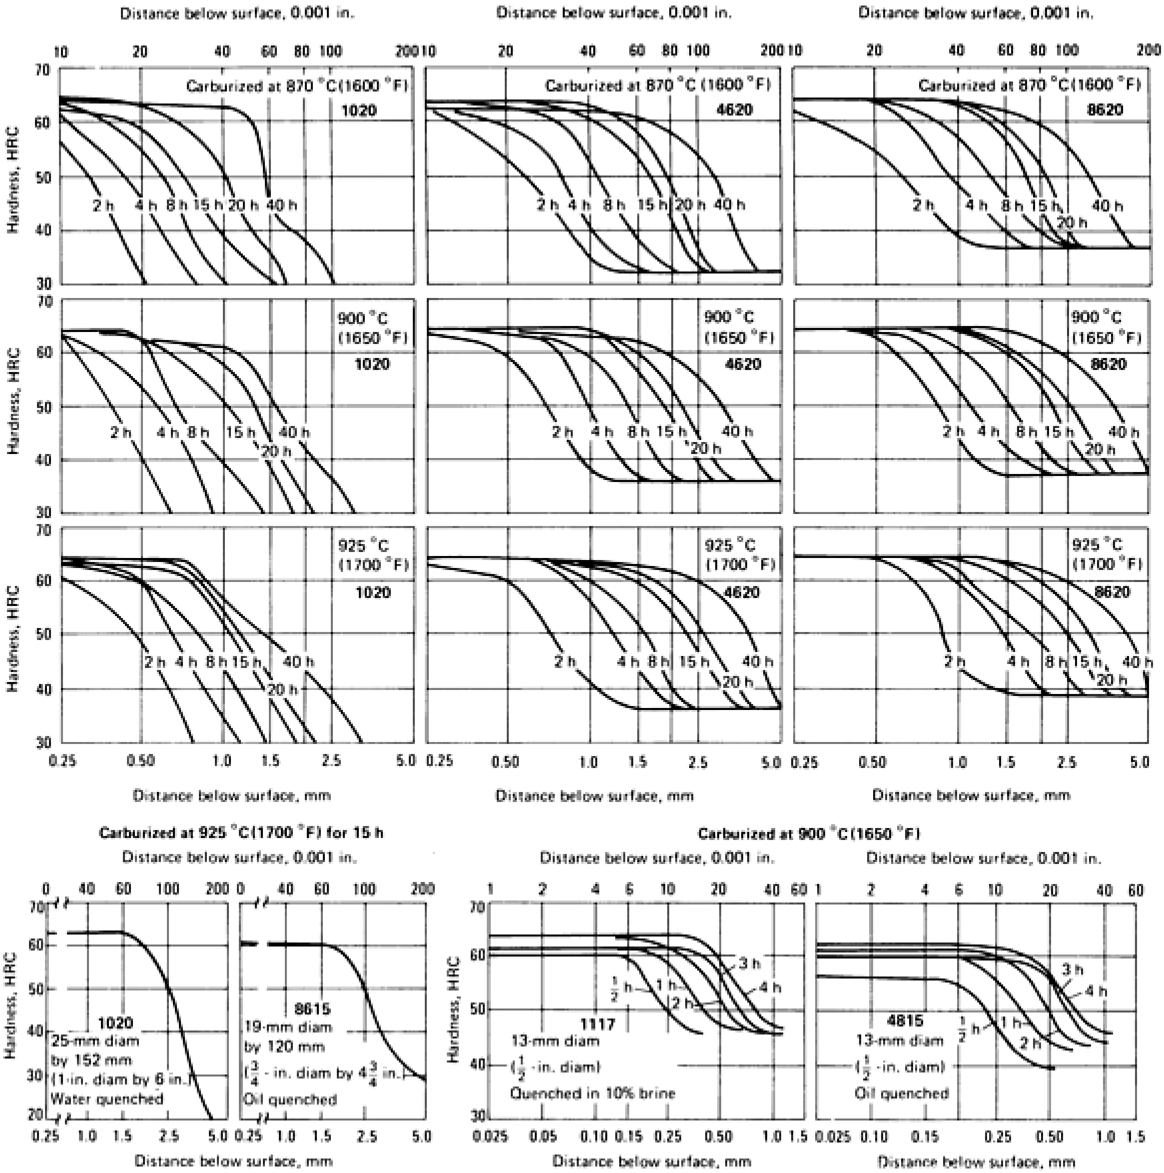

Fig. 2 Case-hardness gradients for two carbon steels and four low-alloy steels showing effects of carburizing temperature and time. Specimens measuring 19 mm diam by 51 mm ($\frac{3}{4}$ in. diam by 2 in.) were carburized, air cooled, reheated in neutral salt at 845 °C (1550 °F), and quenched in nitrate/nitrite salt at 180 °C (360 °F).

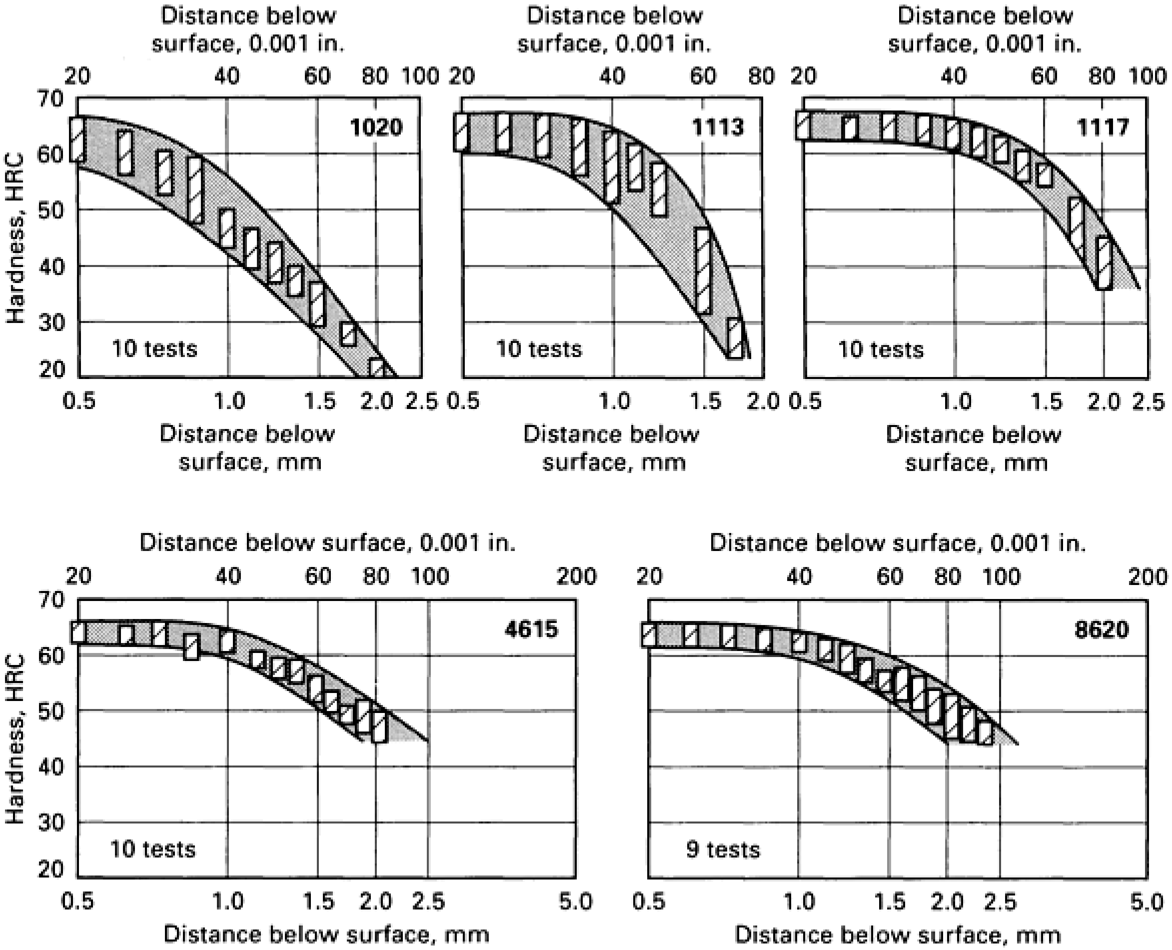

Fig. 3 Case-hardness gradients for selected steels showing scatter resulting from normal variations

Temperatures above 955 °C (1750 °F) produce more rapid carbon penetration and do not adversely affect noncyanide baths, because no cyanide is present to break down and cause carbon scum or frothing. Equipment deterioration is the chief factor that limits operating temperature.

Parts that are slowly cooled following noncyanide carburization are more easily machined than parts slowly cooled following cyanide carburization, because of the absence of nitrogen in noncyanide-carburized cases. For the same reason, parts that are quenched following noncyanide carburization contain less retained austenite than parts quenched following cyanide carburization.

Noncyanide Carburizing Process (Ref 1)

A noncyanide process for the liquid carburizing of steel that consists of a chloride mixture containing a small amount of specially selected carbon has recently been made commercially available. This carbon additive is a blend of selected graphite materials. The mixture should be held in a pot constructed of series 300 stainless steel, Inconel, or a ceramic material.

The chloride mixture laden with carbon is nontoxic and produces a classic carbon case that contains no nitrogen. Parts that have been carburized with this chloride-carbon material can be quenched directly into any nitrate/nitrite salt bath without the need for a neutral wash. Such a step is not recommended with cyanide carburizing salts, because of their incompatibility with strong oxidizers (for example, nitrates and nitrites).

This carbon-containing chloride mixture has the following properties:

Melting point, °C (°F)	663 (1225)
Working range, °C (°F)	954-982 (1750-1800)
Specific heat, J/kg · K (cal/g · °C)	
Solid	960 (0.23)
Liquid	1050 (0.23)
Heat of fusion, kJ/kg (Btu/lb)	414 (178)
Density at 954 °C (1750 °F), g/cm^3(lb/in.^{3})	1.44 (0.0520)

Initial Start-Up. A new bath is prepared by melting the chloride salt mixture and bringing it to an operating temperature of 954 °C (1750 °F). When the bath is molten and has stabilized at operating temperature, small amounts of carbon additive are introduced in the melt until a 13 to 25 mm (0.5 to 1.0 in.) thick cover remains on the surface.

Because the addition of carbon into the bath is necessary to achieve carburizing potential, the bath should be aged at heat for approximately 2 h before processing work through the bath. An adequate carbon cover should be maintained over the bath at all times while at operating temperature to ensure consistent results.

The bath level is maintained via additions of the chloride salt mixture; the carbon cover is maintained by additions of the graphite additive.

Control of Case Depth. Figure 4 shows typical effective case depths (to 50 HRC) obtainable in AISI 1117 carbon steel. Because variables such as surface condition and alloy content can affect the quality and depth of a carburized surface, test coupons should be prepared and examined in order to determine optimum operating parameters.

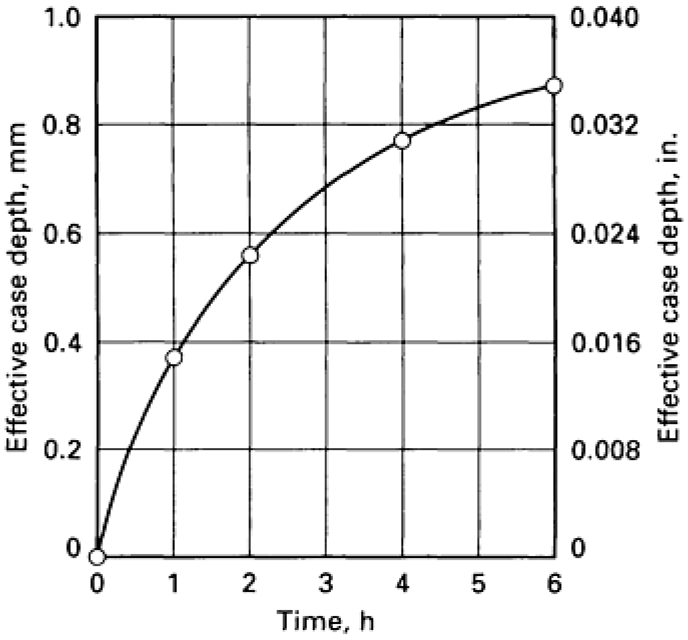

Fig. 4 Plot of carbon penetration versus holding time at 955 °C (1750 °F) for 1117 resulfurized carbon steel heat treated with Pure Case, a noncyanide carburizing process

Maximum carbon penetration can be achieved if parts are cleaned and descaled prior to the noncyanide carburizing Pure Case process. Most soils and oils can be removed with alkaline cleaner. Scale and heavy oxides may require mechanical cleaning (that, is sandblasting) or acid pickling prior to carburizing in the noncyanide mixture. It is vital that parts be completely dry before immersing the components in the molten bath.

Low-Toxicity Regenerable Carburizing and Carbonitriding Salt Bath Process (Ref 2, 3)

Extensive development work has been carried out in recent years to make salt bath processes ecologically attractive. The low-toxicity nitrocarburizing process Tufftride TF1 (see the article "Gaseous and Plasma Nitrocarburizing" in this Volume), which incorporates a nontoxic regenerator to produce the required composition within the working bath, was successfully developed in the mid-1970s (Ref 4, 5). It was apparent, therefore, that the objective of research on carburizing and carbonitriding should be directed at developing a cyanide-free regenerator to yield the required level of CN^- in the process bath. By using a base salt and a regenerator that are both cyanide-free, such a technique would avoid handling, storage, and transportation problems; eliminate the need to bail out the bath; and ease disposal requirements.

Early research to establish an ecologically acceptable process revealed that in order to maintain the high quality hitherto associated with salt bath carburizing, it was necessary to retain CN^- as the active carburizing constituent. Existing alternatives for the development of a new and ecologically safe carburizing process rapidly showed that the quality of the salt bath could only be maintained by using cyanide in the carburizing bath.

Experimental work with alternative active constituents, such as silicon carbide and suspended graphite, showed these approaches to be impracticable. Melts containing silicon carbide became viscous, generating large amounts of sludge, while graphite suspensions were difficult to control and distribute evenly throughout the molten bath. None of the options to CN^- allowed the desired reproducibility with respect to close control of carburized case depth and carbon content. The fundamental carburizing reactions taking place in a salt bath at a temperature on the order of 930 °C (1705 °F) involve the decomposition of cyanide by oxygen:

$$2CN^- + 2O_2 \rightarrow CO_3^{2-} + 2N + CO \quad \textbf{(Eq 15)}$$

followed by the subsequent diffusion of carbon into the surface of the component:

$$2CO \rightarrow C_{Fe} + CO_2 \quad \textbf{(Eq 16)}$$

A small amount of nitrogen also diffuses into the surface, depending on the temperature and composition of the bath. Experience has shown that salt baths completely free from cyanide do not yield reproducible results on a production scale. This not only applies to controlling the surface carbon content but also to the uniformity of carbon diffusion over the surface of the component.

Therefore, a cyanide-free regenerator had to be developed that would produce the required amount of cyanide in the bath. This aim was achieved by the use of an organic polymeric material which converts part of the carbonate present in the molten bath to CN^-. This regenerator is known as CeControl and the process is designated as Durofer (Ref 6, 7). The Durofer process is compared to conventional salt bath carburizing in Fig. 5.

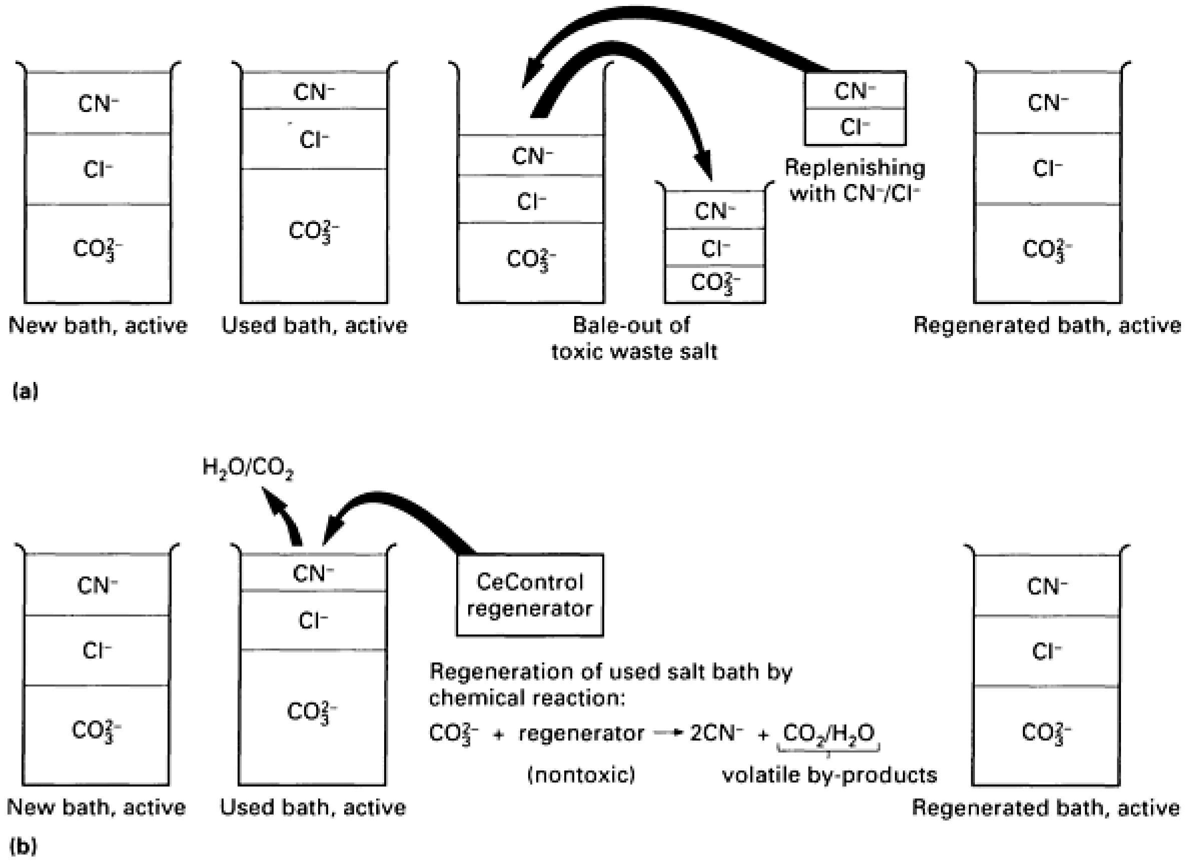

Fig. 5 Sequence of operations for two salt bath carburizing processes. (a) Conventional, requiring daily replenishment of bath with salts having high CN^- concentrations. (b) Durofer, in which CN^- level is maintained with addition of organic polymer material (CeControl regenerator) that converts carbonate in molten salt bath to CN^-

Process Control. The chemical reaction between the regenerator and the carburizing melt does not produce an increase in the molten salt volume, and, consequently, it is no longer necessary to bail out inactive salt. Therefore, the Durofer process does not produce toxic waste salt. The regenerator is manufactured in pellet form and is added to the molten bath by use of an automatic vibratory feeder. The equipment doses the molten salt with a regulated number of pellets at preset intervals, both when work is in the bath and during idling periods. Any deviation from the control range can be detected by regular analysis of the CN^- content and adjustments carried out on the autoregeneration system to compensate for any irregularity. As shown in Fig. 6, the advantage of automatic regeneration is that a very consistent CN^- level can be maintained in the bath, resulting in uniform and reproducible carburizing.

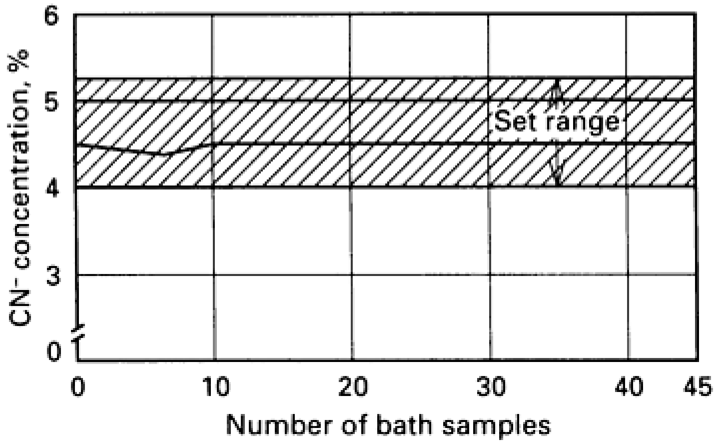

Fig. 6 The consistency of the CN- level maintained in the Durofer process. Test data compiled over 10 working days (3 shifts/day) in a carburizing bath at 930 °C (1705 °F) using CeControl 80 regenerator

Experience has shown that the optimum surface carbon value is 0.8% for alloy steels, and 1.1% is generally accepted as the optimum surface carbon value for unalloyed steels. A choice of base salt is available for use with the new regenerator to give these two carburizing conditions, designated CeControl 80B and CeControl 110B, respectively. Figure 7 shows carbon profiles obtained for samples of SAE 1015 steel after carburizing for 60 min at 930 °C (1705 °F) by the Durofer process using both of these base salts.

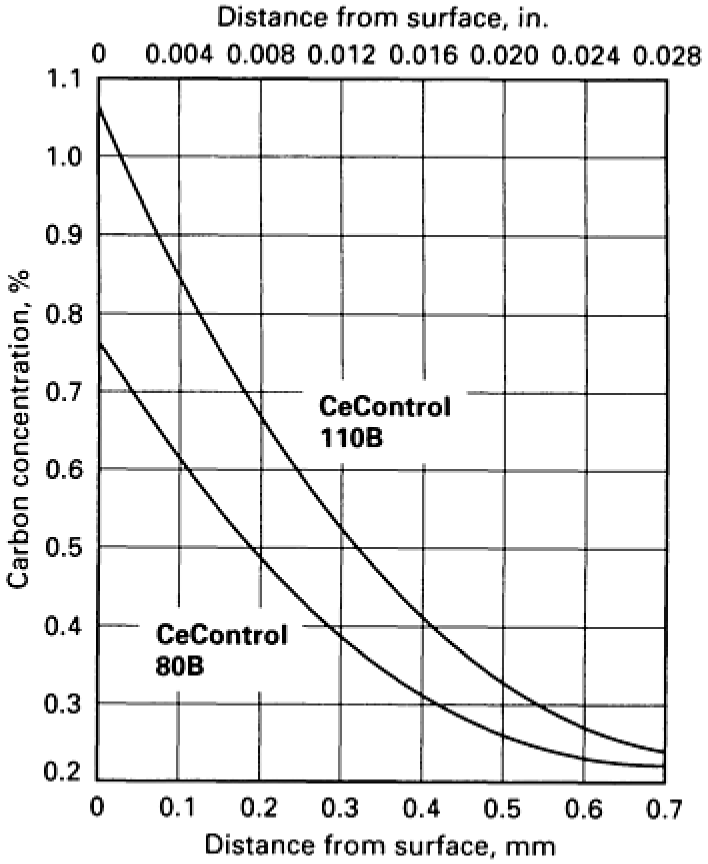

Fig. 7 Plots of carbon concentration versus carbon penetration for 1015 steels that were carburized at 930 °C (1705 °F) for 1 h with two different Durofer process base salt regenerators

Process Bath Preparation. The Durofer process bath is initially prepared by melting out the base salt, which may be either CeControl 80B or CeControl 110B, depending on the application requirements. The carburizing activity is promoted by adding CeControl regenerator via the automatic feeder, increasing the CN^- content up to about 4.5%. Control level is reached in approximately 5 h, when the addition rate is adjusted to that necessary to maintain control. The amount of regenerator required to maintain control is approximately 0.08 to 100 kg (0.18 to 220 lb) bath capacity per hour, for a working bath operating with a graphite economizer at 950 °C (1740 °F). Reduction of the molten salt level due to salt drag-out by the workload is restored by additions of the appropriate cyanide-free base salt.

Quenching. As in traditional salt bath carburizing, components carburized in the Durofer process can be quenched into water or oil. However, the composition of the Durofer bath also permits direct quenching into molten nitrate or nitrite salt baths to minimize distortion (Ref 8). In addition to this technical advantage, the chemical nature of the salt quench decomposes the CN^-, carried over on the components from the Durofer bath, to harmless carbonate. Thus, the need for detoxification of solid deposits in the quench medium and wash-water effluent is eliminated.

Carbon Gradients

Figure 1 shows carbon gradients produced by liquid carburizing 1020 steel bars at 845, 870, and 955 °C (1550, 1600, and 1750 °F) for various lengths of time at carburizing temperature. Carbon-gradient data for two wrought alloy steels (3312 and 8620) and one cast alloy steel (4615 mod) are also shown. After carburizing, the 8620 steel parts were austenitized at 840 °C (1540 °F) and quenched in oil at 55 °C (130 °F). The 4615 steel parts were austenitized at 790 °C (1450 °F), quenched in salt at 190 °C (375 °F) for 3 min, and cooled in air.

Carbon penetration (case depth) in liquid carburizing is determined primarily by the carburizing temperature and the duration of the carburizing cycle. A simple formula for estimating total case depths (measured to base carbon level) obtainable in liquid carburizing is:

$$d = k\sqrt{t} \qquad \textbf{(Eq 17)}$$

where *d* is case depth, *k* is a constant that represents the penetration in the first hour at temperature, and *t* is the time at temperature in hours. Typical values of *k* at three different temperatures are 0.30 mm at 815 °C (0.012 in. at 1500 °F), 0.46 mm at 870 °C (0.018 in. at 1600 °F), and 0.64 mm at 925 °C (0.025 in. at 1700 °F).

Hardness Gradients

A hardness gradient or variation in hardness at different depths below the surface is established in parts that are quenched following liquid carburization. The data in Fig. 2 show typical hardness gradients obtainable with carbon and low-alloy steels and illustrate the influence of carburizing temperature, duration of carburizing, quenching temperature, and quenching medium. Data on 1020, 4620, and 8620 steels are plotted for cycles of 2, 4, 8, 15, 20, and 40 h. These

specimens were air cooled from carburizing temperatures of 870, 900, and 925 °C (1600, 1650, and 1700 °F), reheated in neutral salt at 845 °C (1550 °F), and quenched in molten salt at 180 °C (360 °F). Although the depth of case at maximum hardness is progressively extended in the alloy steels with increases in time and temperature, increases in carburizing temperature have the effect of foreshortening the curves plotted for the 1020 steel. Differences between the responses of 1020 and 8615 steels are shown to be less pronounced after carburizing at 925 °C (1700 °F) for 15 h and quenching directly from the carburizing temperature. A final series of curves indicates the results obtained with 1117 and 4815 steels after carburizing at 900 °C (1650 °F) for periods ranging from $\frac{1}{2}$ to 4 h. The 4815 steel was quenched in oil and the 1117 steel was quenched in a 10% brine solution.

The indentation hardness data presented in Fig. 3 for five different steels indicate the effects of normal variations in practice on the hardness gradient. The shaded bands represent the scatter in results obtained from multiple tests of each steel. Although similar surface hardnesses are obtained with all five steels, depth of hardness increases with the alloy content of the steel. A comparison among the hardnesses of these five steels at a depth of 1 mm (0.040 in.) illustrates this variation. Although a minimum case hardness of 60 HRC cannot be maintained to a depth of 1 mm (0.040 in.) with 1020 (0.30 to 0.60% Mn) steel, it can sometimes be achieved with 1113 (0.70 to 1.00% Mn) steel and can almost always be achieved with 1117 (1.00 to 1.30% Mn), 4615, and 8620 steels.

Cyaniding Time and Temperature

Bath operating temperatures for cyanide hardening vary between 760 and 870 °C (1400 and 1600 °F). Temperatures near the lower end of this range are favored for minimizing distortion during quenching from the bath temperature. Higher temperatures are selected to exceed the Ac_3 point of the steel, to achieve faster penetration, and, depending on alloy content, to produce a fully hardened core after quenching.

When low-carbon and alloy steels are to be cyanided to produce a surface capable of resisting high contact loads, the Surface usually must be backed up with a fine-grain, tough core. This requires an operating bath temperature of about 870 °C (1600 °F).

The high file hardness of salt bath cyanided steel parts is a combined effect of carbon and nitrogen absorption in the carbonitrided case (see Table 5). Usually, immersion times range from 30 min to 1 h and produce case depths and surface carbon and nitrogen concentrations corresponding to those in Table 5. Lower temperatures will provide results proportionately lower than those given in Table 5.

Table 5 Effect of cyaniding temperature and time on case depth and surface carbon and nitrogen contents

Material thickness, 2.03 mm (0.080 in.); cyanide content of bath, 20 to 30%

Steel	Case depth after cyaniding for:				Analysis after 100 min at temperature[a]	
	15 min		100 min			
	mm	in.	mm	in.	Carbon, %	Nitrogen, %
Cyanided at 760 °C (1400 °F)						
1008	0.038	0.0015	0.152	0.006	0.68	0.51
1010	0.038	0.0015	0.152	0.006	0.70	0.50
1022	0.051	0.0020	0.203	0.008	0.72	0.51

Cyanided at 845 °C (1550 °F)						
1008	0.076	0.0030	0.203	0.008	0.75	0.26
1010	0.076	0.0030	0.203	0.008	0.77	0.28
1022	0.089	0.0035	0.254	0.010	0.79	0.27

(a) Carbon and nitrogen contents were determined from analysis of the outermost 0.076 mm (0.003 in.) of cyanided cases.

Furnaces and Equipment

Liquid carburizing is carried out in a salt bath furnace that may be heated either externally or internally. In an externally heated furnace, heat is introduced into an annular space between the salt pot and the surrounding insulation, which usually is made of firebrick. In an internally heated furnace, heat is introduced directly into the salt. Both internally and externally heated furnaces generally have insulated lids that slide to open the bath and allow workpieces and fixtures to be positioned, usually with an overhead crane or with similar mechanized lifting equipment. Additional information is available in the article "Salt Bath Equipment" in this Volume.

Externally Heated Furnaces

Externally heated furnaces may be fired by gas or oil, or may be heated by means of electrical-resistance elements.

Gas-fired or oil-fired furnaces similar in design to the one shown in Fig. 8(a) are commonly used for liquid carburizing. These furnaces are generally lower in initial cost than electrode or resistance-heated furnaces and are simple to install and operate. To contain the molten carburizing salt, fuel-fired furnaces employ a steel or alloy pot, which may be either round or rectangular. Heat is applied by two or more self-cooling burners that fire tangentially between the outer pot wall and the inner surface of the furnace lining. The hot gases are vented through a flue, which is located near the top for atmospheric-type burners, and near the bottom for pressure-type burners and for atmospheric burners for which the flue is connected to a stack 1 to 2 m (3 to 6 ft) high to maintain negative pressure in the firing chamber. The combustion chamber is lined with firebrick and with additional insulation if required. A steel casing completely surrounds all sides of the furnace housing and provides adequate safety in the event of pot failure.

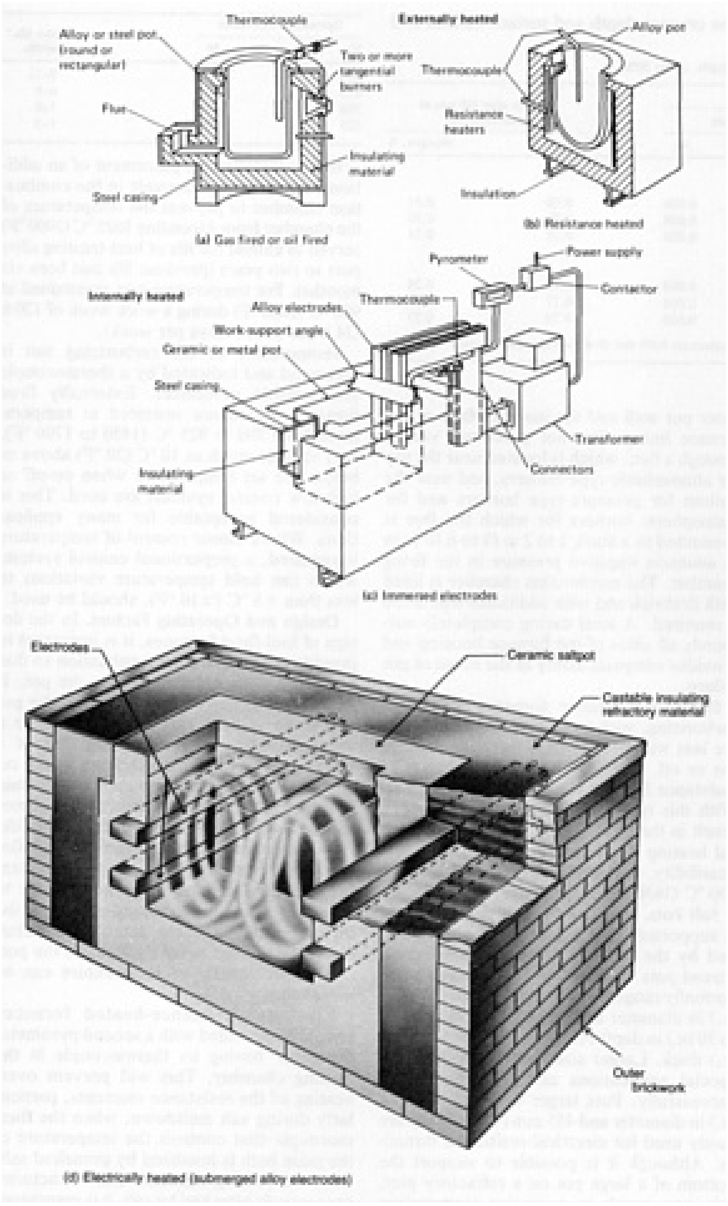

Fig. 8 Principal types of externally and internally heated salt bath furnaces used for liquid carburizing

Electrical-resistance furnaces for liquid carburizing, such as that shown in Fig. 8(b), are less widely used than furnaces fired by gas or oil. They are heated by a series of resistance heaters surrounding the salt pot. With this type of furnace, pot failure may result in the total destruction of the electrical heating elements; to guard against this possibility, carburizing temperatures below 900 °C (1650 °F) are preferred.

Salt Pots. Because the salt pot ordinarily is supported from a flange, pot size is limited by the strength of the material used. Round pots for furnaces fired by gas or oil normally range from 255 to 915 mm (10 to 36 in.) in diameter and from 205 to 760 mm (8 to 30 in.) in depth; they are about 9.5 mm ($\frac{3}{8}$ in.) thick. Larger sizes have been built for special applications and have performed successfully. Pots larger than 355 mm (14 in.) in diameter and 455 mm (18 in.) deep are rarely used for electrical-resistance furnaces. Although it is possible to support the bottom of a large pot on a refractory pier, this may result in excessive temperature gradients.

Pots may be press formed from a single piece of low-carbon steel or iron-nickel-chromium alloy; a composition of Fe-35Ni-15Cr is usually preferred for the latter. Less-expensive welded pots may be fabricated from either of these materials.

In a well-designed furnace, life of round alloy pots will vary with maximum operating temperature as follows:

Operating temperature		Service life, months
°C	°F	
845	1550	9-12
870	1600	6-9
900	1650	3-6

In one installation, placement of an additional control thermocouple in the combustion chamber to prevent the temperature of the chamber from exceeding 1095 °C (2000 °F) served to extend the life of heat-treating alloy pots to two years (previous life had been six months). Pot temperature was maintained at 900 °C (1650 °F) during a work week of 120 h (24 h per day, 5 days per week).

Temperature of the carburizing salt is measured and indicated by a thermocouple and suitable pyrometer. Externally fired furnaces which are operated at temperatures from 790 to 925 °C (1450 to 1700 °F), may vary as much as 10 °C (20 °F) above or below the set temperature when on-off or high-low control systems are used. This is considered acceptable for many applications. Where closer control of temperature is required, a proportional control system, which can hold temperature variations to less than ±5 °C (±10 °F), should be used.

Design and Operating Factors. In the design of fuel-fired furnaces, it is important to provide ample space for combustion so that the flame does not impinge on the pot. If flame impingement is unavoidable, the pot should be rotated slightly at least once a week. Rotation of the pot and use of a sleeve reduce local deterioration in the region of flame impingement and thus prolong pot life. The combustion-chamber atmosphere also has important effects on pot life. A system controlled to range from high fire to low fire is preferable to an on-off system for two reasons: the latter permits air to enter the combustion chamber during the off portion of the cycle, thereby accelerating scaling of the outer surfaces of the pot; and closer control of temperature can be achieved.

Electrical-resistance-heated furnaces should be provided with a second pyrometer controller having its thermocouple in the heating chamber. This will prevent over-heating of the resistance elements, particularly during salt meltdown, when the thermocouple that controls the temperature of the main bath is insulated by unmelted salt. Because heating elements and refractories are severely attacked by salt, it is mandatory that all salt be kept out of the combustion chamber. For this purpose, a mixture of high-temperature refractory cement, with a ceramic fiber for strength, may be used to seal joints where the pot flange rests on the retaining ring at the top of the furnace.

Regardless of the heating means, externally heated pots should be started on low fire (low heat input). After melting of the salt is observed around the top or side of the pot, the heat can be gradually increased to complete the meltdown. Excessive heating of the sidewalls or pot bottom during startup may create pressures sufficient to expel salt violently from the pot. For added safety, the pot should be covered during melt-down with either a cover or an unfastened steel plate.

Waste heat from flue gases may be fed to an adjacent chamber and used for preheating of work. Flue gases should always be visible to the operator; the presence of bluish white or white fumes at the vent is an indication that salts have entered the combustion chamber, and such situations require prompt corrective action.

Advantages and Disadvantages. Because of the ease with which they can be restarted, externally heated furnaces are well suited to intermittent operations. Another advantage of furnaces of this type is that a single furnace can be used for a variety of applications; a separate pot, containing the proper salt, can be used for each application.

Externally heated furnaces have several characteristics, however, that limit their usefulness in certain carburizing operations. They are less adaptable to close and uniform temperature control because they dissipate heat by convection, creating temperature gradients in the bath. Also, the temperature lag of the thermocouple and the recovery time of the furnace may result in overshooting or undershooting a desired temperature control point by as much as 14 °C (25 °F). In addition to requiring an exhaust system for flue gases, these furnaces may overheat at the bottom and sidewalls in restarting, creating in the thermally expanding molten salt a pressure buildup that may cause an explosion. Finally, externally heated furnaces are seldom practical for continuous high-volume production because of the limitations of pots with respect to size and maximum operating temperature. High maintenance cost is also a factor.

Immersed-Electrode Furnaces

The immersed-electrode furnace has greatly extended the useful range and capacity of molten carburizing baths. The electrodes can be removed and replaced without bailing out the furnace, and this design is suitable for both cyanide and non-cyanide carburizing processes. In this type of furnace, the molten salt is contained in a steel or ceramic pot surrounded by suitable insulating materials that separate it from an exterior casing of heavy-gage steel. The salt is heated by passing alternating current through it by means of immersed electrodes. Heat is generated by the passage of current through the salt. This heat is quickly dissipated by a downward stirring action created by current flows. The electrodes are attached by copper connectors to a transformer that converts the line voltage to a much lower voltage (9 to 18 V) across the electrodes. Bath temperature is automatically controlled by a thermocouple-activated system that regulates the input of electric power. A typical immersed-electrode furnace for liquid carburizing is shown in Fig. 8(c).

The depth of salt pots for immersed-electrode carburizing furnaces is usually limited to about 2 m (6 ft) for metal pots. Ceramic pot depth has no limit. Furnaces with pots up to 4.6 m (15 ft) long, and with power input of 360 kW, are presently in operation. They have heating capacities of about 320 kg/h (700 lb/h). In contrast, smaller units with salt pots having work spaces measuring 230 by 455 by 890 mm deep (9 by 7 by 14 in. deep), and with 15 kW power input, can heat about 23 kg/h (50 lb/h) to 925 °C (1700 °F).

Advantages and Disadvantages. Immersed-electrode furnaces do not require iron-chromium-nickel alloy pots. Carbon steel pots of welded construction, set in insulating brick but not cemented in place, have given service life as follows:

Operating temperature		Service life, years
°C	°F	
845[(a)]	1550[(a)]	2-3
870	1600	$1\frac{1}{2}$-2
900	1650	1-$1\frac{1}{2}$

(a) Max

These furnaces require minimum floor space and maintenance and can be used with all types of carburizing salts. Electrodes made of alloy steel should have an average service life equivalent to that indicated for steel pots in the above table. Worn electrodes can be replaced while the furnace is in operation.

Depending on the positioning of the electrodes, temperature control to within ±3 °C (±5 °F) is easily obtained with these furnaces; heat is generated within the bath, and overshooting is readily avoided. The furnaces lend themselves to mechanization and are suitable for high-volume production at operating temperatures from 815 to 955 °C (1500 to 1750 °F).

Maximum pot size is not restricted; pots may vary in length and width to suit requirements, and multiple pairs of electrodes can be installed to furnish the necessary heating capacity. Several batches of work may be carburized simultaneously and removed after different periods of time to produce a variety of case depths. Because the salt bath melts from the top downward, this type of furnace does not present a starting problem or an explosion hazard.

The immersed-electrode furnace is not recommended for intermittent operation. Depending on furnace size, reheating the salt charge may require a day or more. Pots are not intended to be interchangeable. Pot removal usually involves replacement of the surrounding insulation.

If an immersed-electrode-heated salt bath has been shut down completely and the salt has solidified, the salt between the electrodes must be melted with a torch before heating can be resumed. Insertion of an electric-resistance coil into the bath prior to salt solidification provides another means of remelting.

Submerged-Electrode Furnaces

Figure 8(d) illustrates the arrangement of components of a submerged-electrode furnace. The frame is made of heavy angle iron, and a steel plate is placed at the base beneath the brickwork. The outer brickwork consists of hollow ceramic tile or common building brick. The salt pot is made of burned alumina firebrick. The space between the sidewalls and the ceramic pot is filled with castable insulating refractory.

When salt is melted in the pot, it penetrates the refractory until it becomes cool enough to freeze. The resulting shell of solidified salt retains the liquid salt in the furnace. If the refractory develops a crack, bath temperature must be lowered to permit salt to solidify in the crack.

Water-cooled electrodes are submerged in liquid salt in the pot and are sealed in the refractory walls by frozen salt. Current travels between the electrodes, which are flush with the sidewalls. The path of current travel extends a few inches above the top of the electrodes.

Start-up and Shutdown. A submerged-electrode furnace can be started by adding molten salt from another furnace or by using a gas-fired torch or electric starting coil to melt a pool of salt that will wet both electrodes and provide molten salt for the current path. After the current path has been established in the molten salt between the electrodes, salt may be added to bring the bath up to working level. Additional salt will be required to maintain this level because a small amount will seep into the brickwork and freeze.

If the furnace must be shut down, the molten salt should be bailed from the furnace before it freezes. However, if the salt is allowed to remain in the furnace, a resistance-heated starting coil should be submerged in the bottom of the furnace while the salt is still molten. This coil remains in the frozen salt and is connected to the transformer leads to start up the furnace.

Advantages and Disadvantages. In common with immersed-electrode furnaces, submerged-electrode furnaces require minimum floor space and maintenance and are highly adaptable to mechanization. Because the submerged-electrode furnace employs water for cooling of the electrodes and transformer, it may be operated at a 50% overload without overheating the transformer, whereas the immersed-electrode furnace, being air cooled, should not be operated above a 10% overload unless designed for overload.

Because a ceramic pot is used, pot life can be 1 to 3 years. The electrodes are usually first to fail. The furnace can be rebuilt on a planned schedule during annual shutdowns.

Because of the erosive effects that water-soluble salts with high sodium carbonate or sodium cyanide contents have on ceramic pots, submerged-electrode furnaces can be used only with low-cyanide, low-carbonate salts. Baths with high cyanide or carbonate salt require a modified basic brick. The furnace shown in Fig. 8(d) with modified brick and submerged alloy electrodes will give many years of service in both cyanide and noncyanide operation.

Furnace Parts and Fixtures

Table 6 lists wrought and cast materials used for furnace parts and fixtures. As indicated, more than one material may be safely selected for a specific furnace part or fixture. Both cost of material and length of service usually increase with alloy content. Although length of service is influenced by both operating temperature and type of carburizing salt employed, the materials listed may be used in both the low- and high-temperature ranges--that is, at any temperature from 845 to 955 °C (1550 to 1750 °F).

Table 6 Recommended materials for furnace parts and fixtures when liquid carburizing at temperatures between 845 and 955 °C (1550 and 1750 °F)

Product	Material required for selected components[a]						
	Pots		Electrodes		Thermocouple protection tubes	Fixtures	Baskets
	Externally heated	Internally heated	Immersed	Submerged			
Wrought[b]	35-18[c]	Carbon steel[d]	446	Carbon steel	446	35-18[c]	35-18[c]
	Inconel	. . .	35-18[c]	35-18[c]	35-18[c]	Inconel	Inconel
	. . .	. . .	Inconel	. . .	Inconel	. . .	. . .
Cast	HT	[e]	HT	[e]	[e]	[e]	HT

(a) When more than one material is recommended for a specific part, each has proved satisfactory in service. Multiple choices are listed in order of increasing alloy content. Cost and expected service life usually increase as alloy content increases.

(b) Carbon steel has been used for most of the parts listed.

(c) Refers to a series of alloys generally of the 35Ni-15Cr type or modifications that contain from 30 to 40% Ni and 15 to 23% Cr and include RA-330, 35-19, Incoloy, and other proprietary alloys.

(d) For immersed-electrode furnaces. Pots for submerged-electrode furnaces are made of burned alumina firebrick.

(e) These types of parts are not usually cast.

Unless parts can be suspended in the salt bath by simple wiring or by placing them in a basket or similar container, some form of fixturing is required. Some typical workholding fixtures are shown in Fig. 9, together with methods of wiring small parts. The weights of specific parts may influence both the design of the fixture and the selection of material from which it is made.

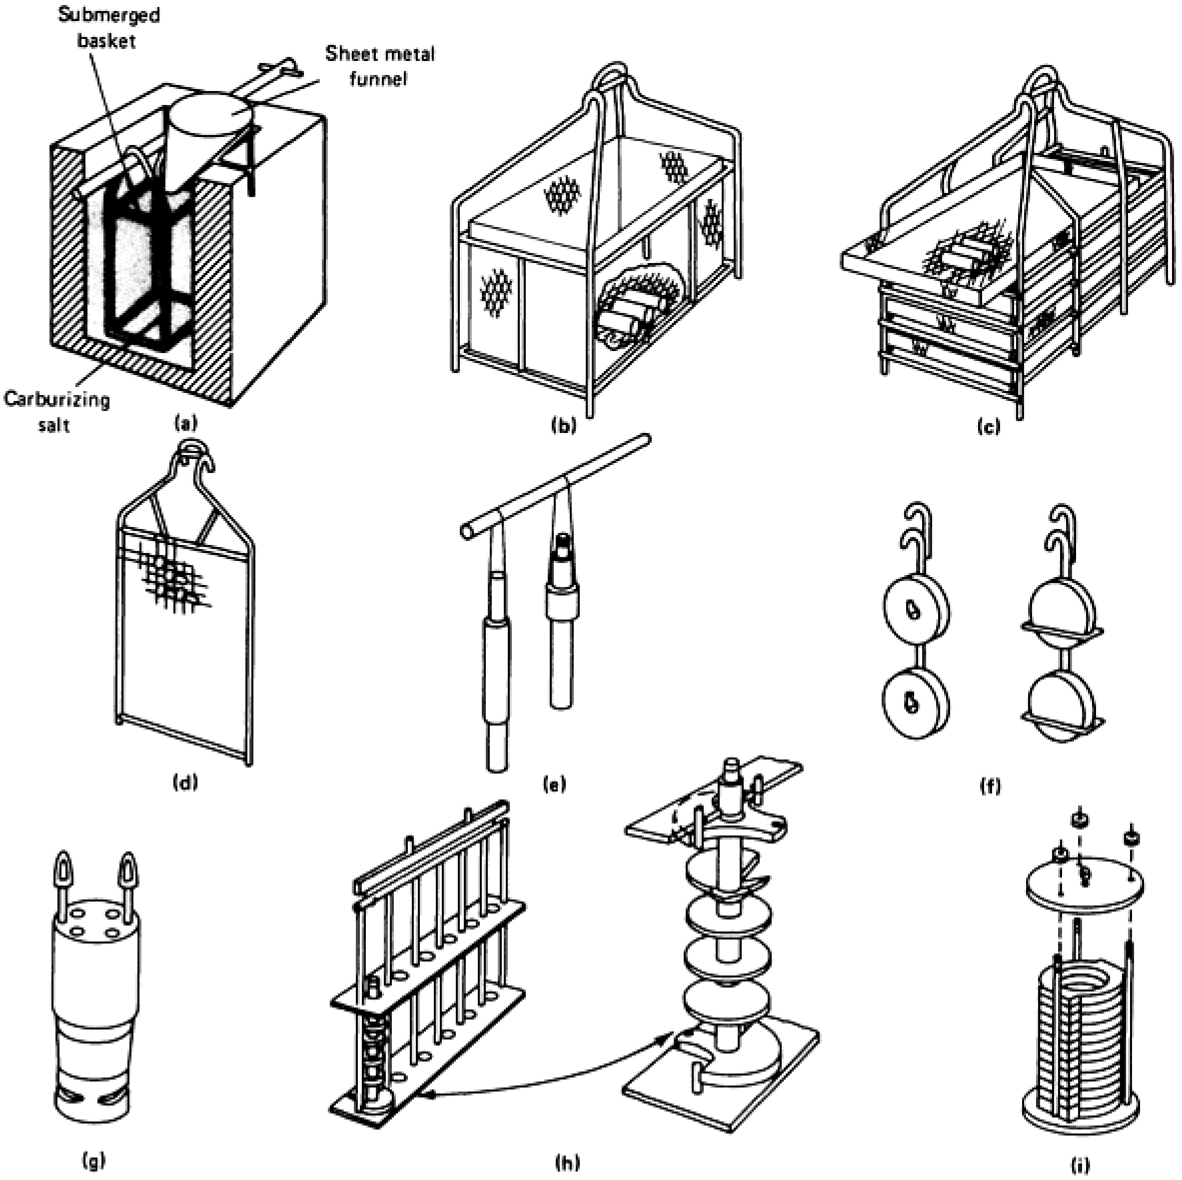

Fig. 9 Work-holding fixtures and wiring techniques used in liquid carburizing. (a) Typical holding basket for small parts, equipped with a funnel for loading parts into the basket without splashing. The funnel, which is made of sheet metal, also ensures that parts are coated with salt before they are nested together. Basket may be made of carbon or alloy steel rod and steel wire mesh. Work must be free from oil, or the parts will stick together. Parts must be dry. (b) Inconel basket of simple design. Upper loop of handle is for lifting; lower loop accommodates a rod that supports the basket over the furnace. (c) Simple basket with trays, intended for small parts. Trays provide maximum loading space without adversely affecting circulation. Entire fixture is made of Inconel. (d) Method of running flat parts. (e) Method of supporting small parts. Black annealed steel wire is used for parts weighing less than 4.5 kg (10 lb); annealed stainless steel wire is used for heavier parts. (f) Hooks, made of nickel alloy rod, for holding circular parts. (g) Method for holding large parts in which tapped handling holes are available or can be provided. Nickel alloys are used for such fixtures because of the need for high-temperature strength. Resistance to oxidation is not a factor, because liquid carburizing salts are reducing. (h) Rack for holding six small crankshafts; exploded view shows a crankshaft positioned in the rack. (i) Special rack for carburizing the outer surfaces of bearing races. Holding plates are made of mild steel; rods, of Inconel.

Holding fixtures and supports used in salt bath carburizing should be kept as simple as possible. Fixture weight should be minimized to conserve heat by lessening the load to be heated. Whenever possible, fixture components should be pinned or riveted rather than welded. This permits freedom of movement of the fixture during heating and quenching, thereby extending its life. Although weldments are not significantly affected by the carburizing bath, they are subject to the stresses imposed by cyclic heating and cooling and thus are susceptible to cracking. Finally, riveting and pinning permit easy replacement of those fixture components that can be replaced.

Additional information is available in the article "Heat-Resistant Materials for Furnace Parts, Trays, and Fixtures" in this Volume.

Automatic and Semiautomatic Lines

Figure 10(a) shows a fully automatic (jackrabbit) mechanism used for salt bath carburizing and hardening. The mechanism has synchronized, continuous-chain conveyors that carry the work through the various operations. Work suspended from horizontal bars is moved through baths at the proper speed by a main conveyor. Transfer conveyors carry the work from bath to bath. Completed work is picked up by a third conveyor and is dried by warm air in the enclosed upper portion of the structure while it is being returned to the loading point.

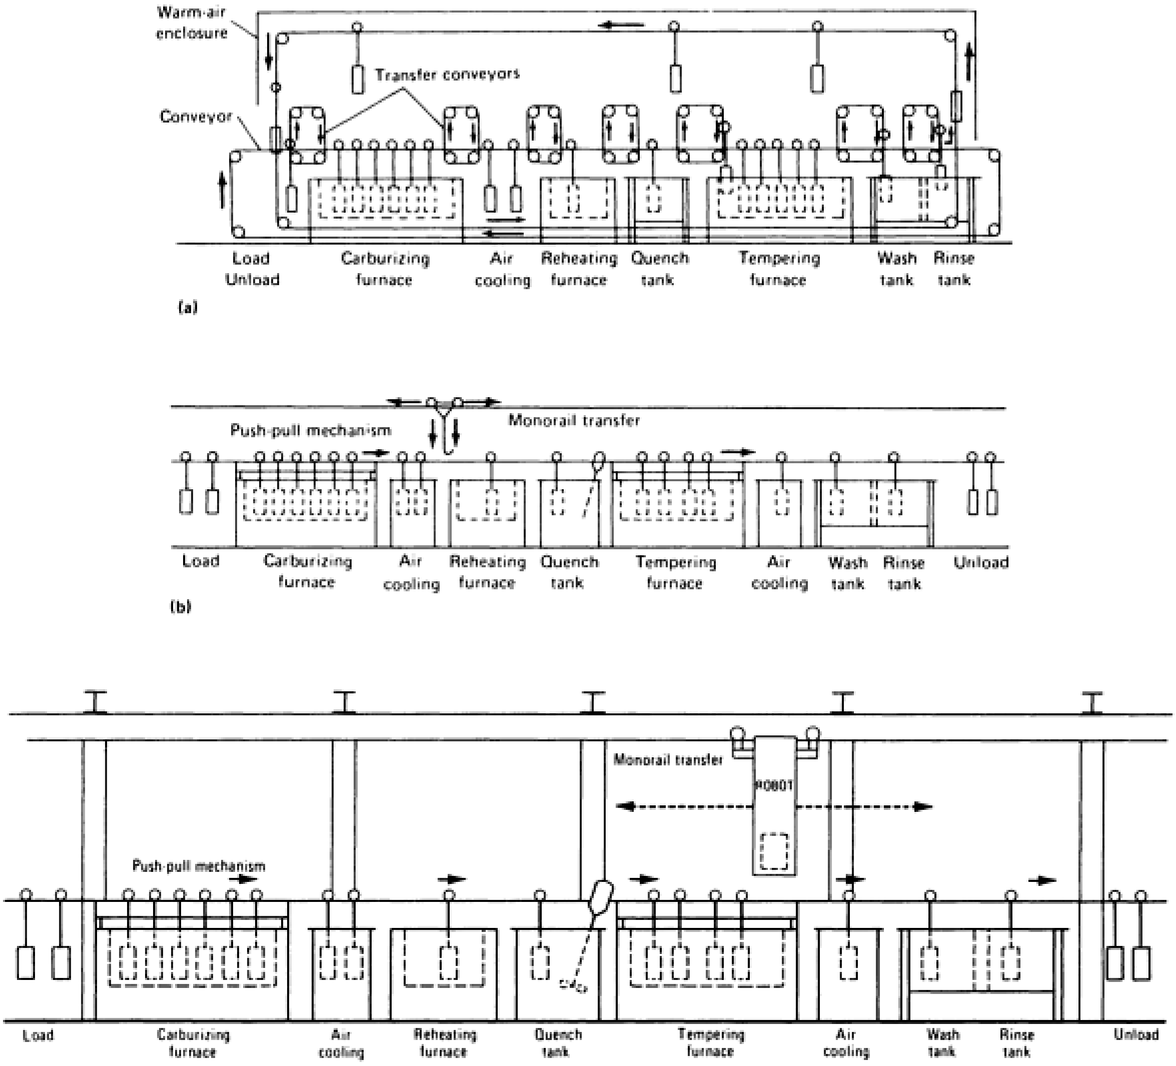

Fig. 10 Fully automatic and semiautomatic production lines for liquid carburizing and related operations (reheating, quenching, tempering, and washing). (a) Fully automatic carburizing line. (b) Semiautomatic carburizing line. (c) Fully automatic programmed-hoist carburizing line. See text for details.

The mechanism can be used only for work having similar requirements. It does not permit the time cycle of any one operation to be varied without affecting the cycles of the other synchronized operations.

Where part requirements vary, a semiautomatic mechanism, such as that shown in Fig. 10(b), may be used. Work is transferred between operations by an overhead monorail and is automatically advanced through the carburizing and tempering furnaces by means of a push-pull mechanism. This mechanism consists of two parallel beams with reciprocating push bars. Driven either hydraulically or electrically, the bars carry the dogs, which are spaced to advance the fixtures at the center of the furnace only a part of the stroke while advancing the end fixtures through the entire stroke. By closer spacing of the work at the center of the furnace and wider spacing at the ends, high productive capacity is achieved with ease of loading and unloading.

A semiautomatic line of this type permits the time cycle for any one operation to be varied without affecting other operations and is less likely to require modification if work requirements change. Figure 10(c) shows a fully automatic programmable-hoist carburizing line. One or more hoists travel simultaneously back and forth, automatically advancing the fixtures that carry the work through the required stations.

The hoist movement may be controlled by a solid-state programmable control, which provides functions that normally would require extensive wiring and hundreds of relays, counters, and switches. Once programmed, the controller will perform the functions specified by the user. Functions such as time cycles, sequences, and skips are entered easily or changed to meet metallurgical requirements. For example, some parts could be programmed to be carburized, air cooled, washed, rinsed, and returned for unloading. A pushbutton command would return the controller to the standard program.

Parts suitable for fully automatic or semiautomatic installations are those that can be fixtured by wiring, racking, or placing in baskets and that do not present problems of either buoyancy or drainage. Case-depth requirements ranging from 0.25 to 3.2 mm (0.010 to 0.125 in.) can be satisfied.

Process Control

Externally heated salt baths can be held within closer temperature limits (±8 °C, or ±14 °F) when a proportional control system employing electronic instrumentation is used. Control by means of valves (on-off or high-low control) requires mechanical instrumentation and is less accurate, although for a majority of applications it is entirely adequate.

Internally heated salt baths (immersed or submerged electrodes) may be regulated to ±5 °C (±9 °F) with either mechanical or electronic on-off controllers. In either type, the temperature-control instrument operates a relay that actuates a large circuit breaker that in turn connects or disconnects the 440-V power to the step-down transformer. Welded thermocouples may be used in installations that employ electrode heating. For safety, two thermocouples are recommended--one for temperature control and one for excess temperature cutoff.

Control of Bath Composition. Control of sodium cyanide content is the most important factor in maintaining the effectiveness of a liquid carburizing bath.

Analysis of a noncyanide liquid carburizing bath is achieved by a rapid performance test in which a 1008 steel wire 1.6 mm ($\frac{1}{16}$ in.) in diameter is immersed for 3 min in the bath, then is water quenched and mechanically bent through 90°. The bath is well activated if the wire breaks before reaching the full 90° bend. A more reliable test of activity can be made by running a 1012 silicon-killed test bar for 1 h, water quenching, and measuring Rockwell C hardness. Readings above 58 HRC indicate a well-activated bath.

Graphite Cover. A graphite cover must be maintained on the surface of a cyanide bath for reduced radiation loss and reduced cyanide loss at 870 to 955 °C (1600 to 1750 °F) and during idling. Either natural flake or artificial graphite powders may be used. The former provides a more fluid cover that has less tendency to cling to the work. However, because natural graphite has a higher ash content, it introduces more impurities into the bath, which can be a problem--particularly at low operating temperatures. Furthermore, to avoid corrosion of parts, natural graphite that contains sulfur should not be used.

A noncyanide liquid carburizing bath must also have a graphite cover. A higher rate of graphite consumption, compared with a cyanide bath, is characteristic. Frequent replenishment (commonly every hour) is necessary for maintenance of proper bath activity.

Daily maintenance routines for liquid carburizing furnaces, whether fuel-fired or electrode-heated, differ in only a few details. The following items, with exceptions as noted, comprise a typical daily maintenance schedule for all types of salt bath equipment:

- Check temperature-control system, using an auxiliary pyrometer and thermocouple. An indicating potentiometer with a long extension wire can be mounted near the furnaces and will provide accurate temperature checks faster than will a laboratory-type instrument
- Check color of exhaust smoke from the combustion chamber of fuel-fired furnaces. A bluish white or white smoke indicates salt leakage
- Remove sludge from bottom of pot while furnace is still at idling temperature, which normally is 705 to 730 °C (1300 to 1350 °F). The electrodes of internally heated furnaces should be scraped clean, and electric power should be shut off during the sludging and cleaning operation
- Add fresh salt to compensate for dragout losses. If required, make room for addition of fresh salt by bailing
- To help maintain bath composition and reduce surface heat losses, add graphite cover material to provide a thin but continuous cover
- Check bath activity by testing for cyanide content or by quenching and examining the fracture case depth
- If possible, rotate the pot of a fuel-fired furnace at least once a week to minimize the effects of flame impingement and thus extend pot life
- If a salt pot is leaking and the salt is still active, remove the salt and place it in sturdy steel containers. This salt may be broken up and re-used in starting another pot (however, it is not recommended that such salt be used thereafter for replenishment)
- Prior to replacement of a pot in a resistance-heated or fuel-fired furnace, the combustion chamber should be rebuilt if contaminated with salt to avoid rapid pot failure
- Consult operating and maintenance instructions provided by the furnace manufacturer and salt supplier

Shutdown and Restarting. For shutdowns of 2 days or longer, externally heated furnaces need not be idled; the heat may be shut off completely. During cooling and reheating, however, the pot should be covered to guard against violent expulsion of salt. The cover recommended by the manufacturer should be used.

It is generally advisable to idle electrode furnaces at 705 to 730 °C (1300 to 1350 °F), even over shutdown periods of one to two weeks. This simplifies restarting and eliminates possible damage to power transformers from condensation of moisture on the windings. For noncyanide carburizing furnaces with steel liners, idling above 845 °C (1550 °F) is recommended. During the idling period, the bath should be protected with a heavy carbon cover. The bath does not visibly fume at idling temperatures; therefore, ventilating air should be reduced. Excessive ventilating air should be avoided, because it will accelerate burn-off of the carbon cover. During the idling period, the transformer tap switch should be set at low voltage or idling tap. This will guard against possible overheating in the event that control-circuit difficulties arise while the equipment is unattended. An extra thermocouple and monitoring instrument equipped with warning alarms is recommended for use in such applications.

Control of Case Depth

The degree of uniformity of case depth obtained in normal production operations is indicated in Fig. 11 by data on 1020, 1117, and 8620 steels. Figures 11(a), 11(b), and 11(c) are based on information obtained with process-control specimens and show depth of case as a function of distance below the surface in terms of a hardness of 50 HRC or higher. These data indicate that variations in case depth can be held within narrow limits when controlled carburizing procedures are employed. At a carburizing temperature of 900 °C (1650 °F), the 1117 steel produced a deeper case to 50 HRC than did the 1020 and 8620 steels, which were carburized at 855 °C (1575 °F). Nevertheless, the total spread in case depth for any one of these steels did not exceed 0.13 mm (0.005 in.). Data presented in Fig. 11(d) indicate the range of hardnesses obtained at depths of 0.25 and 1.25 mm (0.010 and 0.050 in.) below the surface of liquid carburized 8620 steel. These data, based on 24 tests, indicate a slightly larger spread in hardness at 0.25 mm (0.010 in.) than at 1.25 mm (0.050 in.) below the surface.

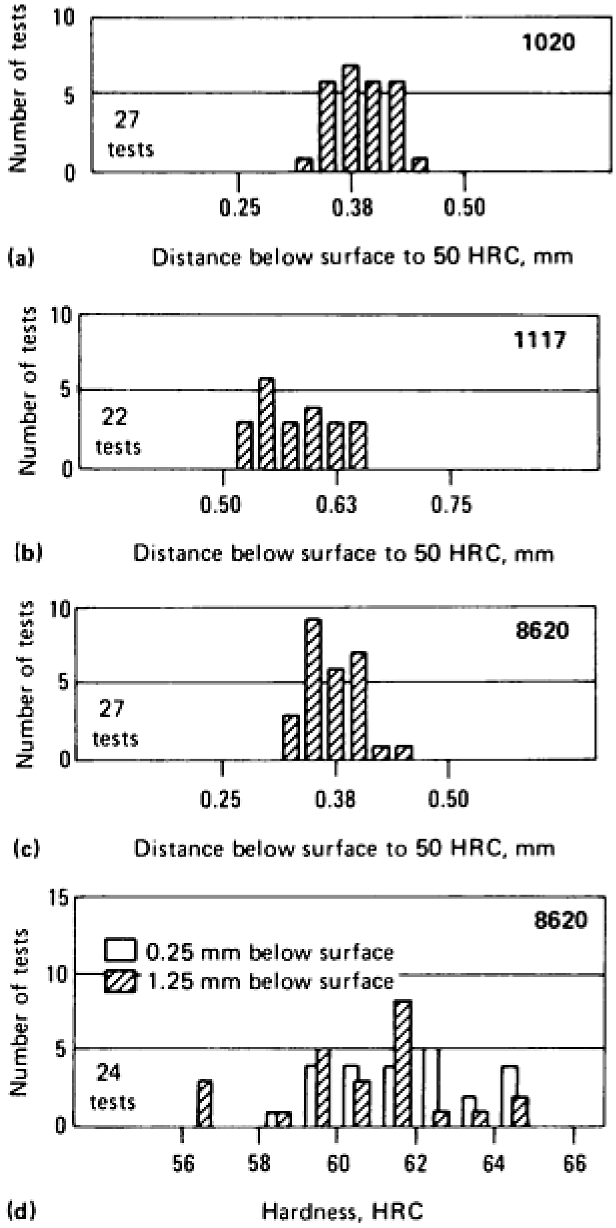

Fig. 11 Comparative case-depth and case-hardness data obtained for liquid carburizing process-control specimens made of three steels. (a) Data are for 11 mm (0.4375 in.) diam by 6.4 mm (0.25 in.) specimens carburized 2 h at 855 °C (1575 °F), brine quenched and tempered at 150 °C (300 °F). (b) Data are for 15.9 mm (0.625 in.) diam specimens carburized 2 h at 900 °C (1650 °F) and brine quenched. (c) Data are for 12.7 mm (0.50 in.) diam by 6.4 mm (0.25 in.) specimens carburized 2 h at 855 °C (1575 °F), oil quenched, and refrigerated to -85 °C (-120 °F). (d) Data are for 19 mm ($\frac{3}{4}$ in.) diam by 51 mm (2 in.) specimens carburized 2.5 h at 915 °C (1675 °F) and water quenched.

Whereas the information in Fig. 11 deals with carburizing cycles of 2 and 2.5 h at temperatures ranging from 855 to 915 °C (1575 to 1675 °F), the data presented in Fig. 3 pertain to a much longer carburizing time ($9\frac{1}{2}$ h) at 925 °C (1700 °F). The spread in case depth at 50 HRC is considerably wider than for the light-case work on which Fig. 11 is based.

Additional data on case depth as a function of time and temperature are given for ten steels in Fig. 12. These data also reflect various criteria that have been applied to evaluate case depth--for example, data relating case depth to minimum hardness, carbon content, and pearlite content.

Dimensional Changes

All parts undergo dimensional changes as a result of carburizing and hardening. From a production standpoint, it is important to know the nature and amount of dimensional change, or distortion, that can be anticipated, and the corrective action that may be taken to hold dimensional changes to a minimum. The following examples relate dimensional change to several shapes that vary in complexity.

Example 1: Carburized, Quenched, and Tempered 8615H Steel Gear with 60 to 62 HRC Surface Hardness.

The small gear shown in Fig. 13(a) closed in along the bore from a minimum dimension of 17.22 mm (0.6780 in.) prior to heat treatment to a minimum of 17.14 mm (0.6750 in.) after heat treatment. In contrast, only slight contraction of the outer bearing surface occurred. The gears, made of 8615H steel, were carburized at 915 °C (1675 °F) to a depth of 0.51 to 0.64 mm (0.020 to 0.025 in.), reheated to 840 °C (1540 °F), quenched in oil at 55 °C (130 °F), and then tempered at 190 °C (375 °F) to a surface hardness of 60 to 62 HRC.

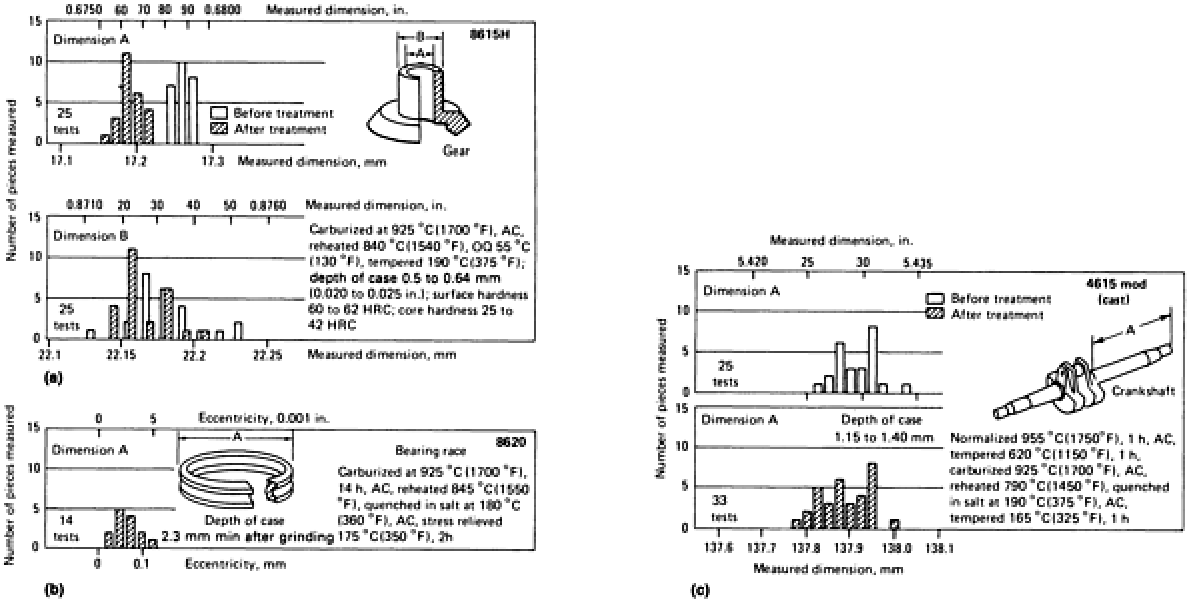

Fig. 13 Dimensional data relating selected low-alloy steel production parts before and after liquid carburizing and hardening. AC, air cooled; OQ, oil quenched

Example 2: Carburized, Quenched, and Stress Relieved 8620 Steel Gear with 61 to 63 HRC Surface Hardness.

The bearing race shown in Fig. 13(b) was subjected to more elaborate processing to minimize dimensional variations before and after carburizing. This 8620 steel forging was normalized and stress relieved prior to being carburized. After being rough ground, it was liquid carburized for 14 h at 925 °C (1700 °F) to produce a minimum case depth of 2.3 mm (0.090 in.). It was air cooled, reheated to 845 °C (1550 °F), and salt bath quenched at 180 °C (360 °F). After being cooled to room temperature, it was tempered for 2 h at 175 °C (350 °F). Final case hardness was 61 to 63 HRC; core hardness was 40 to 43 HRC.

To minimize distortion, which was excessive when these bearing races were wired, a fixture similar to that shown in Fig. 9(i) was used throughout the heat-treating cycle. As indicated by the dimensional data, the combination of fixturing and elaborate processing produced favorable results in terms of out-of-roundness and flatness. Dimensional discrepancy was held to 0.10 mm (0.004 in.) maximum, and in several instances, distortion was held to 0.025 mm (0.001 in.).

Example 3: Normalized, Tempered, Carburized, Quenched, and Retempered 4615 Modified Steel Crankshaft.

The crankshaft shown in Fig. 13(c), a shell-mold casting made of boron-modified 4615 steel, was initially normalized for 1 h at 955 °C (1750 °F) and then tempered for 1 h at 620 °C (1150 °F). After being machined, the part was liquid carburized at 925 °C (1700 °F) (case depth, 1.14 to 1.40 mm, or 0.045 to 0.055 in.), air cooled, reheated to 790 °C (1450 °F), quenched for 5 min in salt at 190 °C (375 °F), air cooled and tempered for 1 h at 165 °C (325 °F). The dimensional data, which apply to a length measurement at one end of the shaft only, indicate a high degree of dimensional stability with a slight tendency in the direction of shrinkage.

Quenching Media

Most conventional quenching media, including water, brine, caustic solution, oil, and molten salts, are suitable for quenching parts that have been liquid carburized. However, the suitability of each medium must be related to specific parts and depends primarily on the hardenability of the steel, surface and core hardness requirements, and the amount of allowable distortion.

Water and brine are the quenchants most commonly used for carbon steels. A water quench is usually maintained at 20 to 30 °C (70 to 90 °F) and agitated. Water helps to dissolve the film of carburizing salt and thus creates a localized brine that suppresses the vapor phase. With continuous use, salt concentration (chlorides, carbonates, and cyanides) increases, and fresh water must be added periodically to control the concentration of contaminants and maintain a desired temperature. Sodium chloride brine (5 to 10%) and caustic (3 to 5%) solutions are used to obtain more drastic quenching. The noncyanide liquid carburizing salt provides a brine-type quench when maintained around 10% concentration by water addition. The effectiveness of brine and caustic can be severely curtailed by an excessive accumulation of contaminants. When a caustic solution is used for quenching, care must be taken to ensure that racks, baskets, and fixtures are washed free from caustic and dried before being returned to the carburizing bath. Small amounts of caustic carried back to the bath will lower its cyanide content significantly.

A water-soluble polymer is sometimes used to modify the quenching rate of a water quench. However, such additives should be avoided in a quenchant used with a liquid carburizing line, unless frequent replacement or continuous salt removal by ultrafiltration can be employed. The polymers may be precipitated by salt carried into the quench, or salt buildup in the quench may render their effect variable. Either condition is undesirable.

Oil quenching is less drastic than water quenching and produces less distortion. It is often desirable to fortify the mineral oil with nonsaponifiable additives that increase its quenching effectiveness and lengthen its useful life. To minimize distortion, special oils are available that can be used at temperatures as high as 175 °C (350 °F). Normally, liquid carburized parts are quenched directly into agitated oil maintained with the range from 25 to 70 °C (80 to 160 °F).

Quenching oil should be kept free of moisture and should be agitated by propellers or impeller-type pumps. Compressed air should not be used for agitation. Because some salt will inevitably precipitate in the oil bath, periodic desludging is necessary. Screens should be placed in front of the lines leading to pumps to prevent entry of sludge.

Salt bath quenching in a nitrate-nitrite bath further minimizes distortion. Salt quench baths are compatible with cyanide as well as noncyanide liquid carburizing baths. *Caution: However, parts should never be transferred directly from a carburizing bath containing more than 5% cyanide to a nitrate-nitrite quench bath, because this will result in a violent reaction and may cause an explosion.* To avoid such reactions, immersion in a neutral salt bath (45 to 55% NaCl, 45 to 55% KCl) held at the desired temperature must precede quenching in a nitrate-nitrite bath. The neutral bath should be tested periodically for sodium cyanide content; it is general practice to limit cyanide content to a level of less than 5%. This level is never reached, as a rule, because of oxidation of the cyanide by oxygen in the air. The neutral stabilizing bath can be used alternatively for through hardening of carbon and alloy steels, provided that complete cyanide oxidation has not occurred.

Many liquid carburizing facilities case harden components at 925 to 955 °C (1700 to 1750 °F), and workpieces are then transferred directly to a neutral chloride salt at 845 °C (1550 °F) for stabilization and finally quenched directly into a marquenching oil at 175 to 260 °C (350 to 500 °F), depending on alloy and hardness requirements. Distortion of the workpieces is minimized when parts are air quenched after carburizing and then reheated prior to quenching.

All traces of nitrate should be removed from quenching fixtures before they are reimmersed in a carburizing bath. This can be accomplished by rinsing in hot water.

The buildup of high-temperature chlorides in a nitrate-nitrite bath impairs its quenching severity. It is desirable, therefore, to remove the chlorides as fast as they are being delivered. Various means of chloride removal are available, and the selection depends on furnace design. Where chloride is allowed to settle to the bottom of the quench area or an area provided for gravity separation, the chlorides can be collected in sludge pans; periodically, either the pans are removed or the bottoms of the pans are manually desludged. Some furnace designs employ continuous filtration of chlorides as the suspended crystals pass through filter baskets; the operator removes the baskets periodically to dump the collected chlorides and then returns the baskets to the furnace.

Maintenance of Quenching Baths. Although a limited amount of dissolved salt increases the efficiency of a water quench bath, amounts in excess of 10% retard the quenching rate. Controlled addition of fresh water to the bath, together with a continuous overflow, serves to keep salt concentration at an acceptably low level. It may be required that the overflow be chemically treated in a special reservoir prior to disposal in order to eliminate cyanide pollution (see the section "Disposal of Cyanide Wastes" in this article). For this reason, changing the water quench bath at scheduled intervals may be more convenient in small operations. For water tanks that are vigorously agitated, it is recommended that a false bottom--in the form of a perforated plate--be used to permit settling of heavier solids, which can be removed during periods of downtime.

Carryover of liquid carburizing salts into brine quench tanks actually helps maintain brine concentration. However, salt concentration should not exceed 10%. The same control of salt content applies to caustic tanks; concentration of caustic must be maintained by additions of sodium hydroxide to control the quench rate of the solution.

Some of the precautions that must be observed in the use of oil baths have already been discussed. It should be recognized that liquid carburizing salts do not dissolve in, or combine with, mineral quenching oils. Salt sludge must be removed periodically, either by mechanical means or by filtering through screens.

Proper maintenance of salt quench baths also requires sludging of contaminants. Use of separating chambers to collect these contaminants has already been discussed. Another technique involves continuous filtering out of higher-melting-point salts by pumping the contaminated quench salts through a filter maintained at a lower temperature. The contaminants are deposited on a wire-mesh basket, and the usable salts are returned to the quench tank.

Quenching Cyanided Parts. Cyanided steel parts are quenched in fast-quenching oils, water, or aqueous salt solutions. Selection of the quenchant depends on the composition of the steel, the required as-quenched hardness, and the shape of the workpiece.

Water or aqueous salt solutions should be as free as possible of dissolved gases, which may cause soft spots. For this reason, pumps or impellers should be used to agitate the quenching water or brine. Compressed air should not be used as the primary means of agitation; mechanical agitation is preferred.

For maximum hardness, the quenchant should be as cold as is feasible and should be well agitated. Typical quenchant temperatures range from room temperature to about 25 °C (75 °F) for plain water and up to about 50 °C (120 °F) for 5 to 10% aqueous salt solutions, including solutions of sodium chloride, sodium hydroxide, or proprietary salt mixtures that provide corrosion protection. Use of higher temperatures with water-based quenchants causes insufficient hardness or soft spots.

Quenching oils are commonly used at temperatures from 50 to 85 °C (120 to 185 °F). Only petroleum-base quenching oils should be used for quenching cyanided parts.

Salt Removal (Washing)

The ease or difficulty with which salt can be removed from liquid carburized parts depends primarily on how simply or intricately shaped the parts are and whether they were quenched in water or in oil. To some extent, removal of salt may be complicated by the presence of insoluble residues. Water-quenched parts of simple design and with no blind holes or deep recesses usually are easy to clean. They may be rinsed thoroughly in water at about 80 °C (180 °F) and then coated with a rust-preventive fluid or soluble oil. Parts that are rinsed free of cyanide by immersion in a chloride salt and then isothermally quenched in a nitrate-nitrite salt are easily cleaned by agitated hot-water washing and rinsing. It is also possible to reclaim the nitrate-nitrite salt from the wash water.

Oil-quenched parts are more difficult to clean because the oil must be removed before the salts can be dissolved. Some salts may be insoluble. Use of power washers with hot water or emulsion cleaners is effective. An economical cleaning procedure begins with soaking of parts in hot water to float off the oil and remove the soluble salts. The parts may then be transferred to a hot agitated dilute alkaline cleaner having high sequestering properties. (Silicated cleaners and those containing carbonates or phosphates are not recommended, because of the formation of insoluble barium compounds in the presence of barium-containing salts.) If a white, powdery overlay of barium carbonate remains on the parts, it may be removed--following removal of all cyanide--by immersion in a dilute solution of acetic or inhibited hydrochloric acid.

Complex parts with blind holes, recesses, and threads are difficult to clean, particularly if they have been oil quenched. Liquid carburizing of parts that contain blind holes for which the depth exceeds twice the diameter is not recommended unless such holes can be plugged. Agitated hot water or a steam jet is probably the best solvent for salt held in recesses, crevices, and blind holes. Normally, it will remove all soluble salts and will soften insoluble residues. When part shape and tolerances permit, tumbling for 10 to 30 min in a mild alkali and a small quantity of sand is most effective in removing insoluble surface residues.

Washing of Cyanided Parts. Cyanide-hardened parts are easy to wash, even after oil quenching, because cyanide and sodium carbonate are good detergents and because all the components of the salt bath are water soluble. The work may be soaked in a tank of agitated boiling water, rinsed in clean hot water, and then rustproofed (if required). Power spray washers, using hot water in a two-stage system, also give satisfactory results.

Typical Applications

The applicability of liquid carburizing is evidenced by the variety of parts listed in Tables 7 and 8, all of which were heat treated on a production basis. For ease of reference, the parts in Table 7 have been separated according to type of steel (carbon, resulfurized, or alloy), and the parts in each group have been arranged in alphabetical order. Tables 7 and 8 also provide details, wherever they were available, regarding case depth, carburizing temperature and cycle time, method of quenching, subsequent treatment, and surface hardness.

Table 7 Typical applications of liquid carburizing in cyanide baths

(c) Preheat at 840 °C (1545 °F); carburize at 920 °C (1690 °F)

The parts listed in Table 7 were carburized in cyanide-type baths. Noncyanide carburizing baths can be used with slight adjustments in operating conditions to do much of the carburizing described in Table 8. Noncyanide carburizing is particularly applicable to parts treated at temperatures above 900 °C (1650 °F). Some specific applications for noncyanide liquid carburizing of production parts are listed in Table 8.

In general, liquid carburizing is best suited to small and medium-size parts. Very large parts, such as rock-bit drill rods 6 m (20 ft) long and rings 2 m (7 ft) in diameter, are too large to be conveniently processed in salt and are commonly carburized by pack methods. Because of the problems associated with salt removal, carburizing in salt baths is not recommended for parts containing small holes, threads, or recessed areas that are difficult to clean.

Stop-Offs and Selective Carburizing

Selective carburizing can be accomplished in liquid carburizing baths by stopping off carbon penetration with either copper plate or copper-base paint. Because cyanide-base salts can dissolve copper, salt baths with relatively low cyanide contents are necessary. One successful formulation operates at 8 to 10% NaCN with approximately 45% $BaCl_2$ energizer. Noncyanide carburizing salts will not dissolve copper.

When copper plate is employed to prevent carbon penetration, the copper layer should be fine-grained, dense, and without pinholes or other porosity. Smooth surfaces require lower plating thicknesses than do rough surfaces. Copper-plate thicknesses recommended for protection against liquid carburizing for various times are as follows:

Time, h	Copper plate thickness	
	mm	in.
Low-temperature salts		
<1	0.013	0.0005
1-5	0.020	0.0008
High-temperature salts		
<7	0.025	0.0010
7-15	0.040	0.0015

Partial Immersion. Another method for selective carburizing in liquid carburizing baths entails partial immersion of the workpiece in the salt bath so that only the immersed areas are carburized. With this method, unless a clean-cut breakoff between carburized and noncarburized areas is required, the use of copper plate or copper-base paint is unnecessary.

Oxidation of the work at the bath surface can be reduced if the parts are initially immersed an inch or two deeper than required, to coat them with salt, and are then withdrawn to the required depth. A piece of plain carbon steel pipe with the bottom closed by welding can be inserted in a corner of the bath to displace salt if a precise adjustment of the bath level is necessary. Typical parts that are well suited to carburizing by the partial-immersion technique are shown in Fig. 14.

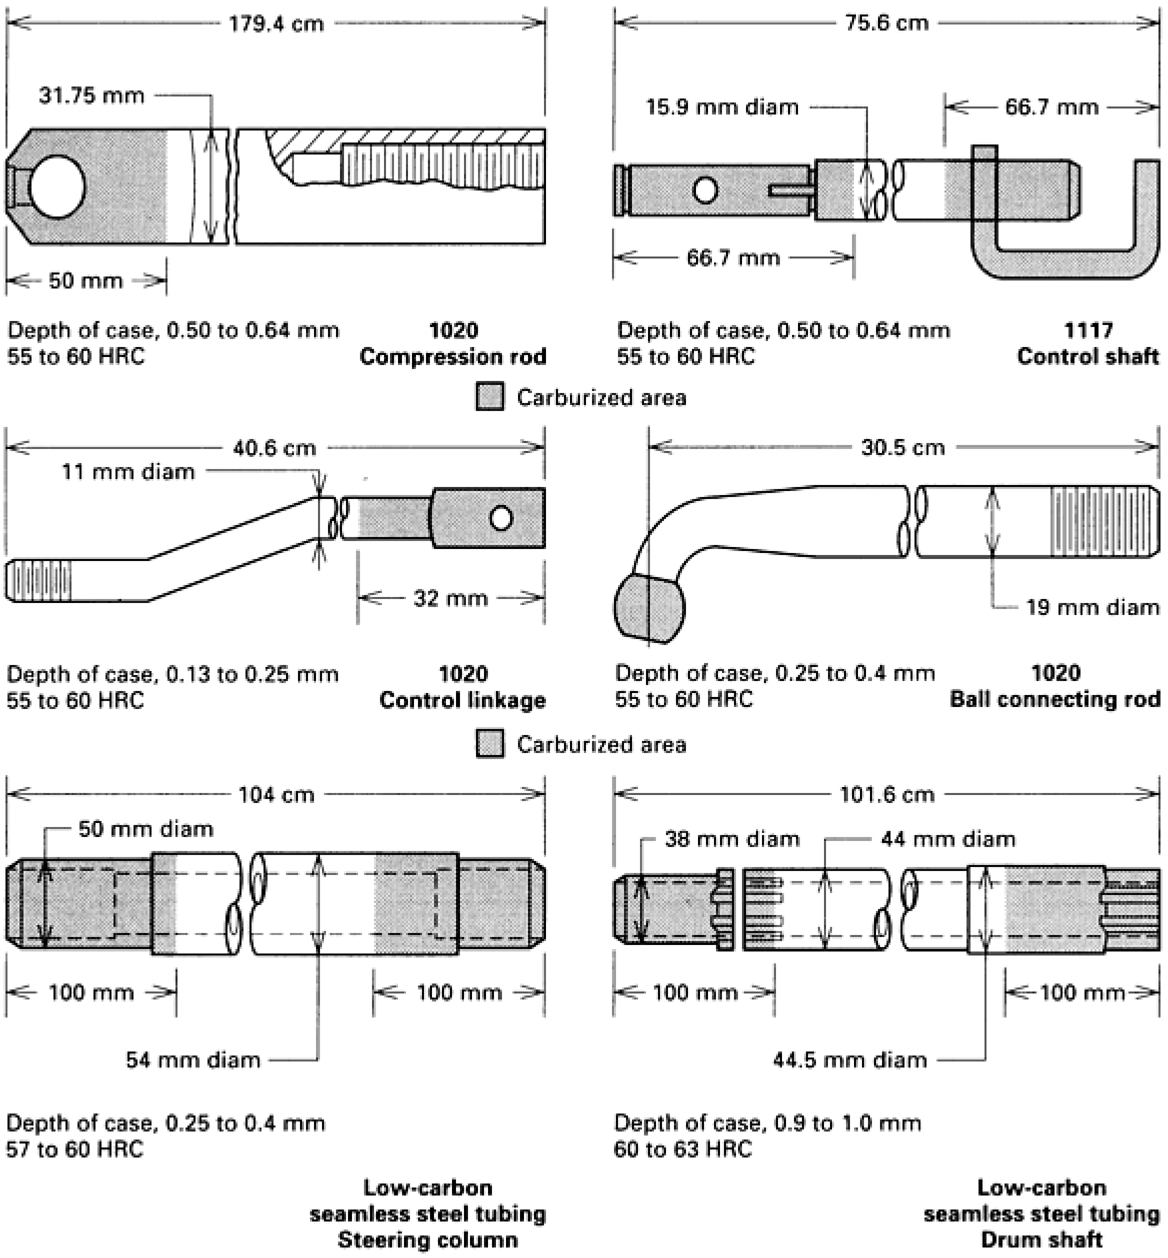

Fig. 14 Typical parts selectively carburized by partial immersion. Only the portion that is to be carburized is immersed in the bath. Area to be carburized is shaded.

Combined Carburizing and Brazing

It is possible to braze and carburize steel parts simultaneously in either a cyanide or a noncyanide liquid carburizing bath, provided that the operating temperature of the bath is high enough to cause the brazing alloy to flow. Initially, the parts are cleaned and degreased and then the components are assembled with brazing alloy enclosed in the joints. One suitable brazing alloy, in the form of wire or thin strip, contains 55% Cu and 45% Zn, melts at 880 °C (1620 °F), and makes a sound joint at 900 to 925 °C (1650 to 1700 °F). No flux is required.

The assembly is immersed in the liquid carburizing bath for a time long enough to produce the desired case depth and at a temperature high enough to cause the brazing alloy to flow. It is then quenched to harden the steel and complete the braze. Press-fit assemblies with carefully designed lap joints are ideal for this application.

Precautions in the Use of Cyanide Salts

Cyanides cause violently poisonous reactions if allowed to come into contact with scratches or wounds (on the hands, for example); they are fatal if taken internally. Also, fatally poisonous fumes are evolved when cyanides are brought into contact with acids. The white deposits that form on hoods and cooler furnace parts consist mainly of sublimed sodium carbonate, with small amounts of sodium, potassium, and barium salts, but may contain some cyanide as the result of splashing.

When cyanide salts are removed from the storage container, the container should be opened in the room in which the cyanide is to be used. The salts should be removed from the container with a metal scoop or gloved hands, or by being dumped out as required. When not in use, the container should be covered with its original cover or with a metal substitute cover.

The precautions that should be observed in handling cyanide-type carburizing salts are the same as for any other cyanide mixture. Work material must be clean and dry, and the bath must be enclosed and well ventilated. Even the slight amount of moisture that may be deposited on parts and fixtures as a result of atmospheric humidity will cause spatter in contact with molten salt. Accordingly, operators should be equipped with long protective gloves, protective aprons, and safety glasses or face shields. When adequate precautions are observed, carburizing salts should not present serious hazards to health or safety.

Remelting a frozen cyanide bath in externally heated furnaces can be potentially hazardous because of the expansion of the salt and gases as the salts are heated. This hazard is not encountered with immersed-electrode furnaces because the salts melt from the top down. If remelting is done in externally heated furnaces, however, the following precaution should be observed: a steel or cast iron wedge should be inserted in the center of the bath before the bath freezes. One end of the wedge should make contact with the bottom of the pot; the other end should extend at least 10 cm (4 in.) above the surface of the bath. Before the bath is remelted, the wedge should be tapped with a hammer, loosened and removed. The space previously occupied by the wedge will provide a vent for expanding salt and gases during remelting. No attempt should be made to remove a wedge from a bath that is not completely solidified, because molten salt may be forcibly blown out through the opening created.

Disposal of Cyanide Wastes

Cyanide wastes, whether dissolved in quench water or in the form of solid salt from pots, pose a serious disposal problem. The cyanide contents of these wastes must be chemically altered to render the material nonpoisonous before it is discharged into sewers or streams. Because of the toxicity of cyanide wastes, local ordinances and pollution authorities should be consulted regarding the proper disposal of wastes.

Chemical Treatment. The simplest treatment consists of oxidizing the cyanide in an alkaline solution to which is added either chlorine gas or its equivalent in the form of a hypochlorite compound, such as sodium or calcium hypochlorite (bleaching powder). The choice between gas or powder depends on the quantity of cyanide to be treated, on the availability of facilities and experienced personnel for handling the oxidizing agents, and on economics. For small quantities of cyanide solutions, it may be more practical to use a hypochlorite compound than to use chlorine gas.

Depending on the oxidizing agent employed, several reactions take place when cyanide is converted into a disposable form. One reaction with chlorine gas is as follows:

$$2NaCN + 4NaOH + 2Cl_2 + 2H_2O \rightarrow (NH_4)_2CO_3 + Na_2CO_3 + 4NaCl \quad \textbf{(Eq 18)}$$

This reaction indicates that, for each kilogram (2.2 lb) of sodium cyanide, 1.42 kg (3.13 lb) of chlorine gas and 1.6 kg (3.5 lb) of sodium hydroxide are required. Because of probable side reactions, however, practical experience indicates an actual requirement of slightly more than 2 kg (4.4 lb) of chlorine for each kilogram of sodium cyanide present in the waste solution. When a hypochlorite compound is used, the amount of powder required may be estimated on the basis of available chlorine content in the compound.

Solid cyanide wastes must be dissolved in water before they can be treated. A tank of suitable capacity, equipped with a coarse screen set well above the bottom, will facilitate solution of the solid material. The tank should also have an agitator, and, for chlorine gas, a perforated pipe placed well below the solution level is required.

When cyanide wastes are to be treated with chlorine gas, the cyanide content must first be determined and the proper amount of caustic added. The gas is then introduced slowly while the temperature of the solution is kept below 50 °C (120 °F). If a sodium hypochlorite solution is used, sufficient caustic should be added to raise the pH of the cyanide solution above 8.5. The reaction between cyanide and the oxidizing agent should continue until a slight excess of chlorine is present in the solution. This can be determined by testing with starch iodide paper or with a solution of potassium iodide and starch. Both the iodide paper and starch solution will turn blue in the presence of free chlorine.

Electrochemical Treatment. Although chemical treatment may be entirely adequate to meet local regulations, a recently developed electrochemical process destroys free cyanide with efficiency and economy superior to those of the chemical conversion processes. In the electrochemical process, cyanide wastes in aqueous solution are circulated through an electrochemical reactor. Within the reactor, an applied direct current potential oxidizes the free cyanide and cyanate according to the reactions:

$$2CN^- + 8OH^- \rightarrow 2CO_2 + N_2 + 4H_2O + 10e^- \quad \textbf{(Eq 19)}$$

$$2CNO^- + 4OH^- \rightarrow 2CO_2 + N_2 + 2H_2O + 6e^- \quad \textbf{(Eq 20)}$$

Free cyanide and cyanate are converted to the nontoxic gases carbon dioxide and nitrogen, which are allowed to escape freely from the vented storage tank into which the reacted solution is circulated.

The electrochemical process is most effective at high cyanide-ion concentrations. With continual recirculation between storage tank and reactor, cyanide can be reduced to 1 ppm or less in about 100 to 150 h. By combining electrochemical and chemical treatments, effective treatment can usually be achieved at minimum cost. Electrochemical removal is used to reduce cyanide concentration to ≈200 to 500 ppm, and then chemical treatment is used to complete the reduction.

Electrochemical treatment offers the following advantages:

- The process uses only electricity--no chemicals are required
- Cost per unit weight of cyanide treated is low, depending only on the cost of electricity (about 6.6 kW · h/kg, or 3 kW · h/lb of free CN^-)
- Capital investment is higher than alkaline chlorination
- The process is simple to control, requiring only periodic determination of cyanide concentration
- There are no toxic or otherwise harmful reaction products
- Upon reaching a concentration of 1 ppm cyanide, the oxidized effluent usually may be drained and further diluted by plant effluent
- The process can also be used to convert nitrite into nitrate

The only significant disadvantage is that the process is time-consuming when levels of cyanide below 200 ppm must be achieved. Increasing the number of reactors decreases process times.

Safety and Disposal of Noncyanide Carburizing Salts

Noncyanide carburizing salts are safe to dispose of directly in municipal or natural water if first diluted to acceptable dissolved-solids levels. There are no significant chemical hazards in the use of these salts. They are somewhat alkaline and should be washed from the skin or eyes if contact is made. When they are used as molten salts, the usual precautions apply: avoid introduction of moisture into the bath and prevent the hot salt from contacting the body.

Further information is available from Occupational Safety and Health Administration (OSHA) and Environmental Protection Agency (EPA) publications.

Vacuum Carburizing of Steels

Jeremy St. Pierre, C.I. Hayes, Inc.

Introduction

VACUUM CARBURIZING is a non-equilibrium, boost-diffusion-type carburizing process in which the steel being processed is austenitized in a rough vacuum, carburized in a partial pressure of hydrocarbon gas, diffused in a rough vacuum, and then quenched in either oil or gas. Compared to conventional atmosphere carburizing (see the articles "Gas Carburizing" and "Pack Carburizing" in this Volume), vacuum carburizing offers excellent uniformity and repeatability because of the high degree of process control possible with vacuum furnaces, improved mechanical properties due to the lack of intergranular oxidation, and potentially reduced cycle times particularly when the higher process temperatures possible with vacuum furnaces are used.

Process Overview

Vacuum carburizing a steel is typically a four-step process:

- Heat and soak step at carburizing temperature to ensure temperature uniformity throughout steel
- Boost step to increase carbon content of austenite
- Diffusion step to provide gradual case/core transition
- Oil-quenching step. In addition, a reheat step prior to quenching may also be necessary for grain refinement

Heat and Soak Step. The first step is to heat the steel being carburized to the desired carburizing temperature, typically in the range of 845 to 1040 °C (1550 to 1900 °F), and to soak at the carburizing temperature only long enough to ensure that the steel is uniformly at temperature. Oversoaking, particularly above 925 °C (1700 °F), can result in a reduction in toughness due to grain growth.

During the first step, surface oxidation must be prevented, and any surface oxides present must be reduced. In a graphite-lined heating chamber consisting of graphite heating elements, a rough vacuum in the range of 13 to 40 Pa (0.1 to 0.3 torr) is usually satisfactory. In a ceramic-lined heating chamber with silicon carbide heating elements, a partial pressure of approximately 40 to 67 Pa (0.3 to 0.5 torr) of hydrogen is effective. Steels with a high chromium content (M-50 NiL, X-2 Modified), a high silicon content (Pyrowear Alloy 53), or other high-oxygen affinity alloying elements usually require a higher vacuum level prior to carburizing but do not normally require preoxidizing.

Boost Step. Second is the boost step of the process. This step results in carbon absorption by the austenite to the limit of carbon solubility in austenite at the process temperature for the steel being carburized. The boost step is achieved by backfilling the vacuum chamber to a partial pressure with either a pure hydrocarbon gas (for example, methane, propane) or a mixture of hydrocarbon gases. Ammonia can be added if nitrogen alloying of the case is desired. An inert gas such as nitrogen can also be added to the gas or gas mixture.

Carbon transfer occurs by dissociation of the hydrocarbon gas on the surface of the steel with direct absorption of the carbon by the austenite and hydrogen gas being liberated. The reactions with methane and propane are:

$$CH_4 + Fe = Fe(C) + 2H_2 \quad \textbf{(Eq 1)}$$

$$C_3H_8 + 3Fe = 3Fe(C) + 4H_2 \quad \textbf{(Eq 2)}$$

At typical carburizing temperatures these reactions proceed rapidly from left to right of the given equations. Because these reactions are difficult to measure *in situ,* they cannot be used to control carbon potential when vacuum carburizing. Because there is no oxygen present, the oxygen-based methods of carbon-potential control used in conventional atmosphere carburizing cannot be used either (see the article "Control of Surface Carbon Content in Heat Treating of

Steel" in this Volume). However, at least one furnace manufacturer has reportedly designed a system for vacuum carburizing that measures and controls the carbon potential of the carburizing gas.

A minimum partial pressure of hydrocarbon gas is required to ensure rapid carburizing of the austenite. The minimum partial pressure required varies with the carburizing temperature, the carburizing gas composition, and the furnace construction. Above the minimum partial pressure, the partial pressure of carburizing gas used has no relationship to the carburizing potential of the atmosphere. Typical partial pressures vary between 1.3 and 6.6 kPa (10 and 50 torr) in furnaces of graphite construction and 13 kPa and 25 kPa (100 and 200 torr) in furnaces of ceramic construction. Partial pressures in excess of 40 kPa (300 torr) are not normally recommended because of the excessive carbon deposition within the furnace that accompanies higher partial pressures.

Diffusion Step. Third in the process is the diffusion step. If a steel were hardened with the carbon gradient resulting from the boost step only, particularly if no means of carbon-potential control were employed during the boost step, an undesirable microstructure adjacent to the carburized surface and an extremely abrupt case/core interface would result. The diffusion step enables the diffusion of carbon inward from the carburized surface, resulting in a lower surface carbon content (relative to the limit of carbon solubility in austenite at the carburizing temperature) and a more gradual case/core transition. The diffusion step is usually performed in a rough vacuum of 67 to 135 Pa (0.5 to 1.0 torr) at the same temperature used for carburizing. If carbon-potential control was used during the boost step, the diffusion segment might be shortened or eliminated.

Oil-Quenching Step. The fourth step of the process is quenching. If a reheat step is not going to be employed, and/or no further machining is required, the steel is directly quenched in oil, usually under a partial pressure of nitrogen.

When vacuum carburizing is performed at a higher temperature than is normally used with conventional atmosphere carburizing, cooling to a lower temperature and stabilizing at that temperature prior to quenching is usually required. Alternatively, if a reheat step is going to be employed for grain refinement, and/or further machining is required, the steel is gas quenched from the diffusion temperature to room temperature, usually under a partial pressure of nitrogen.

Reheating usually consists of austenitizing in the 790 to 845 °C (1450 to 1550 °F) range followed by oil quenching. When air-craft-quality gearing or bearings are being processed, reheating is usually preceded by a subcritical anneal. In some cases it is possible to gas pressure quench following carburizing, but this requires a high-performance gas pressure-quench system, light loads, thin sections, and moderate to high alloying. Interest in gas pressure quenching of carburized gearing is increasing, particularly with distortion-prone geometries. A diagram of temperature and pressure versus time for a typical vacuum-carburizing cycle with a reheat cycle is shown in Fig. 1.

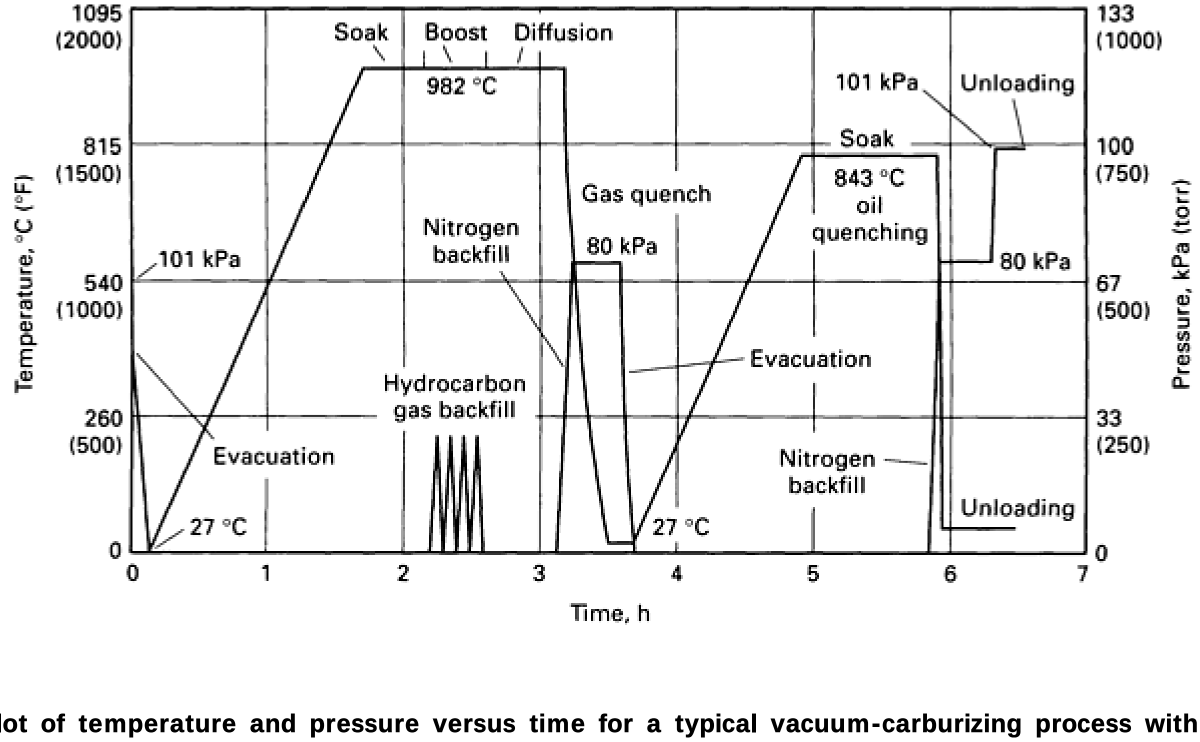

Fig. 1 Plot of temperature and pressure versus time for a typical vacuum-carburizing process with a reheat

cycle

Furnace Design. Vacuum carburizing is usually performed in a furnace specifically designed for this application, with or without oil and/or gas-quenching capability and modified with the controls and plumbing required for vacuum carburizing. The furnace can be of either graphite construction (graphite insulation and heating elements) or ceramic construction (refractory board insulation and silicon carbide heating elements). Graphite construction permits higher operating temperatures useful for a multipurpose furnace, whereas ceramic construction is well suited for vacuum carburizing because it can be safely operated in air at process temperatures for die quenching or for facilitating soot removal. Figure 2 shows a typical continuous ceramic construction vacuum-carburizing furnace. Figure 3 shows a typical batch graphite construction vacuum furnace with carburizing capability.

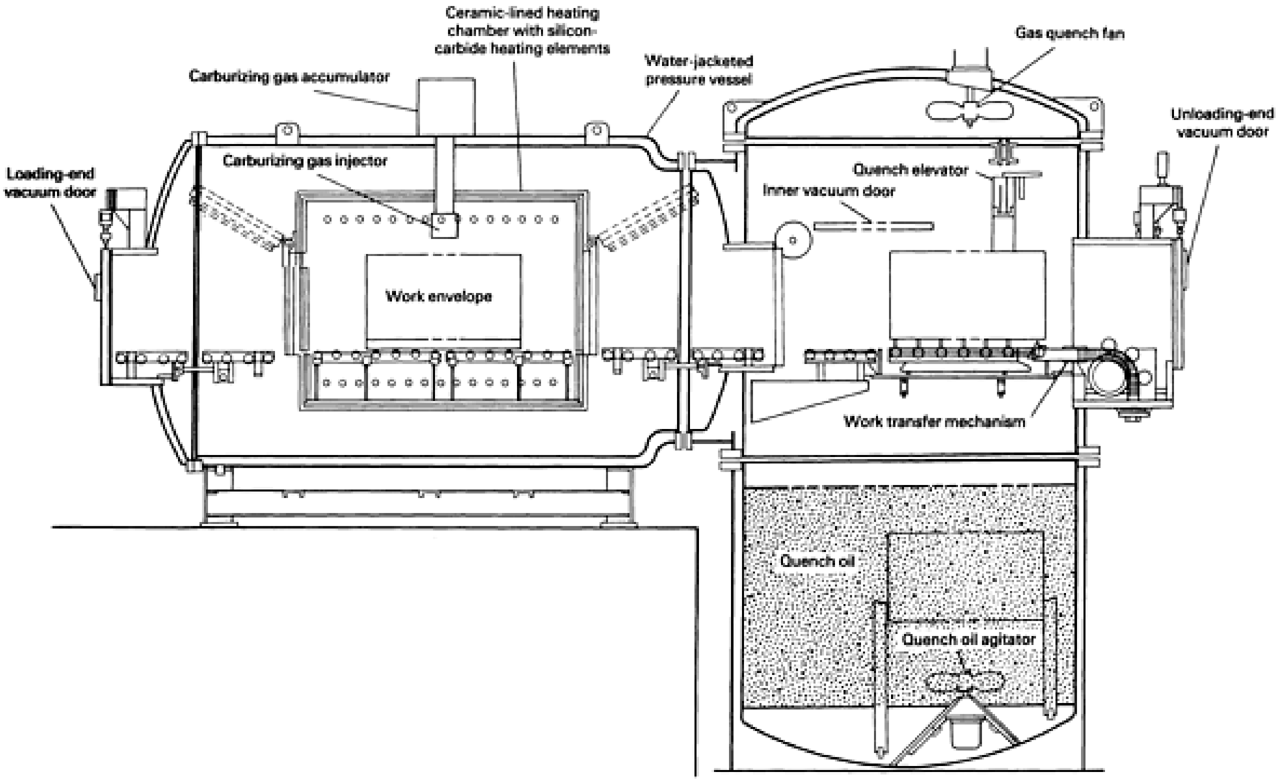

Fig. 2 A continuous ceramic vacuum-carburizing furnace

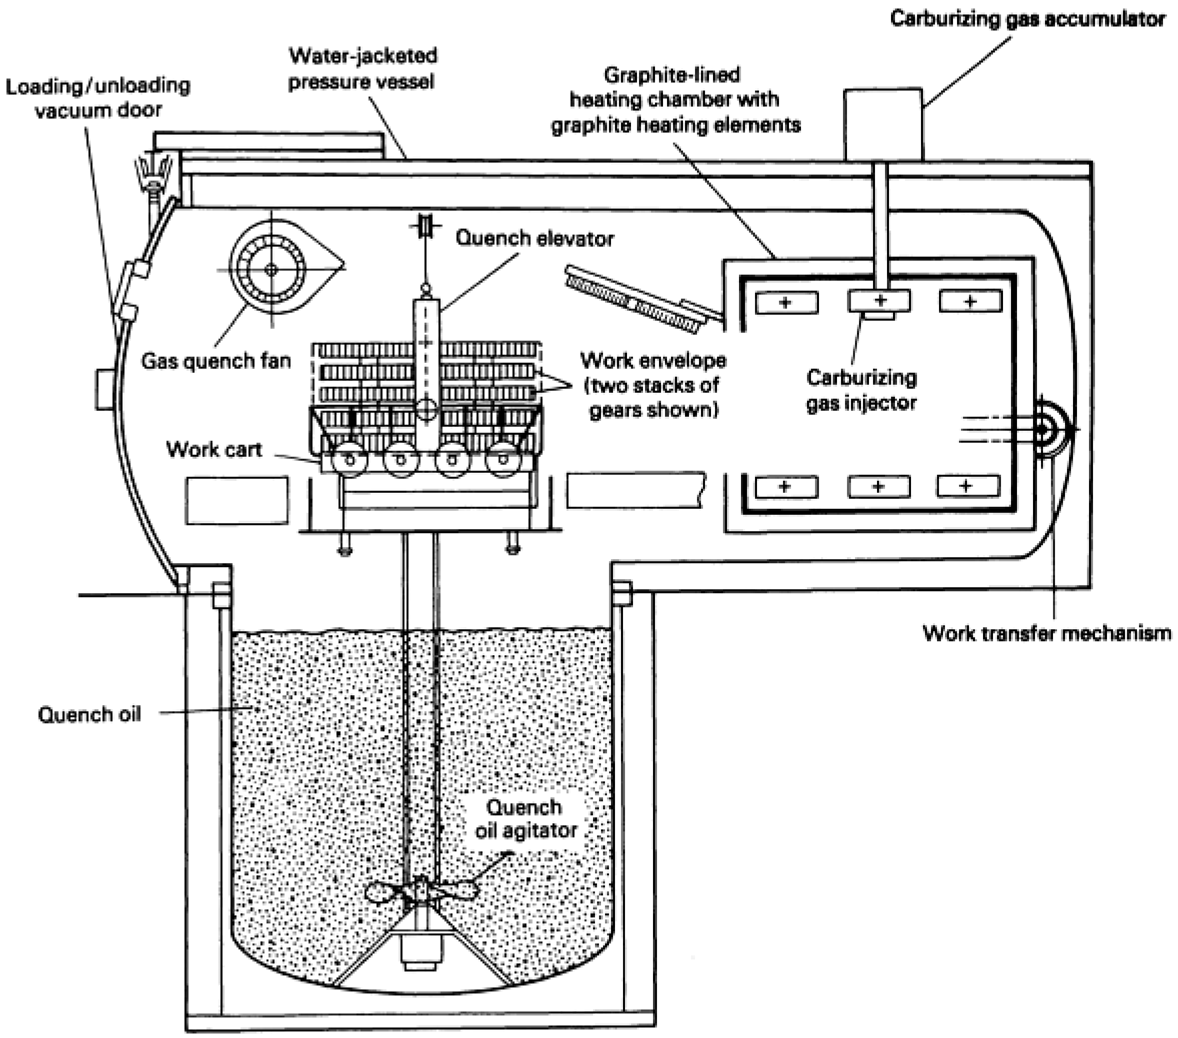

Fig. 3 A batch-graphite integral oil-quench vacuum furnace with vacuum-carburizing capability

Carbon Gradient and Case Depth Prediction

One approach for predicting the carbon gradient in a steel is to use a computer model to calculate the surface carbon content and the carbon profile. In the boost step of the process, the surface carbon content is usually increased to the limit of solubility of carbon in austenite at the process temperature. The surface carbon content and carbon profile resulting from the boost step can be predicted using diffusion theory. In the diffusion step, the carbon diffuses away from the surface. Because carbon is not gained or lost at the surface during the diffusion step, the final surface carbon content and carbon profile are also readily predicted using the same diffusion model. Accurate carbon-diffusivity data for the steel being processed are required if this approach is to produce a meaningful prediction. This approach can be further enhanced using a continuous cooling transformation (CCT) diagram calculated from the composition of the steel and quench rate data to predict case and core microstructures, hardness profile, and residual stress distribution. One major aircraft engine manufacturer is working on such a model for vacuum carburizing.

One method of simply and accurately predicting effective case depths is to use the following equations:

$$D = k\sqrt{t} \quad \textbf{(Eq 3)}$$

$$c = rt \quad \textbf{(Eq 4)}$$

$$t = c + d \quad \textbf{(Eq 5)}$$

where D is the effective case depth required, k is a carburizing constant for a specific carburizing temperature, t is the total time (that is, carburizing time plus diffusion time), c is the carburizing time, r is the boost/diffusion ratio, and d is the diffusion time.

Knowing the effective case depth required and the value of k for the material at the carburizing temperature to be used, Eq 3 can be solved for t or the total time. Knowing the value of r for the surface carbon content desired, also dependent on the carburizing temperature, Eq 4 can be solved for c or for the carburizing time. With t and c known, d or the diffusion time can be calculated using Eq 5. This method has been found to be accurate and repeatable as long as the case depth used to calculate k is accurately measured, the temperature control is accurate, and the actual carburizing and diffusion times used to produce the case depth/surface content from which k and r were determined are known. See Table 1 for typical carburizing constants and boost/diffusion ratios to obtain a surface carbon content of 0.8 to 0.9% with a low-alloy, low-carbon steel.

Table 1 Typical carburizing constants and boost/diffusion ratios needed to obtain a 0.8 to 0.9% surface carbon content in a low-alloy, low-carbon steel

Temperature		Carburizing constant		Boost/diffusion ratio, *r*
°C	°F	$k^{(a)}$	$k^{(b)}$	
840	1550	0.25	0.010	0.75
870	1600	0.33	0.013	0.65
900	1650	0.41	0.016	0.55
925	1700	0.51	0.020	0.50
950	1750	0.64	0.025	0.45
980	1800	0.76	0.030	0.40
1010	1850	0.89	0.035	0.35
1040	1900	1.02	0.040	0.30

(a) To obtain effective case depth (50 HRC hardness), D, in millimeters when $D = k\sqrt{t}$ and t is in hours.

(b) To obtain effective case depth (50 HRC hardness). D, in inches when $D = k\sqrt{t}$ and t is in hours

The two examples that follow demonstrate typical applications of Eq 3, 4, and 5.

Example 1: Workpiece Specifications Require an Effective Case Depth of 0.38 mm (0.015 in.) with a Nominal Surface Carbon Content of 0.85%.

The desired carburizing temperature is 845 °C (1550 °F). Using Table 1, *k* is 0.25 (0.010), and *r* is 0.75. Solving Eq 3 for *t* gives 2.3 h or 138 min total time. Solving Eq 4 and Eq 5 for *c* and *d* gives 104 min carburizing time and 34 min diffusion time.

Example 2: Workpiece Specifications Require an Effective Case Depth of 1.5 mm (0.060 in.) with a Nominal Surface Carbon Content of 0.85%.

The carburizing temperature to be used is undecided, therefore, carburizing temperatures of 925 °C (1700 °F) followed by cooling to a lower temperature and direct quenching, and 1040 °C (1900 °F) followed by reheating and oil quenching will be evaluated. Using Table 1, *k* at 925 °C (1700 °F) is 0.51 (0.020). At 1040 °C (1900 °F), *k* is 1.02 (0.040). Solving Eq 3 for *t* gives 8.7 h total time at 925 °C (1700 °F) and 2.2 h total time at 1040 °C (1900 °F). Therefore, carburizing at 1040 °C (1900 °F) will save 6.7 h; however, a reheat cycle will be required. If a reheat cycle is less than 6.7 h, a time savings may be possible by carburizing at the higher temperature.

Carburizing Gas Circulation

To obtain uniform case depths when vacuum carburizing, there are two principle requirements:

- Temperature uniformity of ±8 °C (15 °F) or better
- Uniform carburizing gas circulation

Pulse/Pump Systems. Effective at obtaining uniformity and minimizing gas consumption is the pulse/pump method, which is a method of gas circulation that has two stages. The first, or pulse, stage consists of repeatedly accumulating a small charge of carburizing gas external to the furnace and then releasing, or pulsing, the charge of gas into the heating chamber through an injector. This pulsing is repeated until the partial pressure setpoint is achieved. At this point, the spent carburizing gas is evacuated, or pumped. The cycle continues, alternately pulsing and pumping for the duration of the boost stage of the process. The principle operating variables of the method are accumulator pressure, release frequency, evacuation time, and carburizing gas partial pressure.

The advantage of the pulse/pump method is that effective gas circulation may be achieved at low partial pressures using relatively simple components. Methods using either hot (in the heating chamber) or cold (external to the heating chamber) gas fans require partial pressures of at least 40 kPa (300 torr) to be effective. With increased partial pressures of carburizing gas, heat losses increase and there tends to be greater soot deposition. Additionally, because of the environment in which the fans operate, they tend to require constant maintenance.

High-Temperature Vacuum Carburizing

The reduction in carburizing time associated with a higher carburizing temperature has long been appreciated. However, typical atmosphere furnace construction generally restricts the maximum carburizing temperature to approximately 955 °C (1750 °F). The higher temperature capability of vacuum furnaces, as compared to typical atmosphere furnaces, permits the use of higher carburizing temperatures with correspondingly reduced cycle times.

High-temperature vacuum carburizing can significantly reduce the overall cycle time required to obtain effective case depths in excess of 0.9 to 1.0 mm (0.035 to 0.040 in.). For obtaining smaller case depths, high-temperature vacuum carburizing does not offer any advantages because a grain refining step is required and the boost times tend to be too short for acceptable uniformity. Table 2 compares the time required to obtain 0.9 mm (0.035 in.) and 1.0 mm (0.050 in.) effective case depths via vacuum carburizing at both 900 °C (1650 °F) and 1040 °C (1900 °F) for an AISI 8620 steel. As is apparent from Table 2, significant reductions in the total cycle time can be obtained by using high-temperature vacuum carburizing.

Table 2 Comparison of time required to obtain a 0.9 mm (0.035 in.) and 1.3 mm (0.050 in.) effective case depth in an AISI 8620 steel at carburizing temperatures of 900 °C (1650 °F) and 1040 °C (1900 °F)

Effective depth	Carburizing temperature	Time, min

mm	in.	°C	°F	Heating to carburizing temperature	Soaking prior to carburizing	Boost	Diffusion	Gas quench to 540 °C (1000 °F)	Reheat to 845 °C (1550 °F)	Soak at 845 °C (1550 °F)	Oil quench	Total
0.9	0.035	900	1650	78	45	101	83	(a)	(a)	(a)	15	>322
		1040	1900	90	30	15	23	20	22	60	15	275
1.3	0.050	900	1650	78	45	206	169	(a)	(a)	(a)	15	>513
		1040	1900	90	30	31	46	20	22	60	15	314

(a) Not available

Metallurgists not familiar with high-temperature vacuum carburizing are often concerned that although reduced cycle times can be obtained by high-temperature carburizing, a degraded microstructure with reduced mechanical properties results. There is no evidence that any reduction in either monotonic or cyclic mechanical properties results from high-temperature vacuum carburizing, provided that the process is properly specified and controlled. One aircraft-quality gearing user has performed extensive work in the area of high-temperature vacuum carburizing and concluded that there is no loss of properties when either AISI 9310 or X-2 Modified are high-temperature vacuum carburized to aircraft-quality gearing process specifications.

There is also concern that the high process temperatures involved will result in excessive distortion and size change. Although it is true that some geometries are sensitive to the ultimate process temperature used, distortion can be minimized by using proper preheating/heating techniques, minimizing times at temperature, proper fixturing, and quenching techniques that are only severe enough to result in the desired microstructure and do not develop excessive nonuniform stresses within the part. Gas pressure quenching holds a lot of promise in this area, particularly with the new moderate- to high-alloy grades of carburizing steels being developed. As far as any dimensional change greater than normal is concerned, the uniformity and repeatability of the vacuum-carburizing process, even at elevated temperatures, allows for dimensional change during manufacturing planning.

Future Outlook

Vacuum carburizing is a sophisticated and powerful carburizing process. When it is properly specified in well-controlled and maintained furnaces, the process offers excellent uniformity throughout the load and good lot-to-lot repeatability--typically better than can be achieved with conventional atmosphere-carburizing methods. The excellent uniformity and repeatability of the process are well recognized in the quality gearing and bearing fields where the process enables less grinding stock to be left on surfaces that require finish grinding to size and/or closer tolerances on those surfaces that are used as heat treated.

Because of the precision with which process variables can be controlled and the tremendous flexibility of vacuum furnaces, vacuum carburizing is well suited to processing both the new, more highly alloyed, high-performance grades of carburizing steels and the current, moderately alloyed grades used commercially. Coupled with the rapidly developing field of gas pressure quenching, tremendous opportunities in higher-performance, low-distortion gearing can be realized with the process.

Vacuum carburizing offers advantages not only in manufacturing planning/process control and engineering, but also in manufacturing. Cycle times can be reduced, particularly if even slightly higher carburizing temperatures are used. Preheating and post-carburizing heat treatment can also be performed in a vacuum, resulting in very clean parts that do not require the postcleaning associated with conventional atmosphere carburizing. The equipment can be started and shut

down quickly using utilities only when the furnace is actually processing work, resulting in significant utilities savings. Heat and exhaust from vacuum-carburizing furnaces are much less than those emitted with conventional atmosphere-carburizing methods. Therefore, the furnace can be located adjacent to other machine tools in a comfortable working environment. Other high-temperature processes, such as brazing, can be performed in the same furnace (depending on furnace construction) and possibly can be combined to reduce cycle time along with the need to heat, cool, and handle the work twice.

Plasma (Ion) Carburizing of Steels

William L. Grube, General Motors Research Laboratories (Retired); Steven Verhoff, Surface Combustion, Inc.

Introduction

IN DIFFUSION PROCESSES involving the migration of interstitial elements through metals (as in the carburizing of steels), the rate of diffusion is influenced by temperature and the atomic concentration of the migrating species at the surface. The concentration of migrating species at the surface is further determined by the supply of species at the surface and their ease in entering the surface. The importance of these three factors (temperature, surface reactions, and species supply at the surface) on diffusion rates depends on the particular process.

Carburizing methods (be it pack, gas, vacuum, or a plasma technique) are seldom limited by iron-carbon reactions and the temperature dependence of diffusion, because carburizing requires austenitizing temperatures (which not only improve diffusion rates but also improve surface rates by the high solubility of carbon in austenite). Rather, the rate at which carburizing can proceed is more often limited by the rate at which active carbon can be generated and brought to the surface of the steel. Thus, the search for means to increase carburizing rates has centered on methods designed to overcome this limitation.

One method of increasing carburizing rates involves the use of plasma (ion) carburizing, which is basically a vacuum process utilizing glow-discharge technology to introduce carbon-bearing ions to the surface of steel for subsequent diffusion below the surface. Plasma carburizing is effective in increasing carburizing rates because the process effectively bypasses several steps in the dissociation process that produces active soluble carbon. With methane (CH_4) gas, for example, active carbon for adsorption can be formed directly from methane due to the ionizing effect of the plasma. Plasma carburizing thus allows higher process rates than conventional gas carburizing, which involves several reaction steps in the dissociation of methane into active carbon (see "Dissociation of Methane to Carbon in Gas and Plasma Carburizing" in this article).

Another possible advantage compared to gas carburizing in some applications of plasma carburizing is that higher temperatures are permissible, because the process is performed in an oxygen-free vacuum. This advantage is similar to the process of vacuum carburizing (described in the previous article in this Volume). However, vacuum carburizing exhibits some potential disadvantages when compared to plasma carburizing. Because vacuum carburizing is conducted at very low pressures, and the rate of flow of the carburizing gas into the furnace is very low, the carbon potential of the gas in deep recesses and blind-holes is quickly depleted. Unless this gas is replenished in these areas, a great nonuniformity in case depth over the surface of the part is likely to occur. If, in an effort to overcome this problem, the gas pressure is increased significantly, another problem arises, namely, free-carbon formation or sooting. Thus, in order to obtain cases of reasonably uniform depth over a part of complex shape, the gas pressure must be periodically increased to replenish the depleted atmosphere in recesses, and then reduced again to the operating pressure. Clearly, a delicate balance exists in vacuum carburizing where the process conditions must be adjusted to obtain the best compromise between case uniformity, risk of sooting, and carburizing rate. Plasma carburizing overcomes both of these major problems, yet retains the desirable features of a simple atmosphere and a higher permissible operating temperature.

General Process Characteristics

Physical Properties of Glow-Discharge Plasma. A plasma is an electrically generated "gaseous" mixture consisting of positively and negatively charged particles as well as neutral species. Although gaseous in nature, it has a cohesive and stable form with a net electrical charge of zero. Plasmas occur in many places throughout the cosmos, but do not exist in stable form on earth due to the rather special conditions they require for initiation. Nevertheless, the necessary conditions can be easily achieved and thus stable man-made plasmas can be produced. Such plasmas have been widely employed in a variety of important industrial applications such as welding, catalyzing chemical reactions, laser pumping, and polymer stabilization.

The plasma utilized for case carburizing is the glow discharge (Ref 1, 2). This plasma is shown on a plot of electron density versus electron energy in Fig. 1. It can be seen that a glow-discharge plasma contains a very high density of electrons ($1 \times 10^{12}/cm^3$) with an average energy in the range of 1 to 10 electron volts (eV)--an energy range very effective

in ionizing and dissociating diatomic molecules. Thus, a plasma provides a ready and prolific source of chemically active atoms, and in plasma (ion) carburizing this is its principal function.

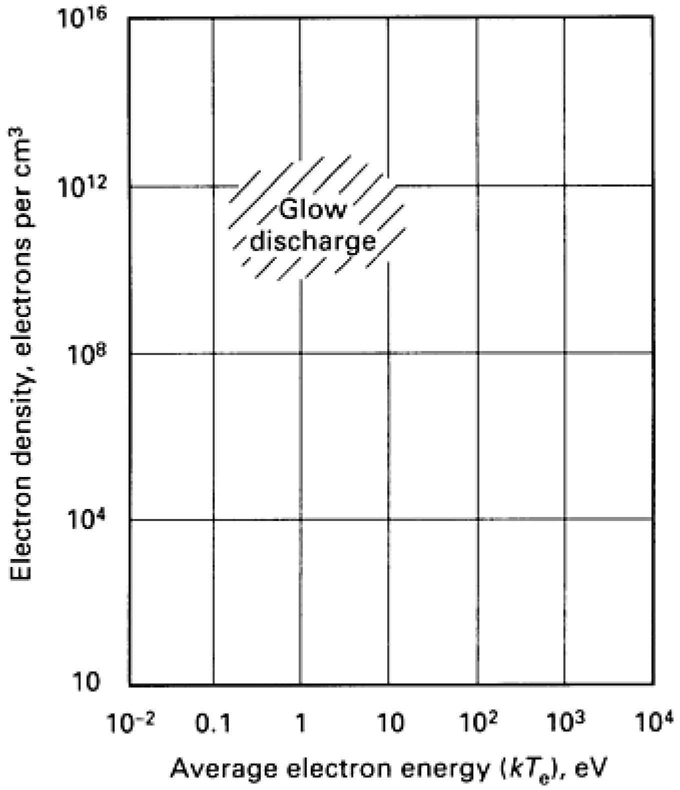

Fig. 1 Electron energy versus electron density in a glow-discharge plasma

A glow-discharge plasma can be easily established and maintained by placing two metal electrodes at opposite ends of a glass enclosure and evacuating it to a few hundred Pascals (Pa) of pressure (or a few torr of pressure with 1 torr = 1 mm of mercury pressure). Upon applying a dc voltage of a few hundred volts, a striated visible glow consisting of various regions (shown schematically in Fig. 2) is observed. All of the major regions are identified in Fig. 2, but in plasma (ion) carburizing, only the cathode and negative glows in the vicinity of the negative electrode are important. It is in this region of highest field strength (the cathodefall region) that ionization of the residual gas in the tube occurs. In fact, most of the advantages achieved by ion carburizing may be attributed to the physical processes which occur in this region. Much has been written on the details of the electron and ionic processes which occur in the cathodefall region (Ref 1, 2, 3), but suffice it to say, it is here that the electron and ion velocities are sufficiently high to dissociate molecules of the low-pressure gas and thus provide the active species required. Because this region is very near the cathode, it is also highly probable that these activated species will reach the cathode during their lifetime, and thus be available for reaction with the cathode surface or absorption into it.

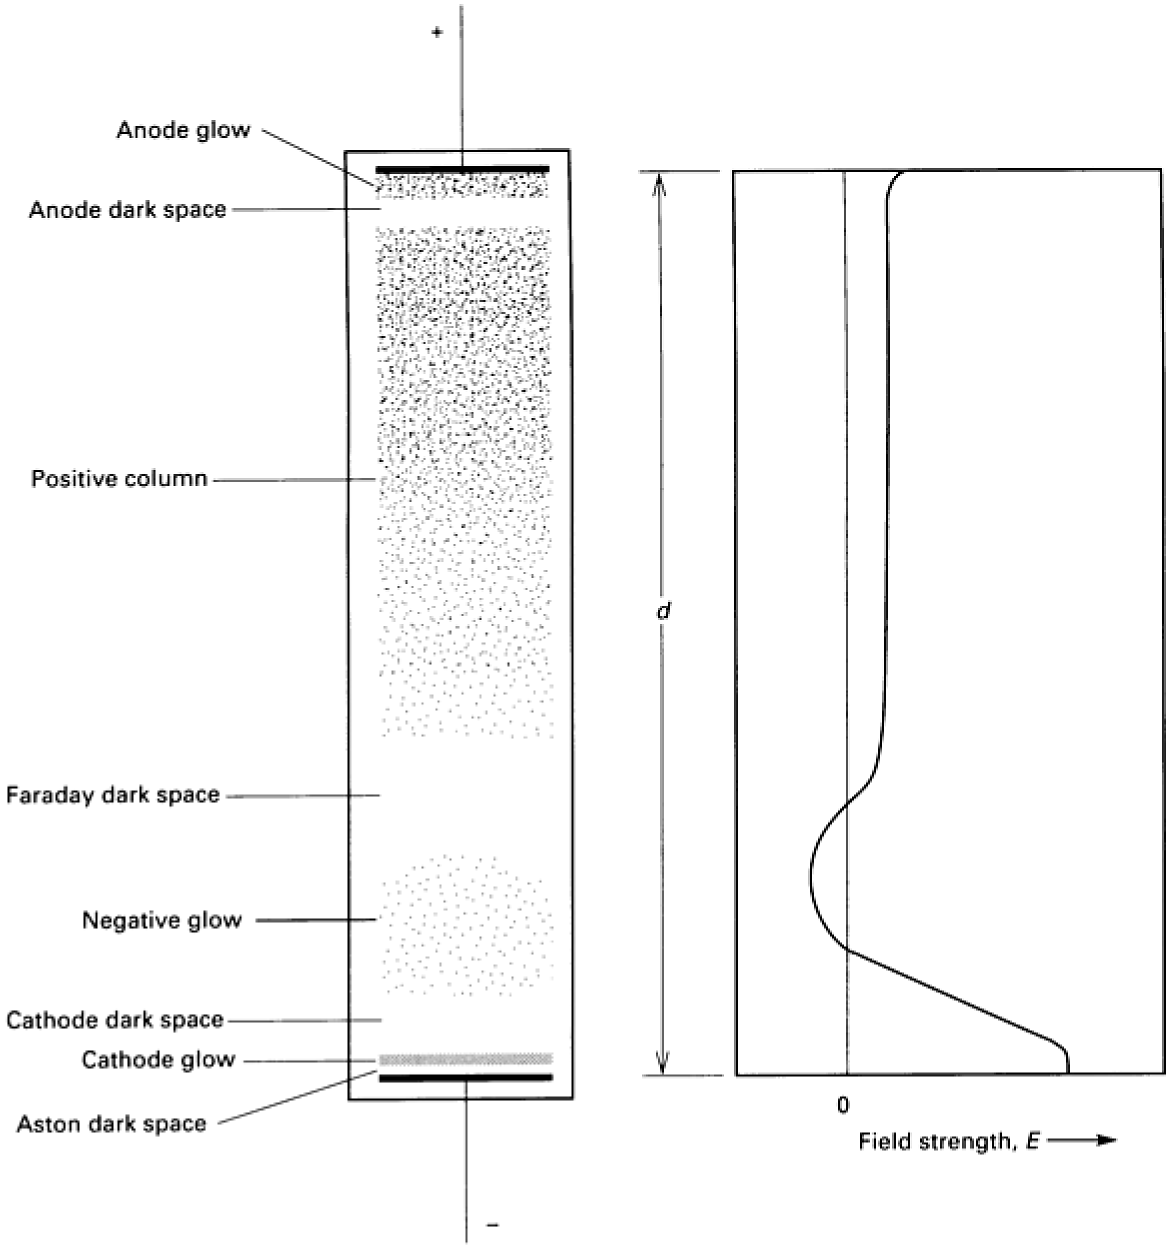

Fig. 2 Elements of a dc glow discharge in a gas at low pressure and field strength *E* versus distance *d* between the electrodes

Range and Limitations of Glow-Discharge Plasma. While glow-discharge plasma can be made to occur over a rather wide range of conditions, there are, nevertheless, some constraints that must be observed to ensure stability and a constant supply of active carbon. Referring again to Fig. 2, only the positive column constitutes a "true" plasma, that is, an ionized gas having no net space charge. This positive column, however, is not essential to the stability of the discharge, and may be eliminated by bringing the two electrodes closer together. In fact, if the pressure and the voltage are held constant and *d* in Fig. 2 is decreased, the positive column simply shrinks in length until it disappears as the anode enters the Faraday dark space (Fig. 2). Not until the anode approaches the negative glow do any of the discharge parameters change appreciably. Even with the anode very near the negative glow, the discharge is still stable, hut at a slightly higher voltage.

As *d* is further decreased, however, the voltage necessary to maintain stable operation will increase unless the pressure is increased in order to maintain approximately the same total amount of gas between the electrodes as when *d* was large. As shown by the Paschen curves in Fig. 3, the voltage required to maintain a stable discharge in a gas at low pressure is a function of both the pressure, *P*, and the distance, *d*, between the electrodes--actually, the product of *P* and *d.* Thus, as *d* is decreased, the pressure must be increased in order to permit operation at the minimum voltage. This dependence of the voltage on both *P* and *d* has important consequences in the practical application of plasma (ion) carburizing as will be shown later.

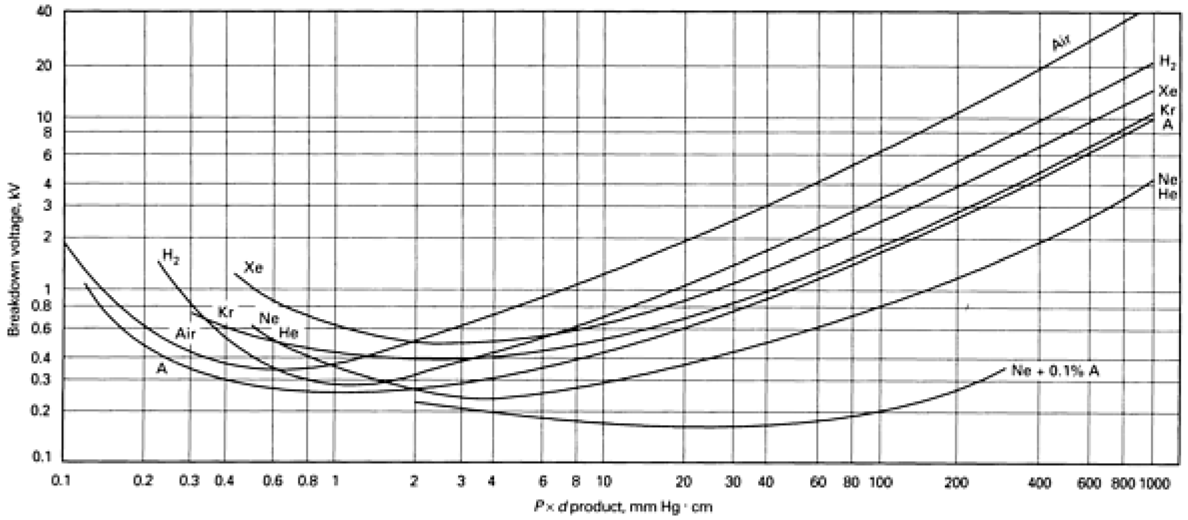

Fig. 3 Paschen curves for a dc glow discharge between parallel-plate electrodes for various gases showing the breakdown voltage versus the product of the gas pressure (*P*) and the distance (*d*) between the electrodes

Voltage Levels in Plasma Carburizing. Although it would be advantageous to be able to operate at the minimum voltage, in ion carburizing there are other more important conditions to be met. For example, it is essential that the plasma completely cover the cathode so that the case over the entire surface of the workpiece (the cathode) will be of uniform depth. A plot of voltage versus current in a gas at low pressure is shown in Fig. 4. The minimum voltage required to ensure complete coverage of the cathode is indicated by X, which is a voltage just above the constant voltage or "normal" glow region. Although the voltage must be high enough to ensure that the point X is on the positive slope region of the current-voltage (*I*-*V*) characteristic curve (for stability), it should not be any greater than that required for complete coverage because higher voltages simply increase the tendency of the discharge to pass into the arc mode (Fig. 4). Thus, in actual practice, the voltage is adjusted (for a given pressure and interelectrode distance, *d*), not only to ensure that the plasma sheath completely covers the workpiece but, simultaneously, to minimize the tendency of the discharge to abruptly enter the arc mode and damage the part.

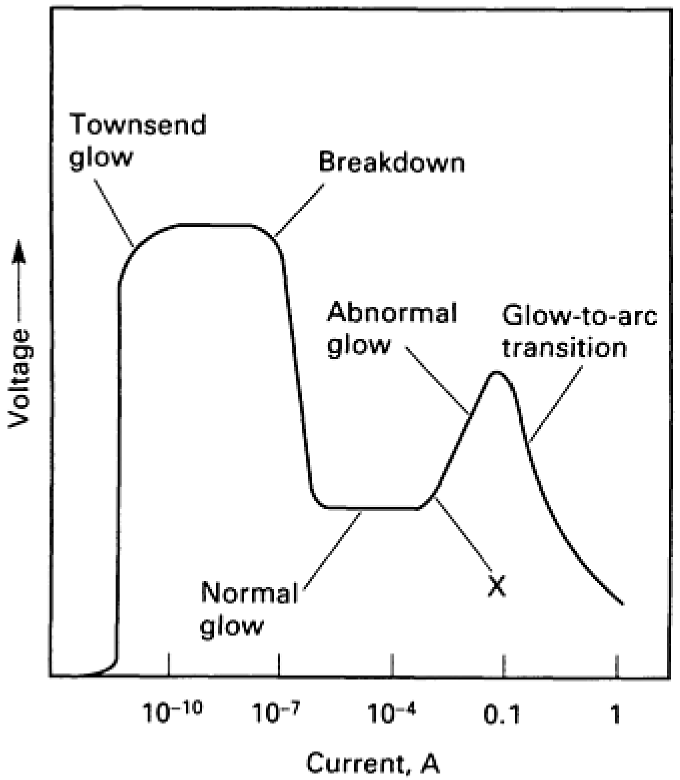

Fig. 4 Schematic current-voltage characteristic for electrical discharges in a gas at low pressure. X, minimum voltage required to ensure complete coverage of the cathode

Coverage and Wrap-Around Effect. While the need to adjust the operating conditions to ensure that the plasma sheath completely covers the workpiece may appear to be a troublesome constraint, this requirement is, in fact, an important advantage. Because a surface reaction will occur on the metal part only where the plasma is in contact with it, operation under conditions where complete coverage occurs ensures that the case will be of fairly uniform depth over the part--even on those areas that are not directly opposite (facing) the counterelectrode (the anode).

Deep recesses and "blind" holes are also carburized provided the depth-to-diameter ratio is not too large. To permit penetration of the plasma, a hole must have a diameter at least twice the thickness of the plasma sheath. The depth of the penetration of the plasma and therefore the extent of "down-hole" carburizing will depend on both the pressure and the interelectrode distance, *d.* This has important consequences in furnace design and furnace loading, as well as an influence on the operating parameters. This is discussed in greater detail in the section "Down-Hole Carburizing" in this article.

Dissociation of Methane to Carbon in Gas and Plasma Carburizing. In conventional gas atmosphere carburizing, the dissociative reactions that produce active soluble carbon from methane are shown in (a) to (f) in Eq 1:

$$\begin{array}{ll} \text{(a)} & CH_4\ \text{(gas)} \rightarrow \text{adsorbed (ad) } CH_4 \\ \text{(b)} & CH_4\ \text{(ad)} \rightarrow CH_3\ \text{(ad)} + H\ \text{(ad)} \\ \text{(c)} & CH_3\ \text{(ad)} \rightarrow CH_2\ \text{(ad)} + H\ \text{(ad)} \\ \text{(d)} & CH_2\ \text{(ad)} \rightarrow CH\ \text{(ad)} + H\ \text{(ad)} \\ \text{(e)} & CH\ \text{(ad)} \rightarrow CH\ \text{(ad)} + H\ \text{(ad)} \\ \text{(f)} & CH\ \text{(ad)} \rightarrow C\ \text{(dissolved)} \end{array} \qquad \textbf{(Eq 1)}$$

Of this series, (c) is the rate-limiting reaction (Ref 4, 5), and therefore the formation of active carbon for adsorption on the hot steel surface (reaction e) can proceed no faster than reaction (c) allows.

In a glow-discharge plasma, on the other hand, active carbon for adsorption can be formed directly from methane owing to the ionizing effect of the plasma. The rate-limiting reaction (c) of Eq 1 is thus effectively bypassed. This is not to say that all of the methane will be dissociated completely in one step. Intermediate dissociative steps may, and will, occur, but the end result is complete dissociation of the available methane. Herein lies the potential of plasma (ion) carburizing as a method of increasing the efficiency and rate of carbon delivery for subsequent dissolution in austenite. However, diffusion time is necessary or else deleterious carbides will form during cooling.

Diffusion Characteristics. Like vacuum carburizing, plasma carburizing is performed in an oxygen-free environment, which permits higher temperatures and thus higher diffusion rates. Higher temperatures also bring about some additional benefits arising from the increased solubility of carbon in austenite as the temperature is increased. As shown in the low-carbon region of the iron-carbon composition diagram in Fig. 5, by raising the temperature from the vicinity of 900 °C (1650 °F) (the normal carburizing temperature for conventional atmosphere carburizing) to 1040 °C (1900 °F), the limit of carbon solubility for carbon in austenite is increased from approximately 1.2 to approximately 1.6 wt% carbon (indicated by the arrows on the abscissa of Fig. 5). Because the surface of the hot steel part becomes saturated to this higher value very quickly in plasma carburizing, the diffusivity (and hence the carburizing rate) increases because of the effect of higher dissolved carbon concentrations on the diffusion coefficient (*D*) for carbon in austenite.

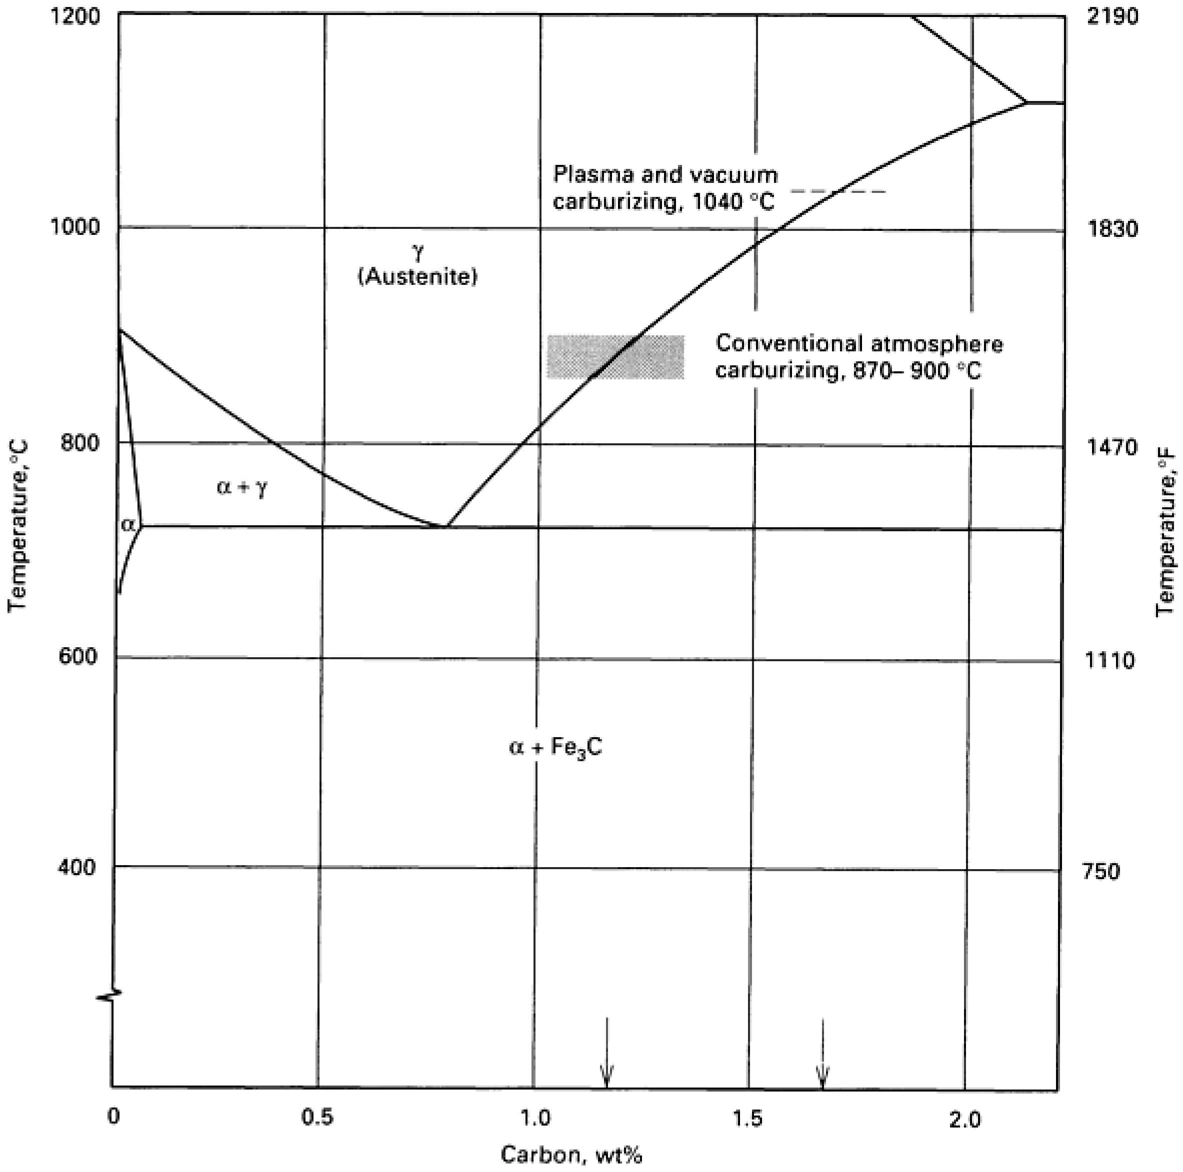

Fig. 5 Low-carbon region of the iron-carbon composition diagram. Arrows indicate the increase in the limit of carbon solubility for carbon in austenite.

The increase in the diffusion coefficient (*D*) with increasing carbon concentration is shown in Fig. 6. It may be seen that for carbon concentrations above approximately 1 wt% C, the diffusion coefficient increases very rapidly. For concentrations in the neighborhood of 1.5 to 1.6 wt% (the limit of solid solubility of carbon in austenite at the temperatures allowed in plasma carburizing), the diffusion coefficient (and hence the diffusivity) is more than twice that for a concentration below 1 wt%. Therefore, temperature has two effects acting simultaneously to increase the diffusion rate of carbon from the surface into the interior of the steel part: first, the effect of the increased temperature on the diffusivity, and second, the increased diffusivity brought about by the increased carbon solubility in the steel.

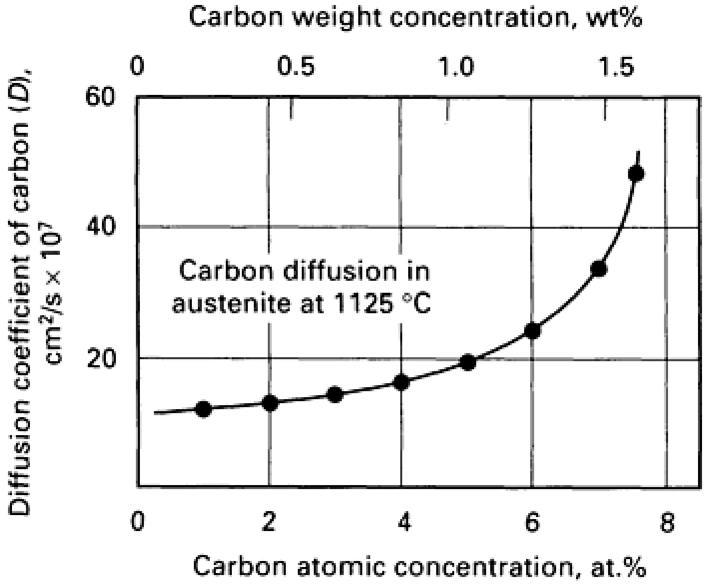

Fig. 6 Diffusion coefficient for carbon in austenite versus carbon concentration at 1125 °C (2060 °F). Source: Ref 6

In addition, because the rate of adding carbon is increased during plasma carburizing, the combined effect is to bring about a profound increase in the rate of carburizing. For example, at a temperature of 1050 °C (1920 °F), enough carbon can be added in only 10 min (Fig. 7) to obtain a case depth of 1 mm (0.040 in.). While an additional diffusion step of 30 min is required to develop the effective case depth of 1 mm (0.040 in.), all of the carbon needed was added in only 10 min from the methane plasma. As also shown in Fig. 7, six h is required to obtain a comparable carbon profile with conventional gas-atmosphere carburizing at 918 °C (1685 °F). Further discussion of the factors which lead to the increased carburizing rates may be found in Ref 8, 9, and 10.

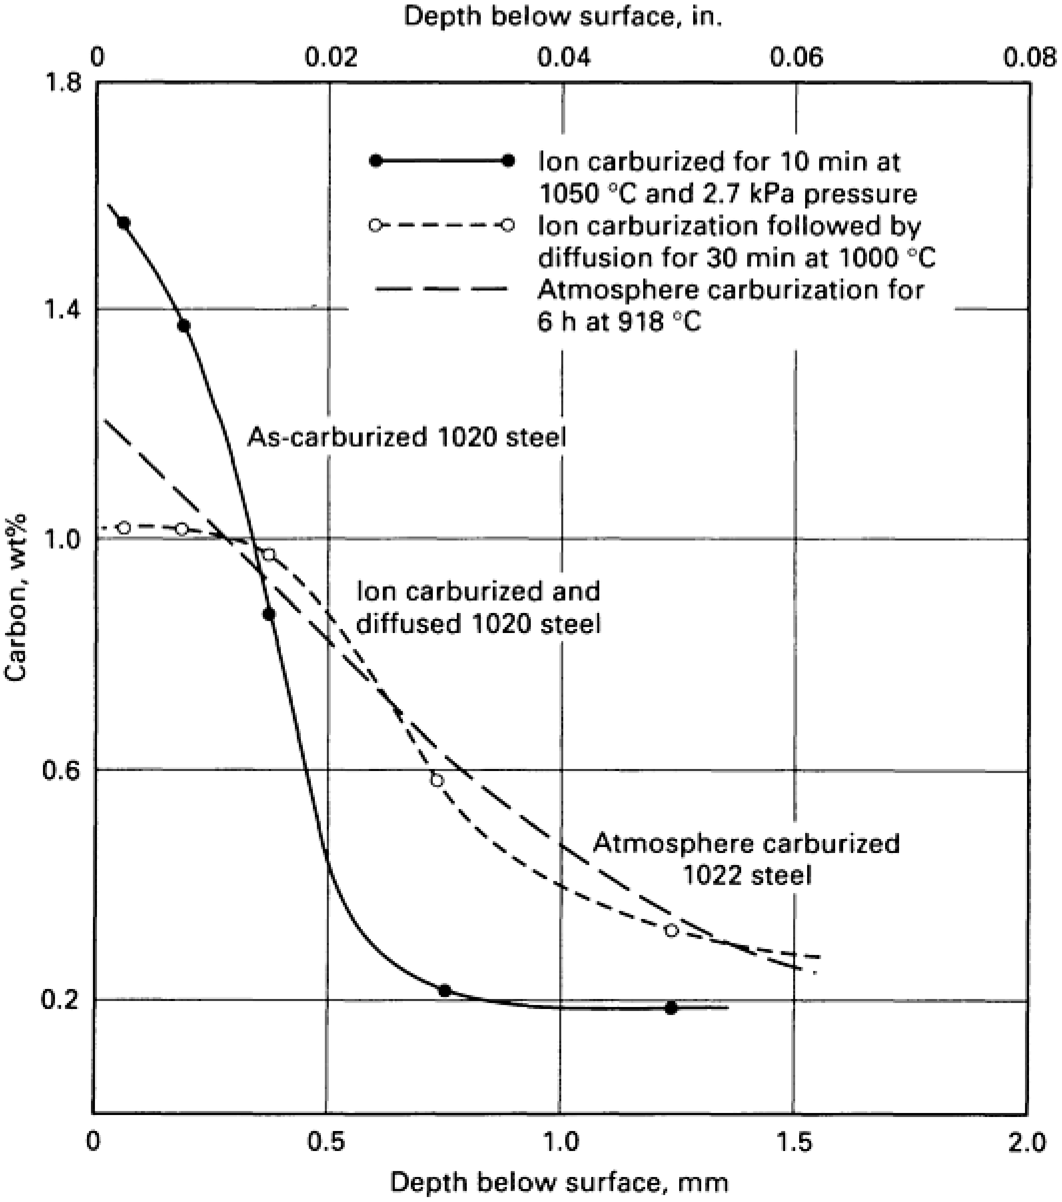

Fig. 7 Carbon concentration profile in AISI 1020 steel after ion carburizing for 10 min at 1050 °C (1920 °F) followed by vacuum diffusing for an additional 30 min at 1000 °C (1830 °F). A similar carbon concentration profile is obtained by atmosphere carburizing for 6 h at 918 °C (1685 °F) Source: Ref 7

Advantages of ion carburizing include several technical factors (such as carburizing and case uniformity) as well as economic and environmental factors. These advantages are briefly discussed below.

High Carburizing Rate. The marked increase in carburizing rate compared to gas or atmosphere carburizing is illustrated in Fig. 8. Shown are the carbon profiles obtained by plasma carburizing at 900 °C (1650 °F) for 10, 30, 60, and 120 min as well as that obtained by atmosphere carburizing for 240 min at the same temperature (Ref 7). It may be seen that the profile obtained by atmosphere carburizing for 240 min at 900 °C (1650 °F) may be obtained in one-half the time by plasma carburizing at the same temperature.

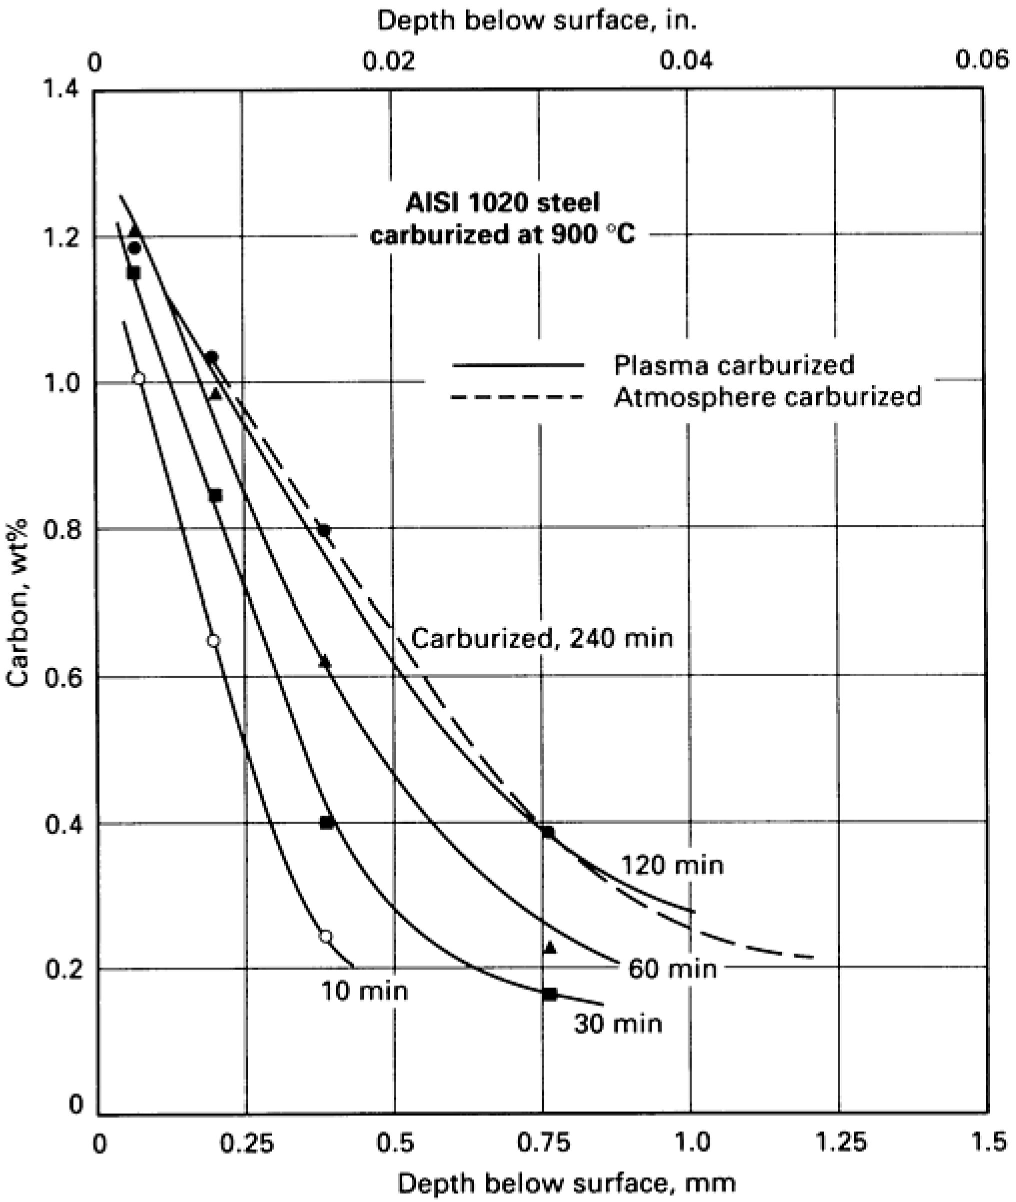

Fig. 8 Carbon concentration profiles in AISI 1020 steel after ion carburizing for 10, 20, 30, 60, and 120 min at 900 °C (1650 °F) Carbon profile after atmosphere carburizing for 240 min at 900 °C (1650 °F) shown for comparison. Source: Ref 7

A similar 2-to-1 advantage is illustrated in Fig. 9 for AISI 8620 steel carburized at 980 °C (1800 °F). Plasma carburizing for 15 min at this temperature matches the carbon profile which required 30 min with atmosphere carburizing. Compared to vacuum carburizing for 30 min, the case depth at the 0.8 wt% C level is 50% deeper with plasma carburizing.

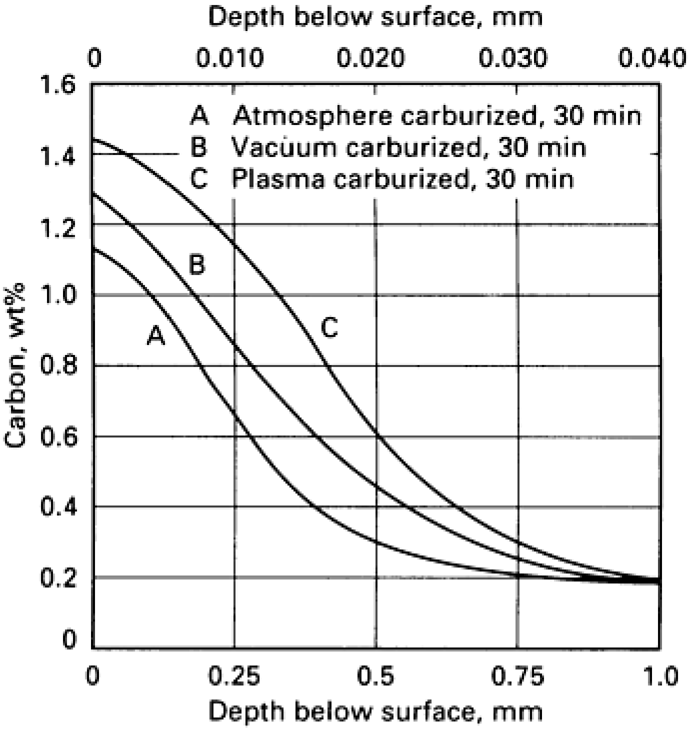

Fig. 9 Carbon gradient profile of atmosphere, vacuum, and plasma carburizing of AISI 8620 steel at 980 °C (1800 °F) saturation conditions for 30 min and followed by direct oil quenching. Source: Ref 11

Typical carbon and hardness profiles through an ion carburized case in the ascarburized and in the carburized-and-diffused condition are shown in Fig. 10. At a carburizing temperature of 1000 °C (1830 °F), a 1 mm (0.040 in.) case is typically obtained with a 10 min carburize, 30 min diffuse cycle.

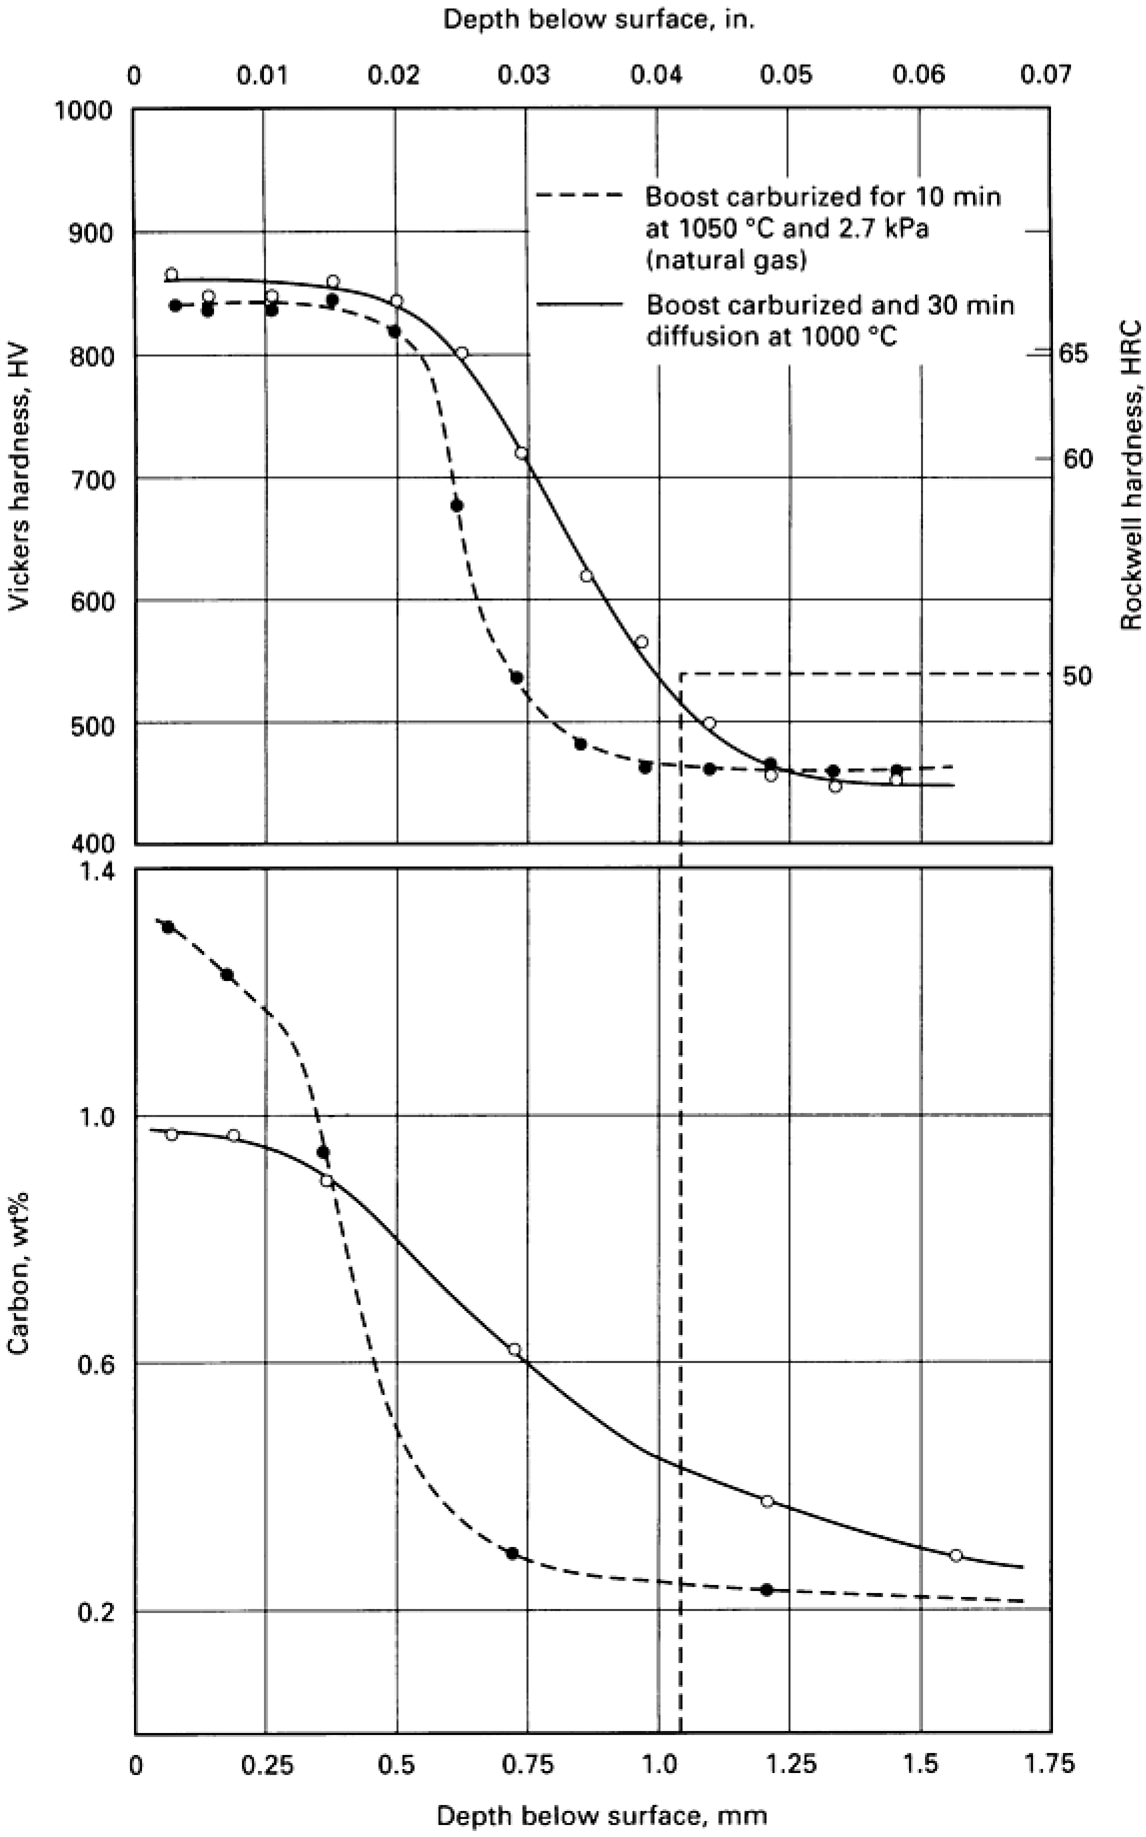

Fig. 10 Carbon concentration and hardness profiles in AISI 1020 steel after ion carburizing for 10 min at 1050 °C (1920 °F) followed by additional vacuum diffusing for 30 min at 1000 °C (1830 °F). Effective case depth is indicated by dotted line.

Improved Case Uniformity. Figure 11 illustrates the improvement in uniformity of case depth in gear-tooth profiles obtained with ion carburizing. Here the case depth profile after ion carburizing at 980 °C (1800 °F) is compared to that obtained with atmosphere carburizing at the same temperature. The improved case depth uniformity obtained by ion carburizing on a part having deep recesses is illustrated in Fig. 12. In this figure, the case uniformity obtained with ion carburizing is compared to that obtained with vacuum carburizing.

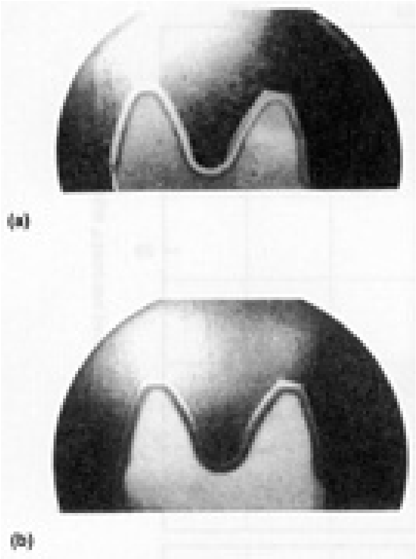

Fig. 11 Comparing uniformity of case depth over gear-tooth profiles. (a) Ion carburized at 980 °C (1800 °F). (b) Atmosphere carburized in a 980 °C (1800 °F) boost-diffuse cycle. Case depth in (a) exhibits more consistency, particularly in the root of the gear profile. Courtesy of Surface Combustion, Inc.

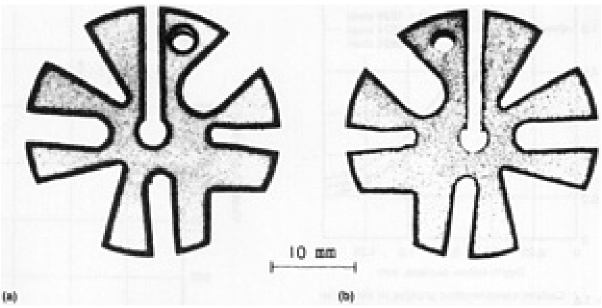

Fig. 12 Comparing uniformity of case depth over a part with deep recesses. (a) Ion carburized. (b) Vacuum carburized. Source: Ref 8

Blind-Hole Penetration. Ion carburizing improves blind-hole penetration, or "down-hole" carburizing. In Fig. 13, for example, plasma carburizing achieves a uniform plateau of case depth of up to an *L*/*D* ratio of about 12. Atmosphere carburizing achieved a uniform case depth for *L*/*D* ratios up to about 9 (Fig. 13).

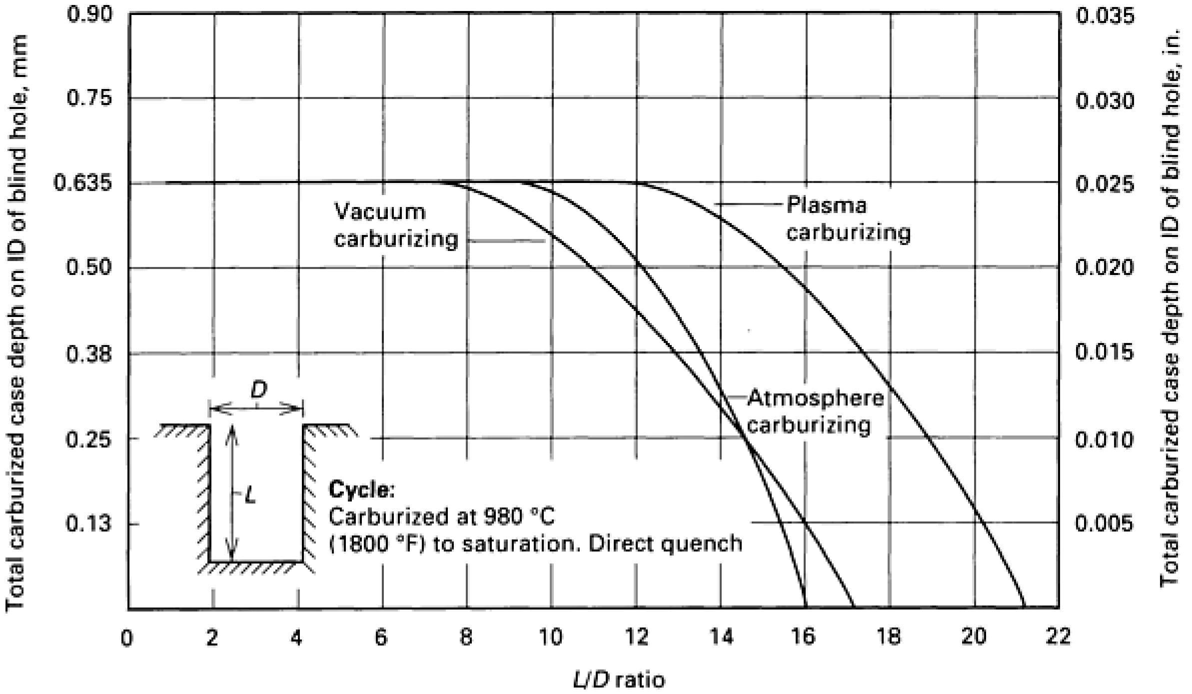

Fig. 13 Uniform case depth of 0.635 mm (0.025 in.) in a blind hole as a function of *L*/*D* ratios for plasma, vacuum, and gas carburizing. The curves were obtained by measuring case depths at different hole depths (*L*) in a 6.35 mm (0.25 in.) diam blind hole. Source: Ref 12

Insensitivity to Steel Composition. The rate at which steel may be ion carburized is quite insensitive to alloy composition, as illustrated in Fig. 14. Essentially the same profile and depth case are obtained in three steels of different alloy content.

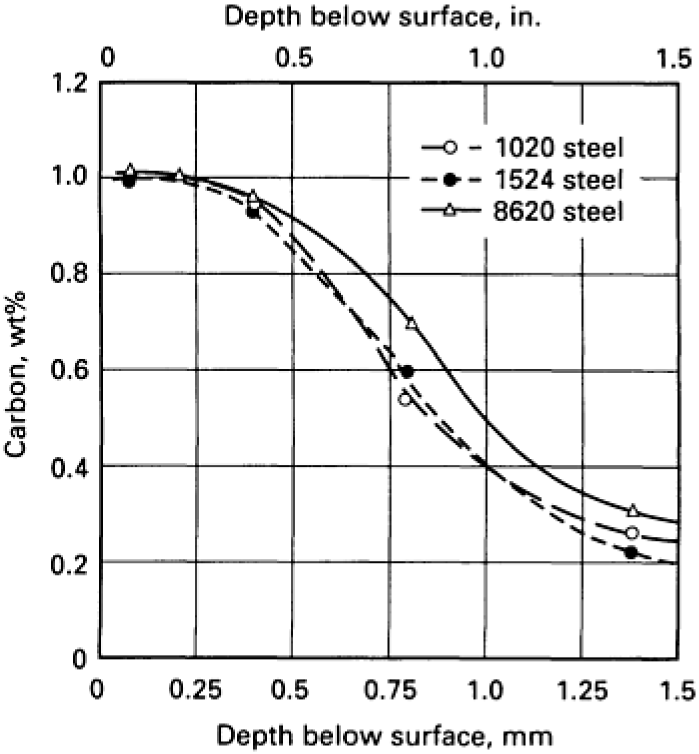

Fig. 14 Carbon concentration profiles in three carburizing steels after ion carburizing illustrating insensitivity to steel composition. Data are based on a boost-diffuse cycle of ion carburizing at 1040 °C (1900 °F) for 10 min followed by diffusion for 30 min at 1000 °C (1830 °F).

Ion carburizing is similarly insensitive to the hydrocarbon gas used as a carbon source. Figure 15 shows similar and comparable carbon and hardness profiles obtained by ion carburizing in methane, natural gas, and nitrogen-propane atmospheres.

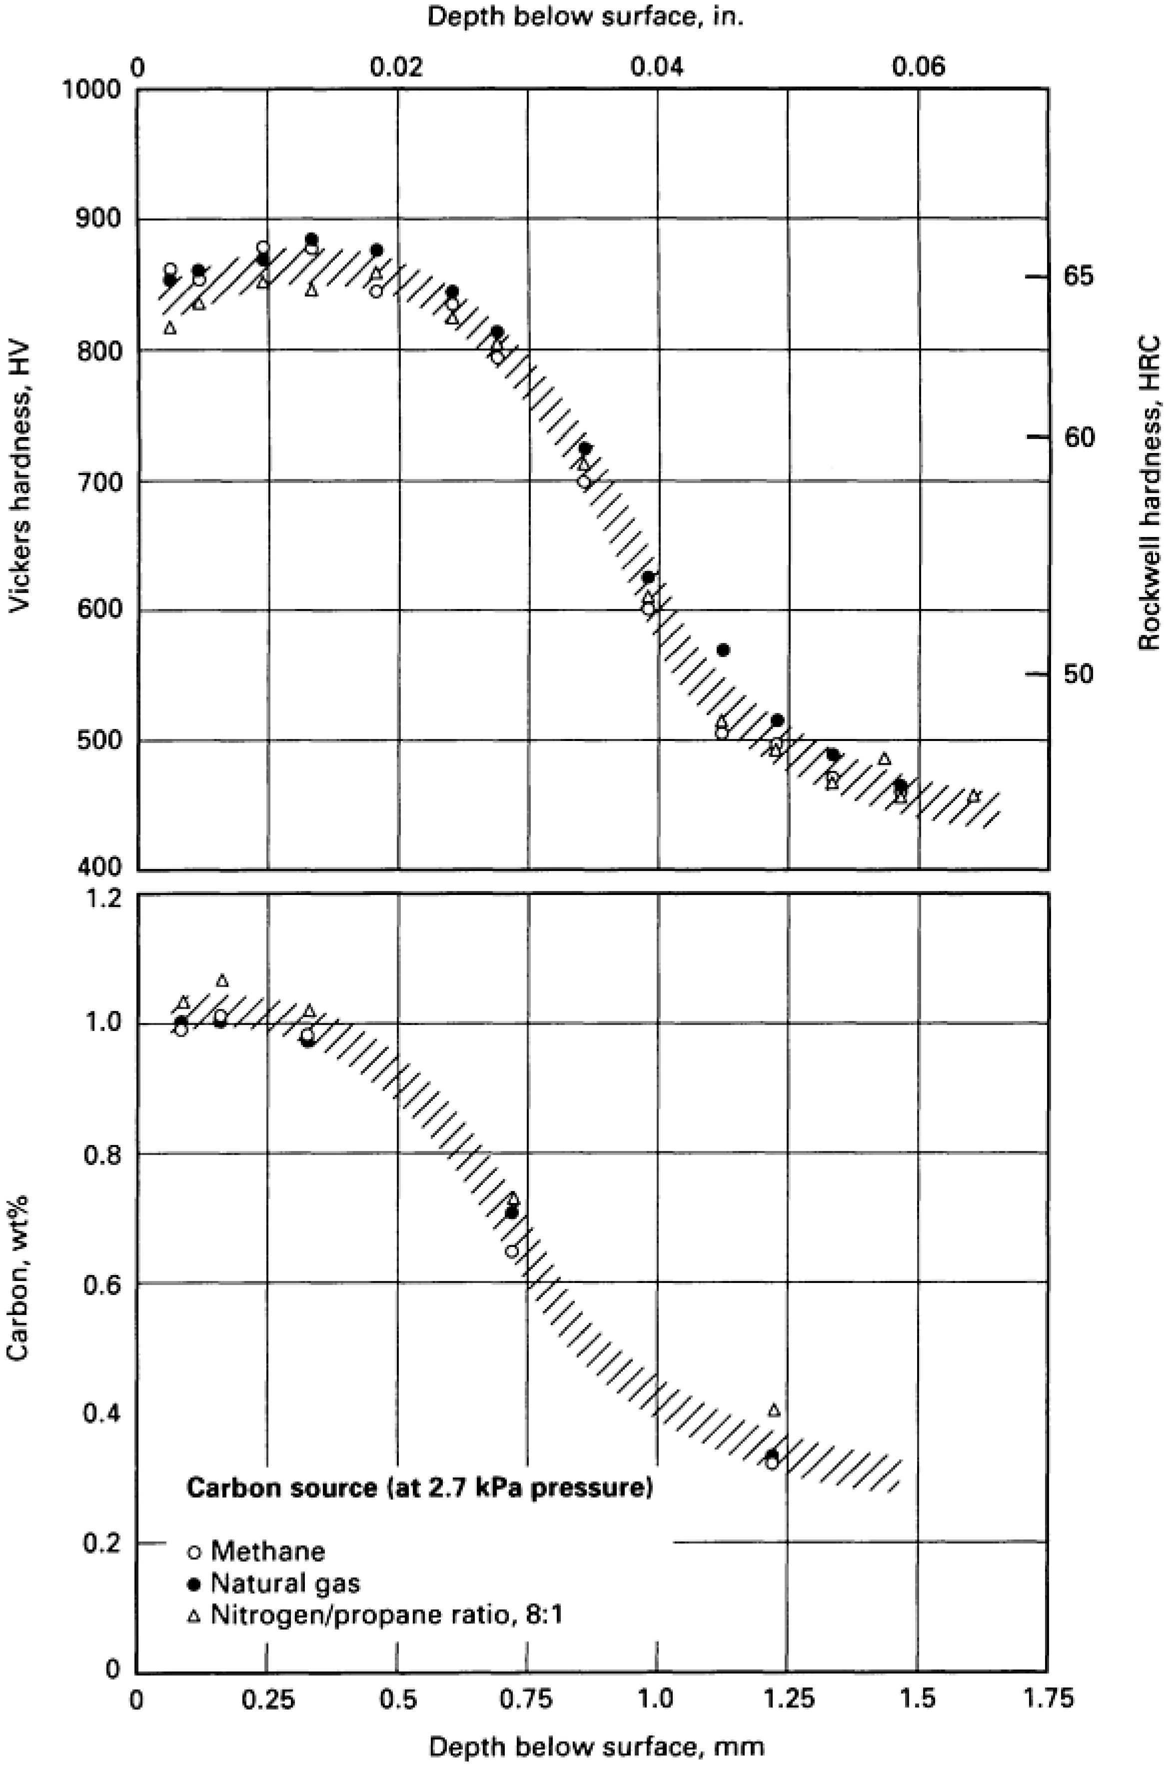

Fig. 15 Carbon concentration and hardness profiles through cases on AISI 1020 steel after ion carburizing in methane, natural gas, and in 8:1 nitrogen/propane combination. Data are based on a boost-diffuse cycle of ion carburizing for 10 min at 1050 °C (1920 °F) followed by 30 min of diffusion at 1000 °C (1830 °F). Source: Ref 13

Environmental Improvements. Plasma carburizing provides a much cleaner and safer environment than gas carburizing systems, and there is no fire hazard or toxic gases such as carbon monoxide from the flame screens on atmosphere furnaces. Because the carburizing zone is completely isolated from the surrounding work space, the furnace may also be placed in-line on the assembly floor. Furthermore, because the ambient temperature of the casing is near tap-water temperature, the furnace may be used in an air-conditioned environment.

Equipment and Operating Costs. Plasma carburizing is done in a special furnace using methane or propane gas at subatmospheric pressure for the carbon source, which eliminates the need for generated gas. Therefore, atmosphere generating equipment is not required, and simple gas-valve manifolds may be used with a resultant reduction in furnace capital equipment costs. However, when all ancillaries are taken into account, the costs of plasma versus atmosphere equipment are comparable.

In terms of an operating cost comparison, ion carburizing reduced the door-to-door processing time by 20% over atmosphere carburizing and by 5% over vacuum carburizing (Table 1). In comparing an electrically fired atmosphere furnace with an ion carburizing furnace, the cost per pound was reduced 45% (Table 1).

Table 1 Operating cost comparison of atmosphere, vacuum, and plasma carburizing methods for 144 gears with a gross weight of 560 kg (1235 lb)

	Atmosphere		Vacuum	Plasma
Cycle, h				
Carburize	2.5		0.9	0.6
Diffusion	0.0		0.7	0.7
Slow cool to 870 °C (1600 °F)	0.5		0.5	0.5
Door-to-door time, h	5.75		4.85	4.55
Atmosphere used, ft^3				
RX	3120 (600 ft^3/h)		. . .	. . .
CH_4	125		100	90
Utility costs/cycle[(a)] based on rates and conditions in:	Gas fired	Electric		
CH_4	$14.42	$2.07	$0.44	$0.38
H_2O	$4.18	$4.18	$7.06	$6.62
Electric	$5.02	$43.44	$20.62	$20.12
Cost/100 lb	$1.91	$4.02	$2.28	$2.20

(a) Utility rates: H_2O rate, $18.19/1000 ft^3; electric, 4.68 c/kWH; natural gas, $4.41/1000 ft^3. Common carburizing conditions: basket size, 24 in. × 36 in. × 5 in.; carburizing temperature of 980 °C (1800 °F); case depth, 1.4 mm (0.055 in.)

An ion carburizing furnace may be maintained in operating condition with 85 to 140 L (3 to 5 ft^3) per hour of air, thus providing minimum degradation of furnace elements and the hearth.

Efficiency in the Utilization of Carburizing Gas. In view of the very high carburizing rates achieved, and the relatively small amount of carburizing gas fed into the furnace, it is safe to assume that the efficiency in the utilization of the carburizing gas should be quite high. Although precise knowledge of this efficiency is not critical to the practice of plasma carburizing, the efficiency of gas utilization should be known so that the flow of carburizing gas through the furnace might be optimized to obtain the best balance between high utilization efficiency and carburizing rate. The quantities which must be measured to permit calculation of this efficiency are shown schematically in Fig. 16. As shown, the hydrocarbon utilization efficiency is given by the ratio:

$$h_h = \frac{V_i - V_c}{V_i} x100 \qquad \textbf{(Eq 2)}$$

The apparatus needed to make these measurements is shown schematically in Fig. 17. Basically, flow meters measure the volume, or mass, flow into the furnace and a large evacuated tank collects the entire effluent from the furnace during carburizing. To avoid contamination of the furnace effluent with vacuum pump oil vapors, the collecting volume is made large in comparison with the volume of the furnace so that it may serve as the vacuum pump for the entire system for the duration of the experiment. The experiment is run under steady-state conditions for 15 min. The collecting volume is then isolated from the system and backfilled with dry nitrogen. The amount of methane in collecting volume is measured with a flame-ionization analyzer which displays the methane concentration directly in parts per million.

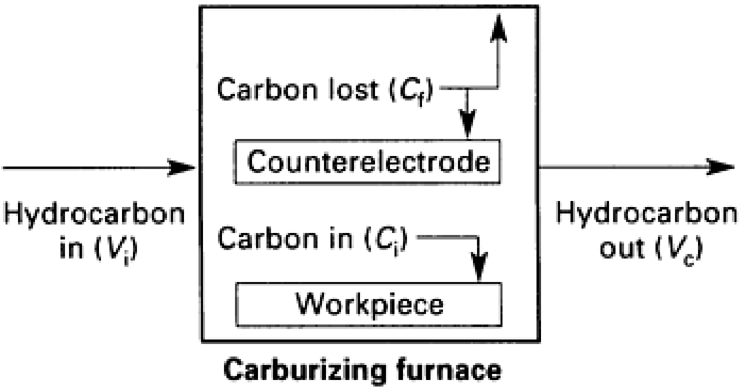

Fig. 16 Schematic measurement of hydrocarbon-utilization efficiency. Source: Ref 7

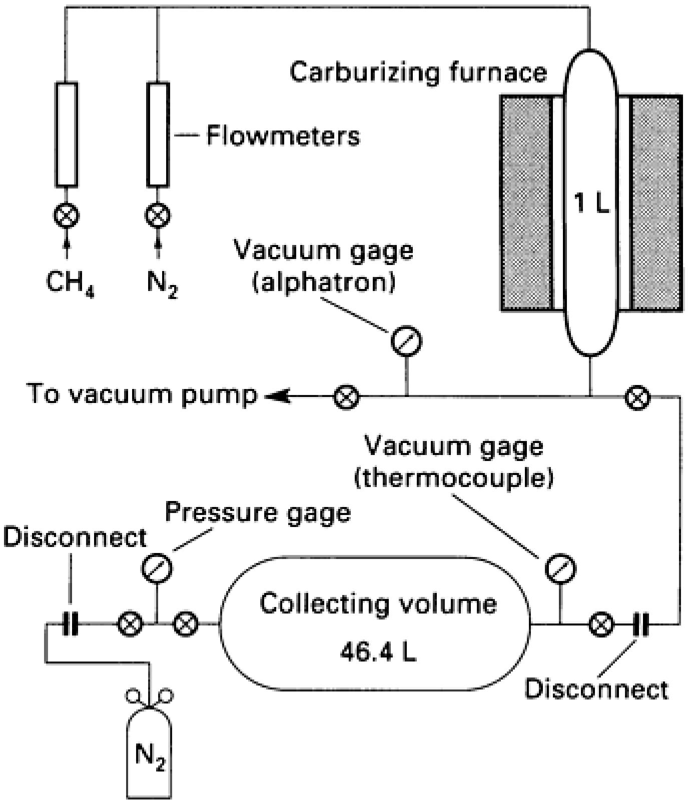

Fig. 17 Schematic of apparatus for measurement of hydrocarbon-utilization efficiency

Results obtained for a carburizing-gas space velocity of approximately one furnace volume per hour is shown in Fig. 18. Here the gas utilization efficiency is plotted versus the degree of dilution with nitrogen. For pure methane the efficiencies obtained are spread over a range of 40 to 75%. As the dilution with nitrogen is increased, the percentage of the methane consumed also increases. At a dilution of 9-to-1, efficiencies in the neighborhood of 90% are consistently obtained, but the carburizing rate is noticeably decreased as shown in Fig. 19. At a ratio of equal parts of nitrogen and methane, the carburizing rate is essentially the same as that obtained with pure methane (Fig. 19) but the efficiency of utilization (Fig. 18) is in the range of 70 to 80%, thus indicating that more hydrocarbon is being added than necessary. At this same dilution, but with the flow reduced by one half (approximately 0.5 furnace volumes per hour), the efficiency (shown by the open circle data points in Fig. 18) again increases to nearly 90%. As shown by the dashed curve in Fig. 19, however, the carburizing rate is less than that obtained with the 1:1 ratio at a flow rate of one furnace volume per hour. These results indicate that a furnace would have to be fine-tuned to achieve the optimum balance between carburizing rate and gas utilization efficiency. Because such a small amount of the hydrocarbon carburizing gas is needed, it is questionable whether efforts to achieve a high efficiency of gas utilization would be worth the risk of reducing the carburizing rate. In addition to carburizing rate, other factors, such as sooting, should govern the hydrocarbon dilution ratio and the atmosphere flow rate.

Equipment Requirements. The physical arrangement of the apparatus and electrical circuitry required for plasma carburizing is shown schematically in Fig. 20. In this arrangement, the workpiece (cathode) is at ground potential and the positive potential needed to establish and maintain the glow discharge is fed into the vacuum enclosure through a suitable insulated lead-through to a counterelectrode (the anode). Auxiliary heating elements (either radiant or induction), surround the workpiece to heat it to the carburizing temperature because the heat losses of the plasma are insufficient to heat the work load to the carburizing temperature (900 to 1000 °C, or 1650 to 1830 °F). An experimental carburizing furnace reflecting this arrangement is shown in Fig. 21. In this furnace, the workpiece and furnace are at ground potential and the high voltage is fed in through a water cooled insulated lead passing through the shell and the heating muffle (Ref 7).

Application to Carburizing Practice

Production Equipment. Figure 22 shows a production two-chamber ion carburizing furnace installation. The addition of the load support insulators and an ion power supply is the only difference between it and a two-chamber integral-oil-quench vacuum furnace. Depending on the manufacturer, these additions may require some periodic maintenance. The ion power supply, for example, needs its cabinet cooling filters cleaned regularly (once a month).

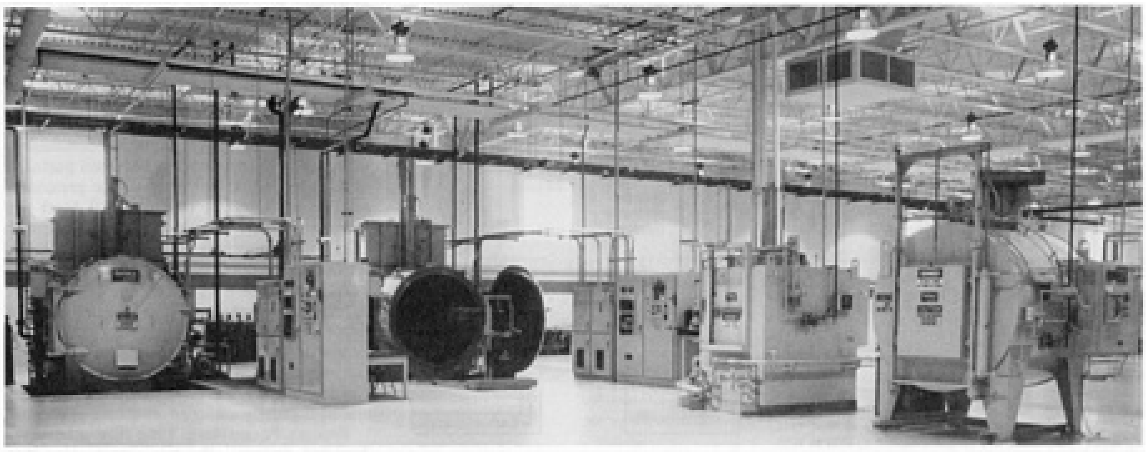

Fig. 22 Production installation of two dual-chamber ion carburizing furnaces. Courtesy of Surface Combustion, Inc.

Periodic maintenance of the furnace itself is minimal, although some plasma carburizing furnaces require cleaning of the load support insulators to remove carbon buildup and thus ensure electrical isolation. In some furnaces, load support devices are self cleaning with only monthly maintenance requirements.

If the load support insulators require cleaning, an air-burnout cycle can be used to remove the carbon deposits. In one manufacturer's equipment, for example, cleaning is accomplished by an automatic program cycle which adds 85 to 140 L/h (3 to 5 ft^3/h) of air to the furnace at 1150 °C (2100 °F) for 1 h. Under normal operating conditions a burnout cycle is recommended after 100 h of carburizing (plasma-on) time. An indication of the need for a burnout is a high count rate on the glow-interruption counter.

Loading Requirements and Limitations. In order to carburize, the plasma envelope must surround the component part. Thus, the parts must be fixtured or positioned such that they do not contact each other. In Fig. 23, for example, the load is composed of gears stacked in layers separated by a woven wire screen between layers. The component gears are carburized uniformly (±0.05 wt% C at the surface). The basket liner and the woven wire screens are chosen to minimize the contact area to the component parts. It is usually less than 3.2 mm (0.125 in.) diameter wire with a wide grid spacing. The parts cannot be shovel loaded because the plasma envelope would be mechanically masked. Thus the parts are positioned so that the plasma envelope of one component part does not touch the plasma envelope of its neighboring part. There is approximately 6.4 mm (0.25 in.) spacing between parts. It should be noted that at absolute pressures of 130 to

3330 Pa (1.0 to 25.0 torr) for plasma or ion carburizing, the methane (CH_4) concentration is too low to carburize without the plasma. To date, tests have indicated that a CH_4 atmosphere must be at a pressure of at least 13 kPa (100 torr) to carburize from the atmosphere alone. This is the minimum absolute pressure required for vacuum carburizing. Thus, the plasma in ion carburizing increases the carbon potential at a greatly reduced absolute pressure.

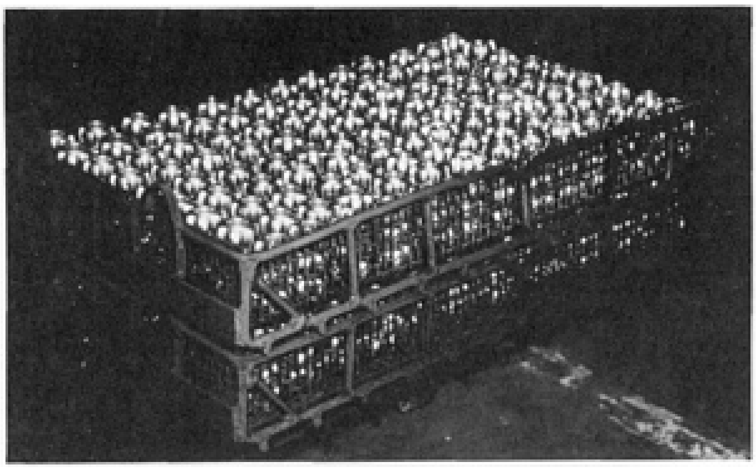

Fig. 23 Racked array of universal-joint components ready for ion carburizing. Two stacked fixtures constitute one furnace load of 1500 parts. Courtesy of Dana Corporation

Process Parameters. Like any other carburizing process, the two parameters that determine the surface carbon and the case depth for an alloy being carburized are time and temperature. The temperature, and indirectly the time, determine the grain size and mechanical properties to be achieved. A higher temperature is used to achieve more rapid diffusion rates. The use of higher temperatures, however, is not considered favorable by aerospace companies because the base properties of the steel are diminished. Higher temperatures also increase the potential for distortion.

Once a temperature is chosen, the time is determined from Harris's equation--case depth proportional to square root of the carburizing time. Diffusion time must be added or else deleterious carbides will still form upon cooling. Plasma carburizing is different from equilibrium atmosphere carburizing in that a constant carbon potential is not maintained, but rather the steel is taken to carbon saturation for the temperature chosen. Then by Fick's Law, the diffusion of the carbon occurs (without the plasma) as a function of time and temperature only. This establishes the surface at the desired carbon potential as well as the carbon gradient of the carbon case from the surface. This boost-diffuse method of carburizing is the only way plasma carburizing can provide predictable case depth from the time and temperature.

Process Pressure. After a time-and-temperature cycle is established, the operating absolute pressure is chosen. The operating pressure can be any value provided the plasma covers the parts and no hollow-cathode effect is evident. The pressure is usually chosen to be low, in the range of 130 to 670 Pa (1 to 5 torr), because optimum carburizing uniformity is achieved in this range. If the inside diameter is the critical area to be carburized, the pressure must be increased to the point that the plasma enters the cavity and covers the sidewall of the cavity. Likewise, if the plasma luminescence or visible glow overlaps within the cavity, a detrimental condition known as hollow-cathode effect can occur (see the section "Hollow-Cathode Problem" in this article).

The key to determining the necessary operating pressure involves a visual observation to ensure the plasma is covering the load. The visual check also verifies that no hollow-cathode effects are observed. Other than this effect, the absolute pressure value chosen is somewhat arbitrary.

Carbon Source. The gas utilized as the carburizing agent can be any hydrocarbon, however, the simplest and most commonly used hydrocarbon is CH_4. Propane (C_3H_8) can be used as well. In addition, a hydrocarbon such as CH_4 or C_3H_8 is used in combination with nitrogen mixtures for carbonitriding applications.

Carbon Mass Flow. The more important parameter than gas composition is the carbon mass flow into the plasma. The amount of carbon mass flow, however, is dependent upon the net surface area of the load that can absorb the carbon. Thus, the surface area of the load, the basket, and tray must be approximated to within 10% of its actual value.

As indicated in Fig. 24, the required uniformity of carburizing can be achieved if a minimum carbon mass flow into the plasma is achieved (Ref 14). A minimum mass flow of 3×10^{-4} grams of carbon per minute per square centimeter of

surface area achieves uniform carburizing This is equivalent to 0.37 L (0.013 ft^3) per minute of CH_4 per square inch of surface area. It is important to remember that this mass flow per unit surface area is based on only the surface area of the load that the plasma will carburize. Even though the baskets and the trays are within the plasma and are being carburized at a lower rate, because of their alloy content, they are not the active part of the load, which is absorbing the carbon. Thus, the surface area used in the calculation for the carbon mass flow should represent the net area that is active to the carbon. This will minimize any sooting of the component parts, baskets, and tray, but still provide optimum carbon for uniform carburizing.

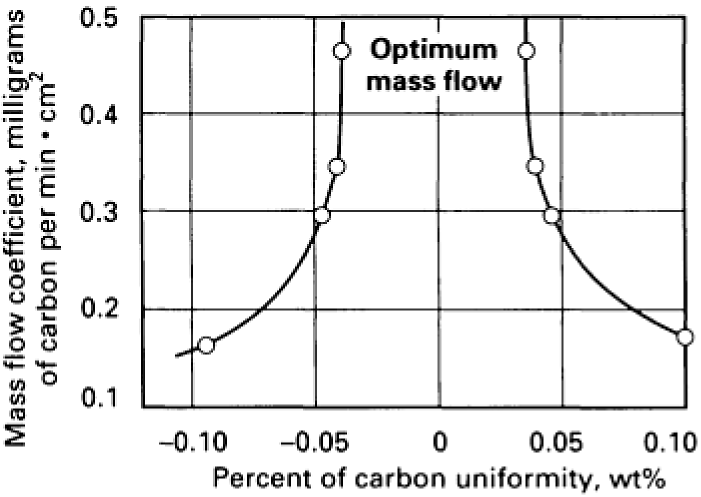

Fig. 24 Carbon mass flow to achieve surface carbon uniformity. Source: Ref 14

The minimum power density (Fig. 25), or the throwing power of the plasma per unit area, is given as function of temperature to achieve a uniform surface carbon potential within ±0.05 wt% C. As the temperature increases, more plasma power must be supplied to maintain carbon saturation level at the surface. As noted earlier, the carbon saturation level increases with temperature as well as the diffusion coefficient (Fig. 5 and 6), such that more carbon must be supplied. As indicated above, at the absolute pressures of 130 to 3330 Pa (1 to 25 torr), the only source of carbon is the plasma.

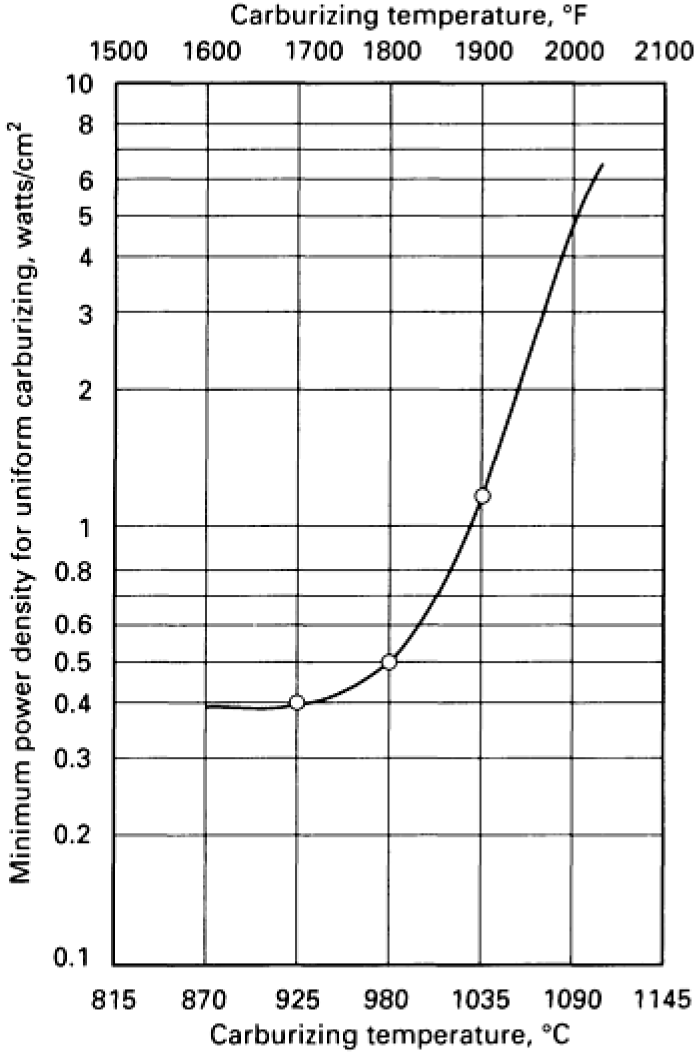

Fig. 25 Minimum power density as a function of the carburizing temperature. These minimum power densities are based on a constant dc supply. Results will differ if a pulsed power supply is used. Source: Ref 14

Again, the surface area must be known to utilize the power density or throwing power of the plasma of the value depicted in Fig. 25. Because the plasma must cover the whole load including the baskets and the tray, the plasma power required must be calculated by taking the total area multiplied by the power density of Fig. 25. The total area of the load must be calculated to within 10% of the actual area and the minimum power density utilized from Fig. 25. Power densities higher than the minimums of Fig. 25 can be used; however, the added power of the plasma can add sufficient energy to heat the load above the furnace operating temperature that is controlled by the resistance heaters. Figure 25 is the minimum watt density required for uniform carburizing and still maintain a ±14 °C (±25 °F) temperature uniformity during carburizing.

Down-Hole Carburizing. As indicated above, one of the operating parameters of the plasma is the absolute pressure. The control of the absolute pressure determines the depth to which the plasma penetrates a hole or cavity. The thickness of the cathode visible glow or luminescence is a function of the pressure, the gas composition, and the temperature. In order for the glow to appear down the cavity, the anode must still be in a line-of-sight with the cavity of the part. Empirically, this has been established at a length/diameter (*L*/*D*) ratio of 10/1. (The *L*/*D* ratio is the length of the hole or cavity divided by the diameter.) This empirical relationship is only applicable to blind-hole cavities.

Hollow-Cathode Problem. The above parameters give the optimum operating conditions for uniform carburizing. It was also indicated that in choosing the pressure, a visual observation of the load must be noted to ensure that the hollow-cathode effect is not present. When observing the load and any cavities within the load, the cathode glow or luminescence overlaps in the cavities, the current density cascades into extreme values and causes severe overheating or possibly melting.

Figure 26 is an empirical relationship that describes the region of hollow cathode at various temperatures and *L*/*D* ratios. These curves were established for a CH_4 atmosphere and would be shifted for other atmosphere compositions. To the right of the curves is the safe region and for a given *L*/*D* ratio the pressure is indicated where the cathode glow or

luminescence does not overlap. At this pressure, the current density remains stable, and no overheating occurs. The data in Fig. 26 were generated in a CH_4 plasma with the diameter of the cavities varying from 3.2 mm (0.125 in.) to 9.5 mm (0.375 in.). As indicated in Fig. 26, the safe region for a specific *L*/*D* is to the right of the curve at each temperature. As indicated above, the thickness of the cathode visible glow or luminescence is a function of the pressure, gas composition, and temperature. The glow luminescence becomes thicker as the temperature increases due to the kinetic activity. Thus, a hollow cathode may exist at one pressure and temperature, but disappear as the temperature is lowered or the pressure is increased. Figure 26 gives a starting point, however, the visual observation of the load is still required to ensure against hollow-cathode effects.

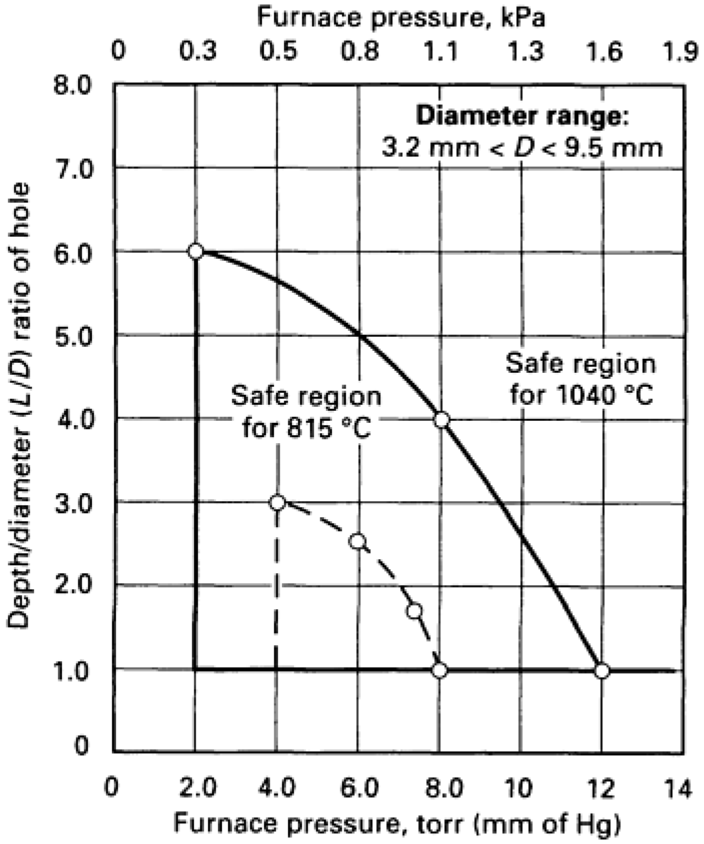

Fig. 26 Hollow cathode regions as a function of pressure for two different operating temperatures

Properties of Ion Carburized Parts. Aside from the faster carburizing rates associated with the fast rate of reaching carbon saturation, plasma (ion) carburizing offers some additional metallurgical advantages. Because the glow-discharge parameters can be adjusted to give more control of the carburizing mechanism (carbon saturation and, in turn, diffusion), greater uniformity of the carburized case can be achieved.

Because carburizing and oil quench hardening occurs under a vacuum, grain boundary oxides do not form in plasma carburizing. This elimination of intergranular oxides improves fatigue performance in the unground condition (see, for example, Ref 15). In atmosphere carburizing, grain boundary oxides to a depth of 0.05 mm (0.002 in.) to 0.12 mm (0.005 in.) are commonly found. The carbide level in the microstructure is no different than that found in atmosphere carburizing.

Parts in a load can be mechanically masked effectively by simply preventing the glow discharge from coming into contact with the areas not to be carburized, for example, by stacking or proper fixturing. Likewise, copper plating selected areas is effective for masking. The water-based and organic-based paint-on stop-offs have not been effective to date in masking for plasma carburizing. The plasma tends to spall off the coatings used and at high pressures the plasma gets under the coating and carburizes the area that was masked.

Microstructures and Properties of Carburized Steels

George Krauss, Advanced Steel Processing and Products Research Center, Colorado School of Mines

Introduction

CARBURIZING is a remarkable method of enhancing the surface properties of shafts, gears, bearings, and other highly stressed machine parts. Low-carbon steel bars are fabricated, by forging and machining, into finished shapes and then are converted by carburizing into a composite material consisting of a high-carbon steel case and low-carbon steel core. When this steel composite is quenched to martensite and tempered, the high hardness and strength of the case microstructure, combined with the favorable case compressive residual stress developed by interactions between the case and core during quenching, produce very high resistance to wear, bending fatigue, and rolling-contact fatigue.

The furnaces, atmospheres, control, and kinetics of carburizing are described in other articles in this Volume. The purpose of this article is to describe the microstructure, properties, and performance of carburized steels. At first glance, the microstructures of carburized steels appear to be quite straightforward: high-carbon martensite gradually replaced by martensite of lower carbon content with increasing distance from the carburized surface. This view of the microstructures of carburized steel is essentially correct. Lightly tempered martensite is the dominant microstructural constituent of properly carburized steel. However the martensite changes in morphology, amount, and properties as a function of distance from the surface. Other microstructural constituents may also be present and may significantly affect the performance of carburized parts. These other microstructural components include retained austenite; carbides of various origins, sizes, and morphologies; inclusions; processing-induced surface oxides; prior austenite grain boundaries embrittled by phosphorus segregation; and nonmartensitic transformation products of austenite, such as bainite and pearlite.

Because most carburized parts are subjected to cyclic loading, by far the most important property or measure of their performance is fatigue resistance. Hardness is another property commonly measured in carburized steels and is used as a quality control parameter to document carburizing success and to establish case depths. However, although many carburized steels have the same hardness profiles, they may have different microstructures and perform quite differently. Mechanical properties as measured by tensile testing are of little value because of the gradients in microstructures and properties between the surface and center of carburized steels. Thus strength and fracture toughness, which are useful in estimating critical flaw or crack sizes, are largely inferred from measurements on through-hardened steels of medium and high carbon content, although some measurements of fracture toughness have been made on carburized specimens (Ref 1, 2).

Throughout this article, the various microstructural components are described. Where possible, the effect of microstructure on properties, primarily hardness and fatigue resistance, are incorporated into the discussion of a particular microstructural feature.

Much of the published work on carburizing is devoted to processing (Ref 3, 4), aided by computer modelling and control technology (Ref 5, 6). Nevertheless, the understanding of the role microstructure plays in optimizing the performance of carburized steels continues to grow. Parrish thoroughly reviewed microstructures and properties of carburized steels up to 1977 (Ref 7) and, with Harper, authored a comprehensive treatment of all aspects of gas carburizing (Ref 8). An atlas of the microstructures of carburized steels has also been published (Ref 4). Proceedings of recent conferences on carburizing include articles on structure-property correlations as well as processing advances (Ref 1, 5, 6). The above list of major references is far from exhaustive, especially in view of the many articles published in journals, but it provides a good starting point for readers interested in more information regarding the processing, selection, and performance of carburized steels.

Carbon and Hardness Profiles

The object of carburizing is to produce a high-hardness, high-carbon case on a low-carbon steel core with low-to-medium hardness. This objective is accomplished by the introduction of carbon into austenite by various gas-metal surface reactions (Ref 9, 10) and the diffusion of carbon through the austenite from the surface into the core (Ref 9, 11). The austenite is then quenched and is converted to microstructural gradients by solid-state phase transformations during cooling. The microstructural gradients in turn produce hardness gradients. Figures 1 and 2 show, respectively, typical carbon and hardness gradients from test bars of gas-carburized SAE 8620 steel. The microstructural gradients associated with such carbon and hardness gradients are described in the section below. Residual-stress gradients, which develop because of transformation and temperature gradients during quenching, are described in the section "Residual Stresses" in this article.

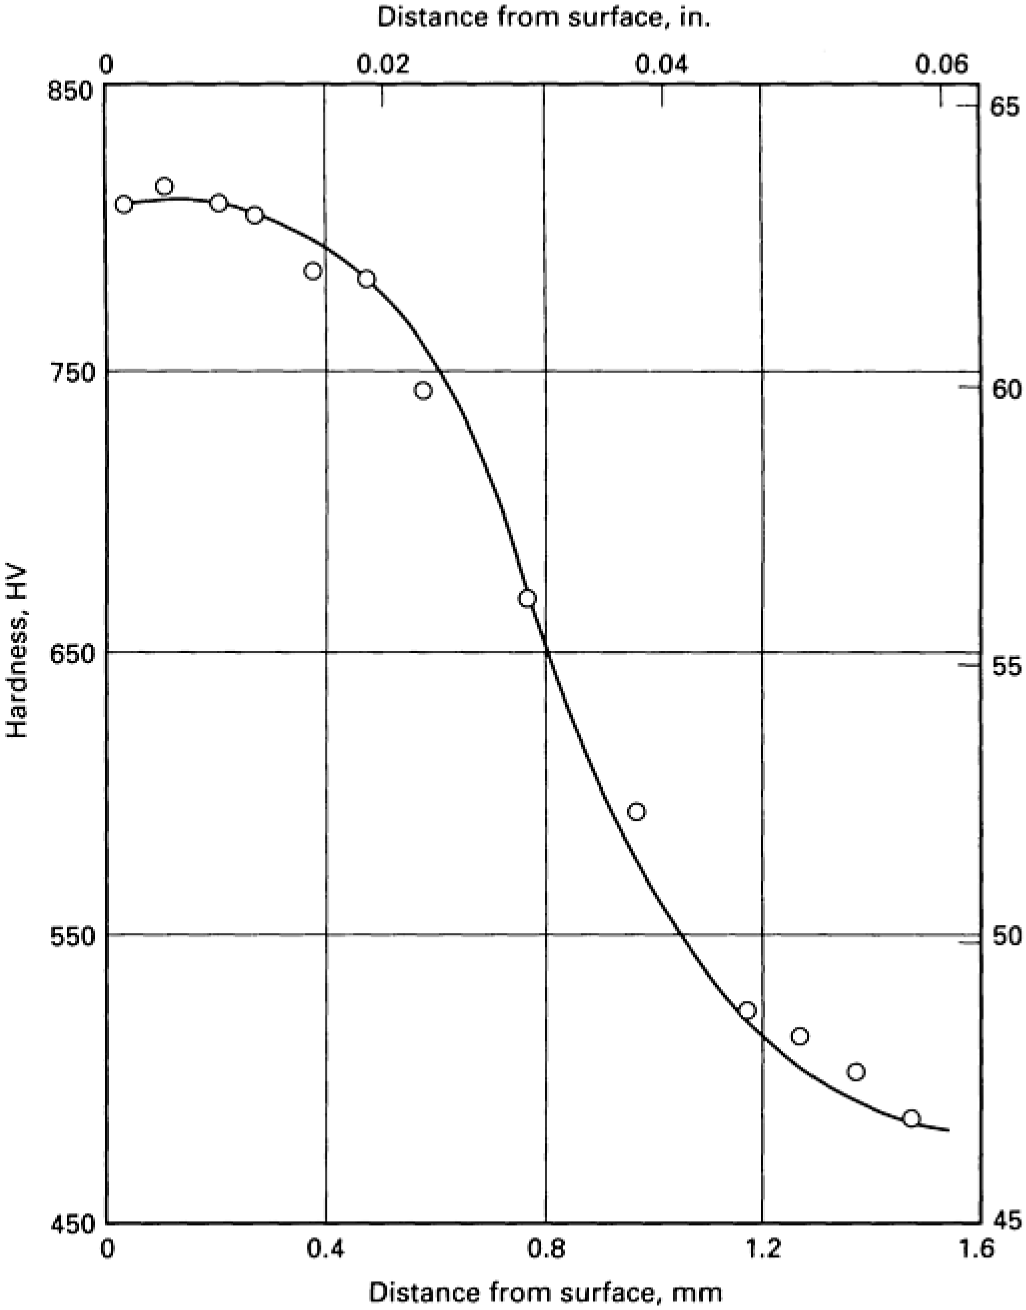

Fig. 2 Microhardness profile of 16 mm (0.63 in.) test bar of 8620 steel after gas carburization at 925 °C (1700 °F). Source: Ref 12

Case Depth Measurement. There are several ways to measure the depth of the case produced by a given carburizing schedule (Ref 4). Total case depths can be estimated from etching differences between the case and core. One of the most commonly accepted techniques is to section a part or test bar and measure the hardness profile. The perpendicular distance from the surface to the point where the hardness drops to a given hardness, often specified as 50 HRC (510 HV), is defined as the case depth (see the article "Methods of Measuring Case Depth" in this Volume for further information).

Factors Affecting Case Depth. Many factors, especially those that control surface carbon concentration, such as time and temperature during the various stages of a carburizing process, affect case depth. Frequently the first stage of carburizing introduces a high surface carbon content, on the order of 1.1 to 1.2 wt%, depending on the maximum solubility of carbon in austenite at the temperature of that stage. Such carbon contents would produce undesirable quenched microstructures. Therefore to produce optimum surface carbon concentrations of 0.8 to 0.9%, the second stage of carburizing is performed with lower carburizing atmosphere carbon potentials. Carbon already introduced in the first stage then adjusts to the lower surface potential and also diffuses deeper into the core. This two-stage approach is commonly referred to as the boost-diffuse method of carburizing.

Hardenability, as measured by the hardness method, also affects case depths. Generally, it is assumed that austenite of a given carbon concentration transforms to martensite of a given hardness. However, in carburizing steels with low hardenability or in massive carburized parts, which cool slowly, the austenite may transform to bainitic or pearlitic microstructures of lower hardness than martensite. Therefore, identical carbon gradients may produce quite different hardness gradients, depending on hardenability considerations.

Part shape or geometry also affects case depth. Access of the carburizing atmosphere or the quench severity may be affected by complex part shapes. For example the case depths of carburized gear teeth vary between the pitch line and root areas. Figure 3 shows recommended locations for hardness traverses and core hardness measurements for gear teeth, and Fig. 4 shows differences in pitch line and root traverses for a carburized 8620H gear. The effective case depth is less at the root than at the pitch line.

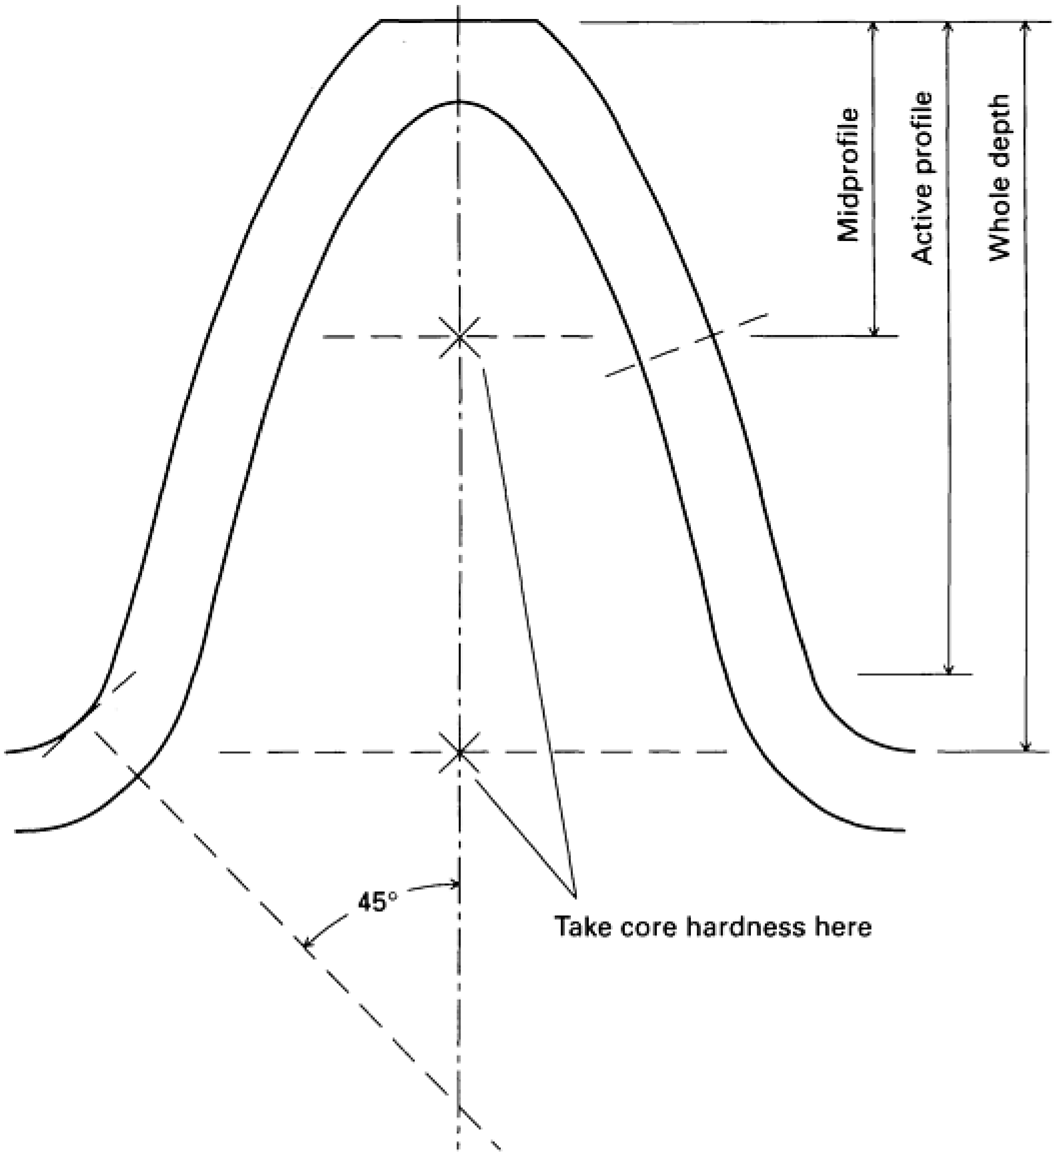

Fig. 3 Recommended locations for hardness traverses (dashed lines normal to tooth surface at midprofile, the pitch line, and root radius) and core hardness measurements of a gear tooth. Source: Ref 13

Martensite and Austenite

Figure 5 shows the typical martensite-austenite microstructure formed close to the surface of carburized steels quenched directly after carburizing. The high-carbon martensite (dark) is formed by a diffusion-less, shear transformation of the austenite and has a morphology characterized by nonparallel plate-shaped crystals (Ref 15, 16). The martensite plates have $\{225\}_A$ and $\{259\}_A$ habit planes with many equivalent variants and therefore assume the many orientations shown in

the micrograph. The sizes of the martensite plates are determined by the austenite grain size and the continuous formation of additional plates with decreasing temperature. The first plates form at the martensite start (M_s) temperature and span the austenite grains; the longest dimension of these plates is therefore equivalent to the austenitic grain size. With decreasing temperature, more martensite plates form between large plates, and they become finer as the austenite is increasingly partitioned by more transformation. According to this sequence of martensite formation, the finer the austenite grain size, the finer is the array of martensite plates.

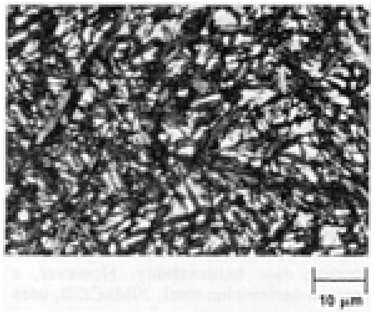

Fig. 5 Plate martensite-austenite microstructure in case of carburized and direct-quenched SAE 4121 (formerly EX24 steel) (0.89Mn-0.55Cr-0.24Mo). Light micrograph. Source: Ref 14

The white areas of Fig. 5 are regions of austenite that have not transformed. This austenite is referred to as retained austenite and is present because of the high stability of high-carbon austenite. Increasing carbon content significantly lowers M_s temperatures and depresses the entire temperature range for martensitic transformation to below room temperature. Consequently there are always significant amounts of retained austenite in the cases of carburized steels quenched to room temperature. Retained austenite plays a significant role in the fatigue of carburized steels, as discussed below, and amounts on the order of 30 to 35% are common in the near-surface cases of specimens quenched directly after carburizing.

Carburized parts may be cooled to room temperature after carburizing and reheated for hardening (Ref 17). Such reheating treatments invariably refine austenitic grain size. If reheating is performed above A_{cm}, that is, the temperature that defines the boundary between the austenite and austenite-cementite phase fields in steels, the structure is completely converted to austenite. Grain size is kept fine by setting austenitizing temperatures just above A_{cm}.

Reheating carburized steels below A_{cm} causes spheroidized carbides to be retained in the case austenite. As a result, the carbon content of the austenite is reduced, M_s is increased, and the quenched microstructure has less retained austenite. Also the carbide particles inhibit grain growth and maintain very fine austenitic grain sizes. Figure 6 shows a martensite-carbide microstructure formed by reheating and quenching a carburized 8620 steel. The small, white, spherical particles are carbides retained during austenitizing and quenching. The matrix structure etches dark and consists of martensite and retained austenite too fine for resolution in the light microscope.

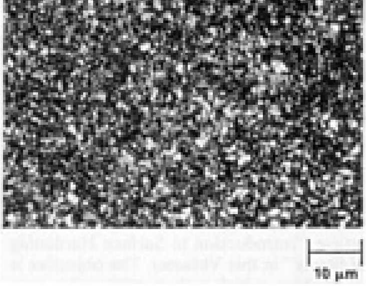

Fig. 6 Martensite-dispersed carbide microstructure in case of reheated and quenched carburized 8620 steel. The carbides are the circular, white features dispersed in the dark, martensitic matrix. Light micrograph. Source: Ref 14

The hardness and strength of martensite increase with increasing carbon content (Ref 16). Therefore the highest hardness of a hardened carburized steel is at or close to the surface. Hardness may peak at a distance from the surface if large amounts of retained austenite, which is much softer than martensite, offset the high hardness of martensite immediately adjacent to the surface where the carbon content, and therefore the retained-austenite content, are at their highest levels. With increasing distance from the carburized surface, the carbon concentration of the martensite decreases, and hardness drops (Fig. 2 and 4). Retained austenite also decreases with increasing distance from the surface; as the carbon

concentration of the austenite decreases (Fig. 1), the M_s temperature increases and more martensite forms on cooling to room temperature. Figure 7 shows retained austenite gradients in direct-quenched and reheated carburized 8620 steel specimens. The dramatic reduction of retained austenite content as a result of reheating below A_{cm} (double reheat) is apparent.

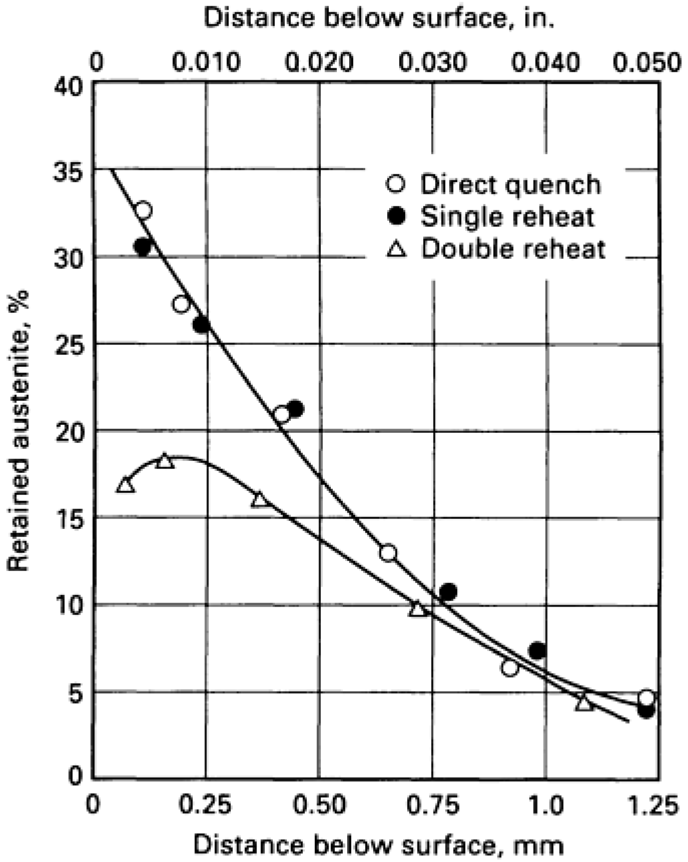

Fig. 7 Retained austenite, measured by x-ray diffraction, as a function of distance from the surface of an 8620 steel carburized at 925 °C (1700 °F). The single and double reheats were accomplished by heating to 845 and 790 °C (1550 and 1450 °F), respectively. Source: Ref 18

The core microstructures of carburized steels are determined by the low carbon content and base hardenability of the carburizing steel. If the steel has low hardenability, the low-carbon core may transform to ferrite and small amounts of pearlite, depending on quench rate. If the steel has high hardenability, the core may transform to martensite. For most highly stressed applications, a martensitic core is desired. Low-carbon martensite has higher strength and fracture resistance or toughness than do ferrite-pearlite microstructures. This increased strength is necessary to prevent subsurface crack initiation, sometimes referred to as case crushing (Ref 8, 13, 19). This mode of fracture occurs at case-core interfaces when heavy contact loads create stresses that exceed the strength of the microstructure at some distance below the surface. Subsurface crack initiation is prevented by producing deeper cases by carburizing for longer times, by using alloy steels with higher base hardenability that transform completely to martensite in the core as well as the case, or by increasing core carbon content. Thus strength is raised above applied stresses at critical subsurface locations.

Figure 8 shows the martensitic core microstructure of a carburized steel containing 1.06% Mn, 0.52% Cr, 0.50% Ni, and 0.17% Mo. The low-carbon martensite is referred to as lath martensite, and the morphology consists of fine laths arranged parallel to one another in regions termed packets (Ref 15, 16). The packets are visible in the light microscope, but most of the laths or individual crystals of martensite are too fine to be resolved by light microscopy.

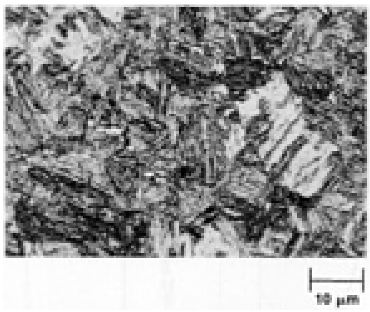

Fig. 8 Lath martensite microstructure in core of gas-carburized type 8719 steel containing 1.06% Mn, 0.52% Cr, 0.50% Ni, and 0.17% Mo. Light micrograph. Source: Ref 20

As-quenched carburized steels are generally tempered between 150 and 200 °C (300 and 400 °F). This final heat treatment step increases toughness slightly and relieves some residual stresses, but case hardness and compressive residual stresses are largely preserved. These changes in properties are accomplished by very fine scale changes of the microstructure. The major change consists of the precipitation of a transition carbide from the martensite supersaturated with carbon by quenching (Ref 16). This carbide, termed eta (η)-carbide, has been shown to have an orthorhombic crystal structure and to precipitate in rows of very fine particles, about 2 nm in size, within the martensite plates. These microstructural changes are much too fine to be resolved in the light microscope, but are reflected by an increased tendency of the martensite plates to appear black after etching. Retained austenite is not transformed by tempering at temperatures of 200 °C (400 °F) or lower. Therefore, the typical polished and etched case structure of a carburized steel consists of dark-etching martensite in a matrix of retained austenite, as shown in Fig. 5.

Figure 9 shows impact and fracture toughness measured for hardened 52100 steel as a function of tempering temperature. The microstructures consisted of retained carbides in a matrix of tempered martensite, typical of that formed in bearing steels or in the surface of carburized steel reheated below the A_{cm} (Fig. 6). The toughness of the 52100 steel was low, even after tempering at 200 °C (400 °F). Other studies show that plane-strain fracture toughness (K_{Ic}) for high-carbon martensite-austenite microstructures tempered between 150 and 200 °C (300 and 400 °F), equivalent to the near-surface case microstructures of carburized steels, ranges between 15 and 25 MPa $\sqrt{m}$ (14 and 23 ksi $\sqrt{in}$) (Ref 22).

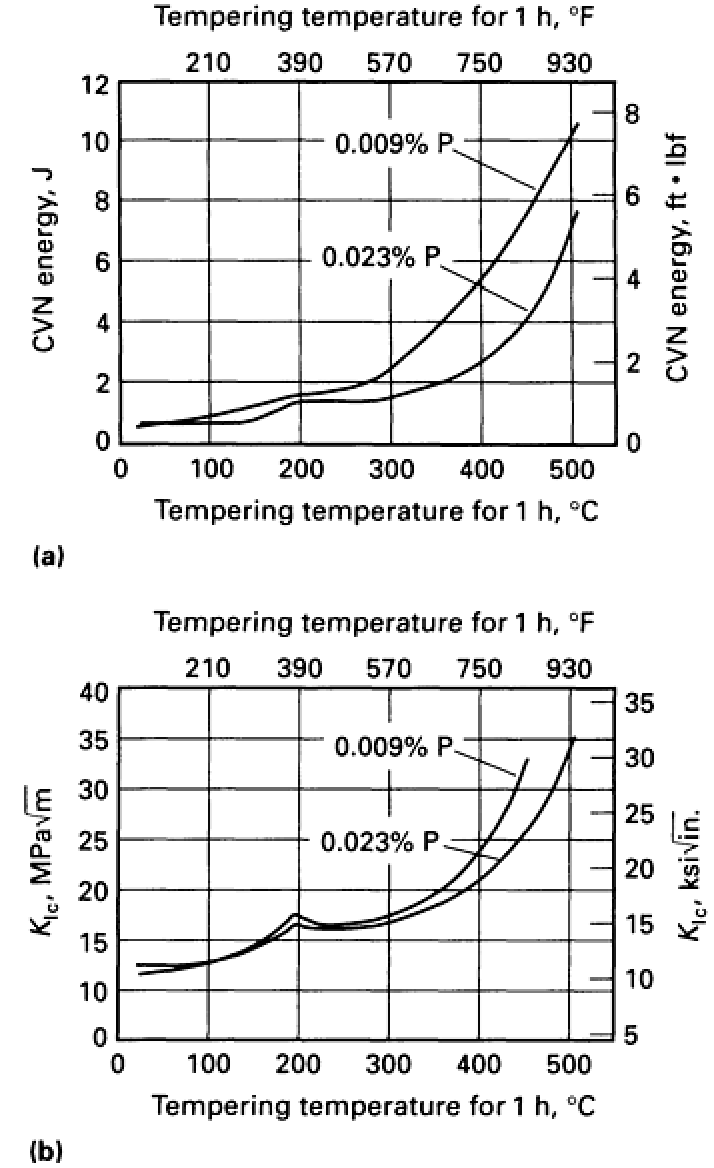

Fig. 9 Toughness of 52100 steel (oil quenched from 850 °C, or 1560 °F) with microstructures of dispersed spherical carbides in tempered martensite similar to microstructures formed in the case of carburized steels reheated below A_{cm}. Alloying Effects

The primary concern in alloy development and the selection of carburizing steels is hardenability. In carburizing steels, a given composition must provide adequate hardenability over a range of carbon contents because hardenability is important for both the case region and the core (see the article "Introduction to Surface Hardening of Steels" in this Volume). The objective is to produce a high-carbon martensitic case (for wear and fatigue resistance) and a low-carbon martensitic core to provide sufficient strength to resist case-core failures as described previously.

The goal of hardenability is the formation of hard martensite in preference to microstructures of lower hardness (Ref 16, 23, 24). The controlling factors may be metallurgical, such as the effects of substitutional alloying elements that retard solid-state, diffusion-controlled transformation of austenite to bainite, pearlite, or ferrite; or they may be technological, such as the selection of quenchants, or compensating for slow cooling rates in heavy sections, which provide time for diffusion-controlled transformation at the expense of martensitic transformation. The alloying elements traditionally used for improving hardenability in carburized steels are manganese, chromium, molybdenum, and nickel. Combinations of moderate amounts of several elements have been found to be more effective than large amounts of a single element. Boron is most effective in improving the hardenability of low-carbon steels but loses its effectiveness as carbon content increases. Therefore, it is not expected to improve case hardenability. However, a German carburizing steel, 20MnCr5B, uses boron to remove nitrogen from solution and thereby improve toughness (Ref 25).

Most carburizing steels are deoxidized with aluminum for grain size control. Aluminum combines with nitrogen to form aluminum nitride particles, which limit austenite grain growth during carburizing (Ref 16). Fine grain size reduces hardenability, and Cook has shown that the case hardenability of plain carbon steels is reduced because of the grain-refining effect of aluminum additions (Ref 26). This effect of aluminum on hardenability is not noted in alloy carburizing steels.

Alloy Effects on Hardenability. Hardenability is important for both the case and core regions of carburized steels, and a given steel must have adequate hardenability over a range of carbon contents. Figure 10 shows Jominy end-quench data for the core and for all carbon levels up to 0.9% for an SAE 4620 carburizing steel. The powerful, beneficial effect of increasing carbon on hardenability is shown. Nevertheless, in heavy sections, where cooling rates are low, even case regions may transform to microstructures other than martensite. Jatczak (Ref 27) has evaluated the effects of various alloying elements on the hardenability of high-carbon steels and has shown that higher austenitizing temperatures increase hardenability by dissolving alloy carbides and increasing the amount of carbon and alloying elements in solution in the austenite. Other investigators have also evaluated various aspects of the hardenability of carburized steels (Ref 28, 29, 30, 31).

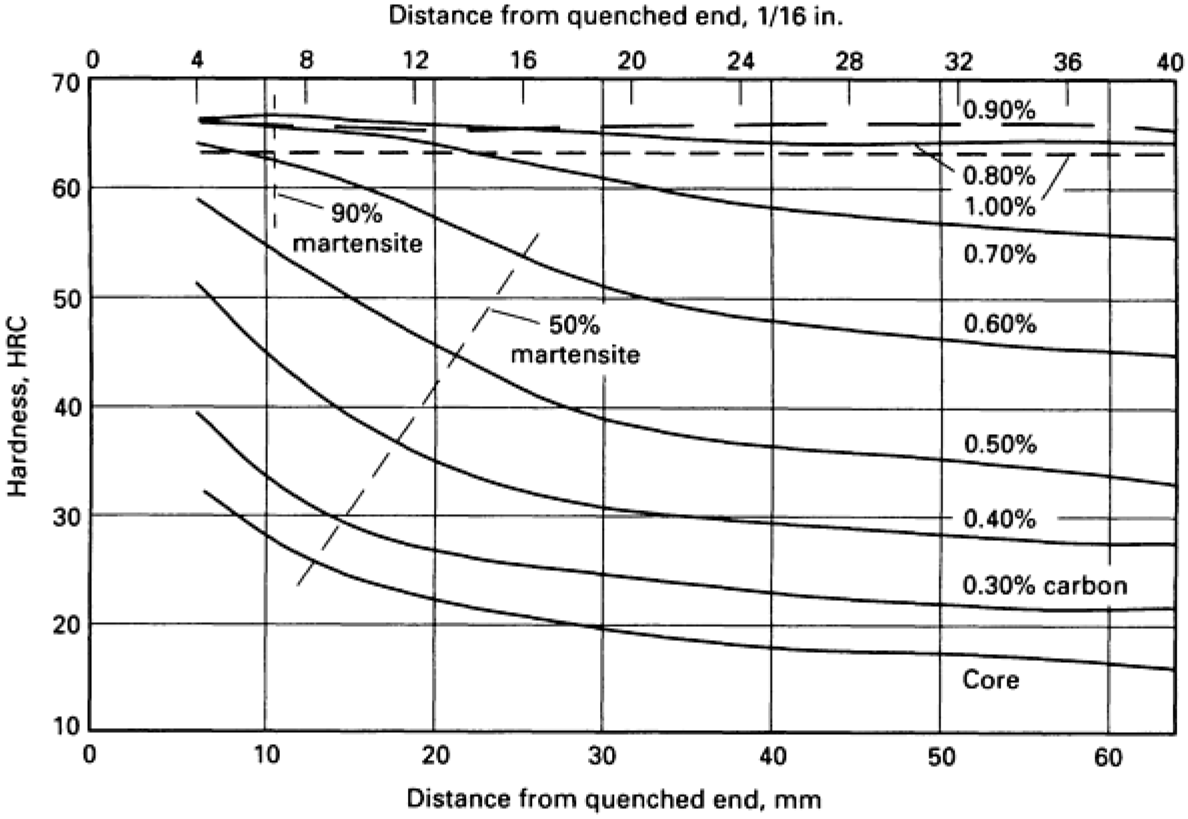

Fig. 10 Jominy end-quench curves showing hardenability differences as a function of carbon content in direct-quenched SAE 4620 steel. Source: Ref 2

Other Alloy Effects. Although hardenability is a major concern in alloying and the selection of carburizing steels, alloy elements also affect other aspects of microstructure. Many of the alloying elements, in particular chromium and molybdenum, are strong carbide and ferrite formers. Those elements shift A_{cm} temperatures (Fig. 11) and raise Ae_1 temperatures, the lowest temperatures at which austenite is stable under equilibrium conditions. The shift in A_{cm} by carbide-forming elements limits the amount of carbon that can be dissolved in austenite and increases the possibility of carbide formation in carburized steels.

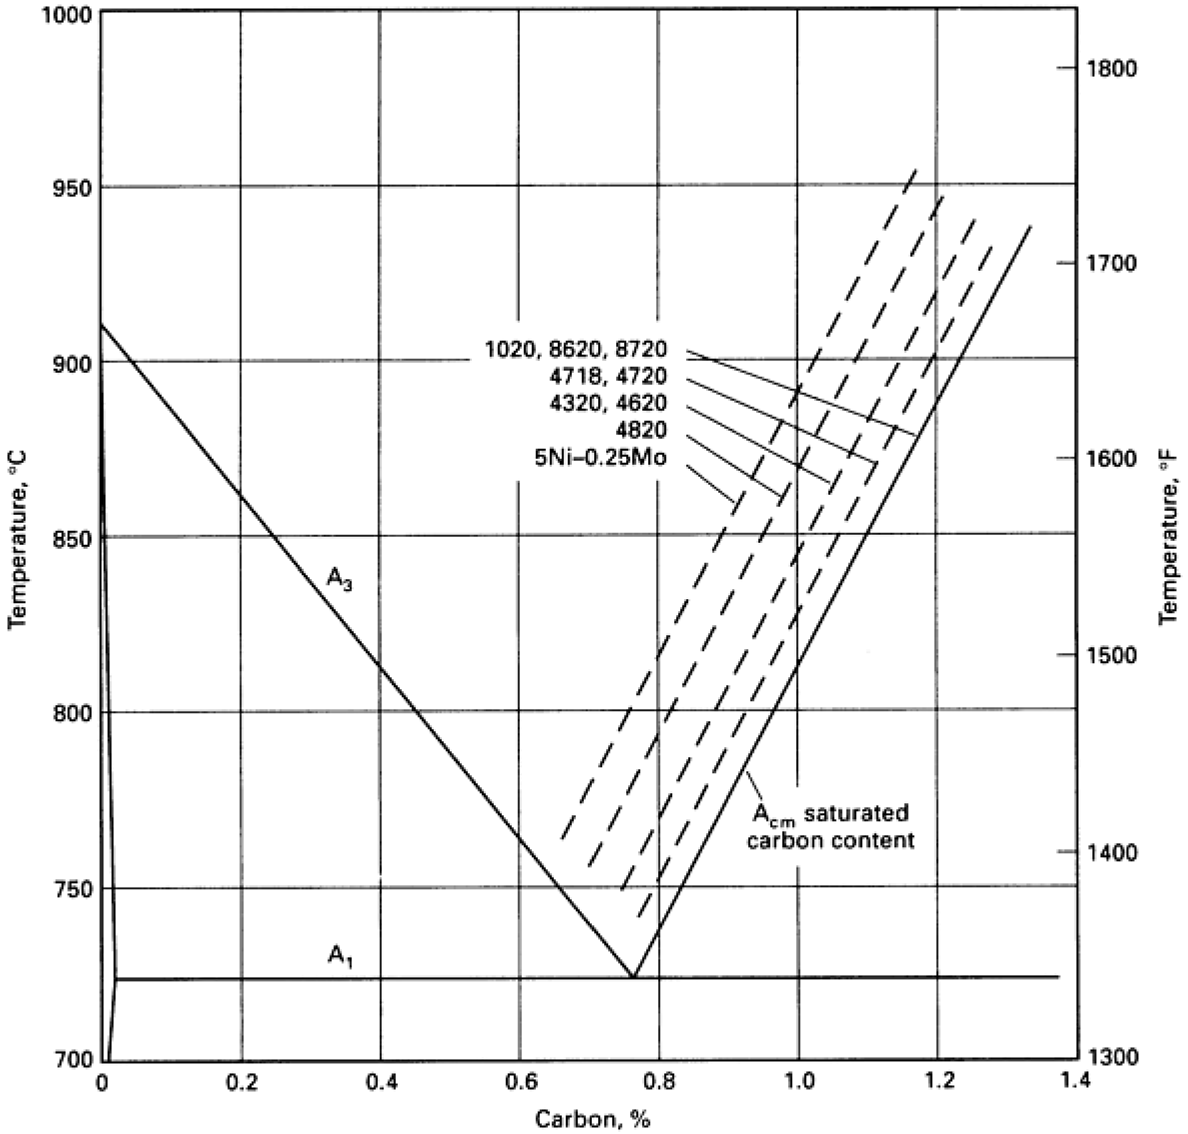

Fig. 11 The shift in A_{cm} temperatures with alloying in various carburizing steels. Source: Ref 32

Many alloying elements also lower M_s temperatures and the transformation temperature ranges for martensite formation (Ref 16, 33). Therefore increased alloying increases the amounts of austenite that are retained in carburized and hardened steels.

Intergranular Fracture at Austenite Grain Boundaries

Figure 12 shows an example of intergranular fracture at prior austenite grain boundaries in the case overload fracture zone of a carburized 8620 steel. Such intergranular cracking is a major fracture mode of high-carbon hardened steels that have been quenched from temperatures at which the microstructure consists only of polycrystalline austenite. Thus cracking can occur in the case regions of steel directly quenched after carburizing, but rarely in carburized steels that have been reheated to produce finer-grained structures with retained carbides (Ref 17, 22). Fracture in the latter microstructures is low-toughness ductile fracture characterized by closely spaced microvoids that form around the dispersed carbide particles. Intergranular fracture occurs even in carburized steels tempered between 150 and 200 °C (300 and 400 °F), tempering temperatures that are too low to cause tempered martensite embrittlement (Ref 16).

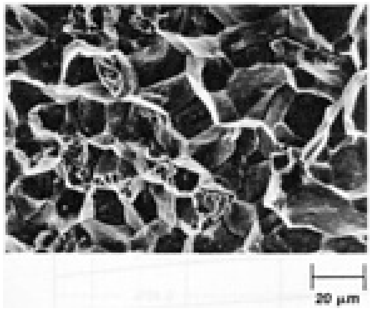

Fig. 12 Intergranular fracture from the overload fracture zone in the case of a carburized SAE 8620 steel. Scanning electron microscope (SEM) micrograph. Source: Ref 14

The reasons for the intergranular fracture of high-carbon case microstructures have been difficult to establish because no associated grain-boundary features are discernible in the light microscope. However, several studies suggest that the sensitivity to grain-boundary fracture is due to a two-step process (Ref 17, 34, 35): first, the segregation of phosphorus to austenite grain boundaries during carburizing or austenitizing for hardening and, second, the nucleation and growth of very thin cementite particles on austenite grain boundaries during quenching. The phosphorus segregation and carbide formation are largely on an atomic scale, but their combined effect is sufficient to produce interfaces that fracture at lower stresses than do the matrix martensite and austenite.

The key to the identification of microstructural features leading to intergranular fracture has been the application of Auger electron spectroscopy (AES), an analytical technique that has very high depth resolution. Auger electrons of specific energies are emitted from specific atoms on a surface that is irradiated with an electron beam in a high vacuum chamber. The Auger electrons have very low energy and originate from a depth of less than 1 nm from the surface of a specimen (Ref 36).

Figure 13 shows Auger spectra from case fracture surfaces of a carburized 8620 steel. The spectra in Fig. 13(a) is from a transgranular fracture surface, while that in Fig. 13(b) is from an intergranular fracture surface. No phosphorus peak is detectable in the spectrum produced from the transgranular fracture, and a small phosphorus peak, clearly shown by the 10× magnification, is produced from the intergranular fracture surface. These observations are consistent with other investigations that show that phosphorus segregates to austenite grain boundaries during austenitizing (Ref 35, 37). A

major difference between the two spectra is the significantly larger carbon peak in the Auger spectrum from the intergranular fracture surface. The carbon peak shape, characterized by a major peak and several auxiliary peaks, is identical to that produced by AES of cementite (Ref 35). Thus AES analysis provides evidence for cementite formation on austenite grain boundaries.

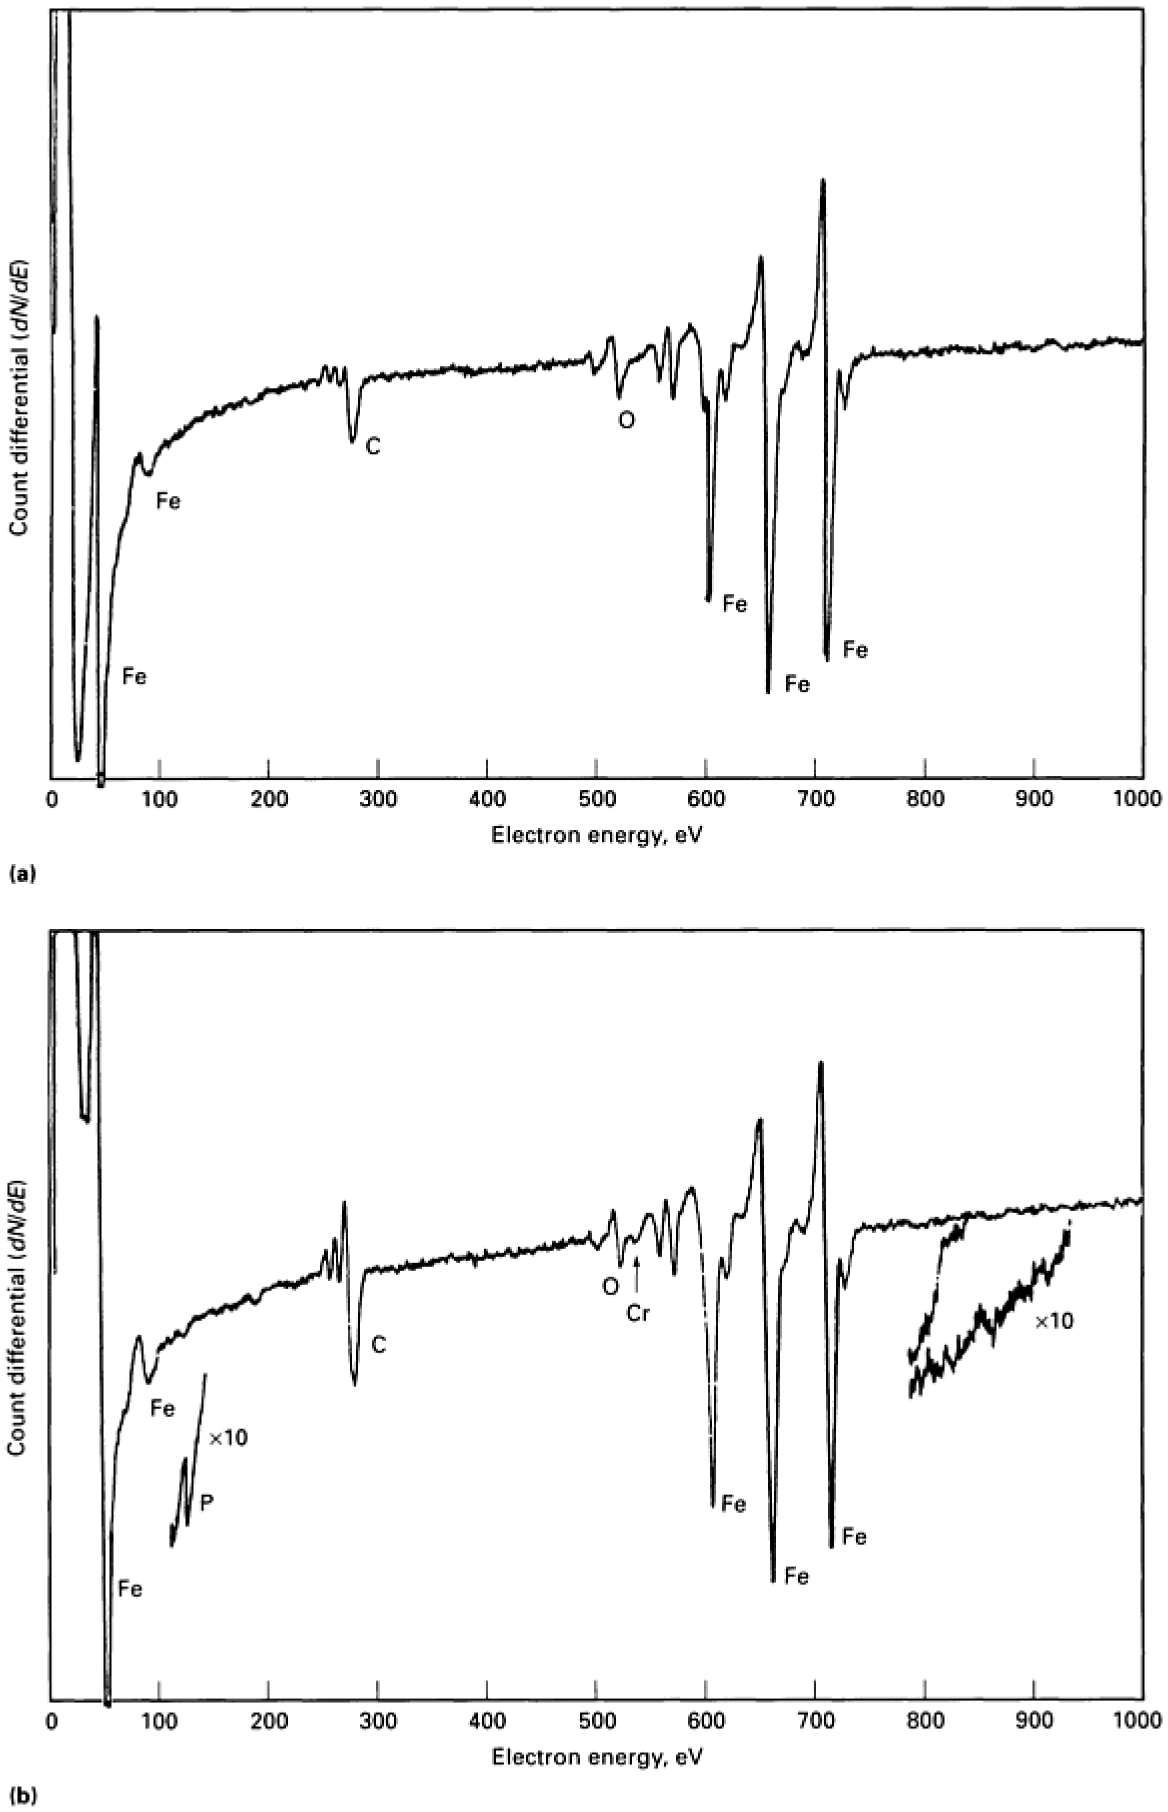

Fig. 13 Auger electron spectra from case fracture surfaces of carburized 8620 steel. (a) From transgranular fracture surface. (b) From intergranular fracture surface. Source: Ref 17

A fracture toughness study on a set of EX24-type steels (or SAE 4121) containing 0.85% C with 0.044 and 0.002% P verified the above observations (Ref 34). The high carbon content was designed to simulate the high-carbon case of carburized specimens. High phosphorus content greatly increased the amount of intergranular fracture. Intergranular fracture was significantly reduced, but not completely eliminated, in the low-phosphorus steel. Oil-quenched specimens developed more intergranular fracture than brine-quenched specimens, a result explained by increased coverage of austenite grain boundaries by cementite due to more time for diffusion during quenching at slower rates.

Ando (Ref 38, 39) has modelled the growth kinetics of cementite allotriomorphs in high-carbon, iron-chromium-carbon alloys. Figure 14 shows that growth takes place in several stages. At first, rapid thickening occurs in a stage controlled only by carbon diffusion, and no partitioning of chromium takes place. However, equilibrium considerations eventually require the diffusion of chromium to the carbide particles, and at that stage the growth of grain-boundary cementite slows significantly. Therefore, the formation of very thin cementite particles, even during the oil quenching of carburized steels, is explained by the very rapid first-stage growth, shown in Fig. 14. High phosphorus content has also been shown to accelerate the formation of cementite grain-boundary allotriomorphs (Ref 35).

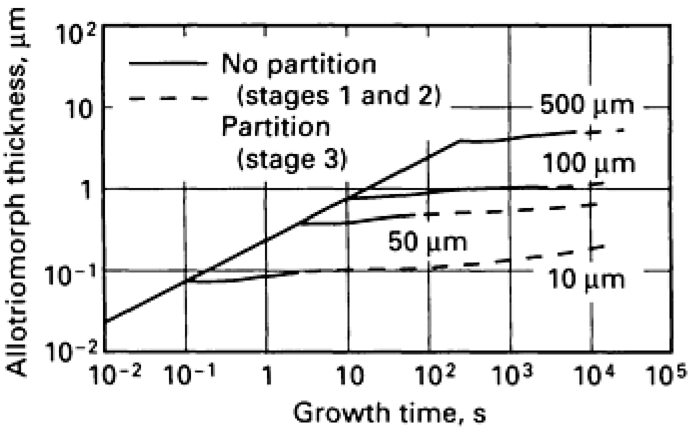

Fig. 14 Simulated growth curves for cementite allotriomorph formation on austenite grain boundaries in an iron-chromium-carbon alloy (Fe, 4.5 at.% C, 1.5 at.% Cr) at 740 °C (1365 °F). Source: Ref 38

Prevention of Intergranular Fracture. As described later in the section "Fatigue Mechanisms," intergranular fracture frequently initiates fatigue cracks in carburized steels. Lower phosphorus contents would reduce intergranular cracking, but the reduction of phosphorus to extremely low levels that might completely eliminate intergranular cracking is dependent on the economics of steelmaking. Reheating carburized specimens with nominal phosphorus contents to produce very fine austenite grain sizes eliminates intergranular cracking (Ref 18, 20), perhaps because of the dilution of phosphorus segregation by a high grain-boundary area. Finally, alloying might be used to eliminate intergranular fracture. Carburizing steels with high nickel contents have high toughness and do not seem to be sensitive to intergranular fracture (Ref 40, 41).

Microcracking in Carburized Steels

Microcracks frequently form in martensite plates of high-carbon steels. Examples of martensite microcracks are shown in Fig. 15. Marder and Benscoter have shown by serial metallographic sectioning that the cracks form at points of contact between impinging martensite plates (Ref 43). Because the microcracks are formed by the impingement of nonparallel plates of martensite, microcracking density decreases with the transition from plate to lath martensite (Ref 44). Fine austenite grain size also limits microcracking (Ref 42, 45), apparently because smaller martensite plates do not create sufficient stresses to produce cracks.

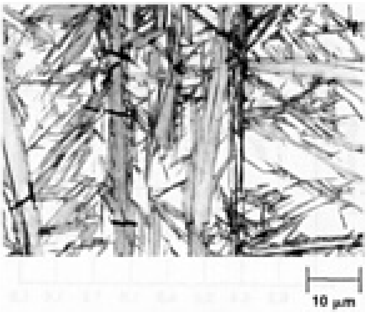

Fig. 15 Microcracks in martensite plates of an Fe-1.86C alloy. Light micrograph. Source: Ref 42

Microcracks have long been known to be present in the case microstructures of carburized steels (Ref 18, 46, 47), especially in coarse-grained microstructures with large martensite plates. The presence of microcracks may contribute to impaired fatigue performance of carburized steels. However, microcracks may have only a very secondary effect on fatigue, in light of the fact that many fatigue cracks initiate at embrittled austenite grain boundaries, as discussed in the previous section. Such grain-boundary cracks effectively bypass the microcracked martensite plates within austenite grains, and therefore the presence or absence of microcracks is immaterial to fatigue crack initiation. On the other hand, the influence of microcracks in martensite plates on transgranular crack propagation would be expected.

A study of grain size effects on microcracking in an Fe-1.22% C alloy provides a link between microcracking and grain-boundary fracture (Ref 45). In that study microcracks were found both in martensite plates and at prior austenite grain boundaries. As grain size decreased, both types of microcracks decreased, but the number of grain-boundary microcracks became a higher fraction of the total. The intergranular microcracks may have formed partly because of martensite plate impingement on embrittled grain boundaries. If such grain-boundary microcracks are present in carburized steels, intergranular fatigue crack initiation will occur at lower stresses.

Excessive Retained Austenite and Massive Carbides

Moderate amounts of retained austenite are proper and unavoidable in the high-carbon case microstructure of carburized steels. However, excessive amounts of retained austenite, that is, greater than 50%, lower hardness significantly and reduce bending fatigue resistance. The most important cause of excessive amounts of retained austenite is too high a surface carbon content. This condition drives M_s temperatures down and shifts the balance of the temperature range for martensite transformation to well below room temperature. High alloy content also lowers M_s temperatures.

Common locations of excessive surface carbon concentration are specimen corners at which the austenite is saturated with carbon during the first part of a carburizing cycle (Ref 48, 49). The carbon has access to both surfaces of the corner during carburizing but has little physical access to the interior of the specimen during the diffusion part of a cycle. As a result, although carbon content falls to desired levels on the flat or gradually curved surfaces of a part, the carbon content at a corner remains much higher than desired. Figure 16 shows carbon contours determined at the corners of an 8620 steel specimen carburized at 1050 °C (1920 °F). Carbon contents as high as 1.20% were measured at the corner. Excessive retained austenite in the corner microstructure of a 4121 carburized specimen is shown in Fig. 17. Figure 18 shows hardness profiles from corner and plane surface regions of 8620 steel carburized at 930 °C (1700 °F). The corner surface hardness is much lower than that of the plane surface because of high retained austenite content. Reheating of direct-quenched specimens eliminates excessive retained austenite and raises surface hardness (Ref 48, 49).

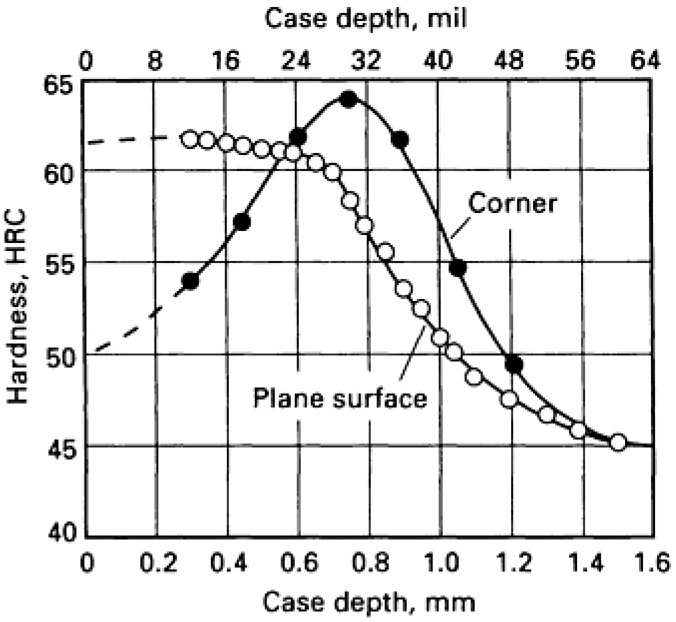

Fig. 18 Corner and plane surface microhardness profiles from 8620 steel specimen carburized at 930 °C (1700 °F). Source: Ref 48

Another consequence of too high a surface carbon content is the formation of massive carbides. The carbides form at austenite grain boundaries and may have different morphologies, depending on alloy content. As discussed relative to Fig. 14, large carbide grain-boundary allotriomorphs require considerable diffusion to grow, and therefore they form during the high-temperature stages of carburizing or when the temperature of the part is lowered to about 845 °C (1550 °F) just prior to quenching. Figure 19 shows two morphologies of massive carbides that have formed in the corners of carburized specimens. Figure 19(a) shows blocky, angular particles formed in an 8620 steel containing nominally 0.5% Cr, 0.5% Ni, and 0.2% Mo. Figure 19(b) shows long, thin carbides formed in an SAE 4121 steel containing 0.55% Cr and 0.24% Mo but no nickel.

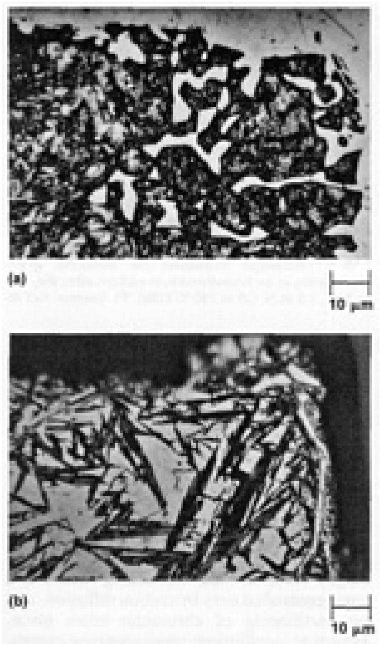

Fig. 19 Examples of massive carbides formed at the corners of carburized specimens. (a) Blocky carbides in 8620 steel. (b) Thin, continuous grain-boundary carbides in SAE 4121 steel. Light micrographs. Source: Ref 49

Effect on Fatigue Cracking. The combination of excessive retained austenite and massive carbides, together with stress concentration at sharp changes in section, causes fatigue crack initiation at specimen corners. Figure 20(a) shows

fatigue initiation at the corner of a carburized specimen of SAE 4121 steel. Details of the corner fracture along the massive carbides are shown in Fig. 20(b). Carbide grain-boundary allotriomorphs grow by ledges, which make up the interface between the carbides and the martensite-austenite matrix (Ref 39). These ledges provide preferred fracture paths, as shown in Fig. 20(b).

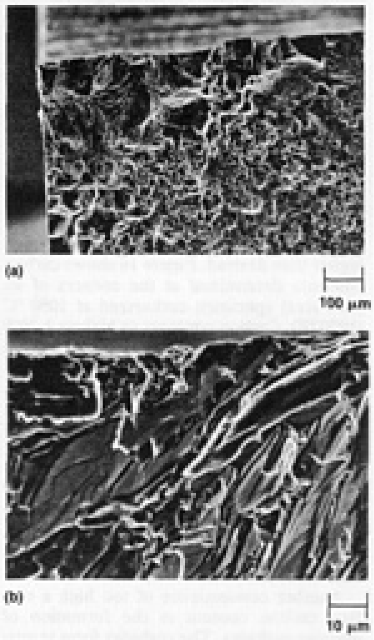

Fig. 20 Fracture surfaces of carburized SAE 4121 steel. (a) Low-magnification view of corner initiation. (b) Detail of fracture at carbide-matrix interface. SEM micrographs. source: Ref 48

Although massive network carbides are detrimental to the bending fatigue and fracture performance of carburized steels in many applications, a process referred to as super carburizing is occasionally used for special applications (Ref 50). This process supersaturates a part surface with carbon and results in the formation of large volumes of massive carbide particles. Surface carbon contents of 1.80% to greater than 3.0% are produced, and steels with large amounts of carbide-forming elements such as chromium and molybdenum respond most effectively. High volume fractions of hard alloy carbide particles significantly increase resistance to abrasive wear, but also may create problems in the grinding of the very hard surfaces.

Residual Stresses

A major benefit of carburizing is the introduction of compressive residual stresses into the surfaces of carburized parts. These stresses counteract applied tensile stresses and therefore improve bending fatigue performance. Because of the importance of residual stresses to the performance of carburized parts, considerable effort has been devoted to modelling, measuring, and understanding their effects (Ref 1, 7, 8, 51, 52, 53, 54).

Figure 21 shows schematically the residual stress profiles that develop in properly carburized and hardened steels. The compressive stresses reach a maximum at some distance from the surface, gradually decrease, and are eventually

balanced by tensile residual stresses in the core of the carburized part. A survey of a number of carburized parts showed that measured peak compressive stresses ranged from -200 to -450 MPa (-29 to -65 ksi) (Ref 8).

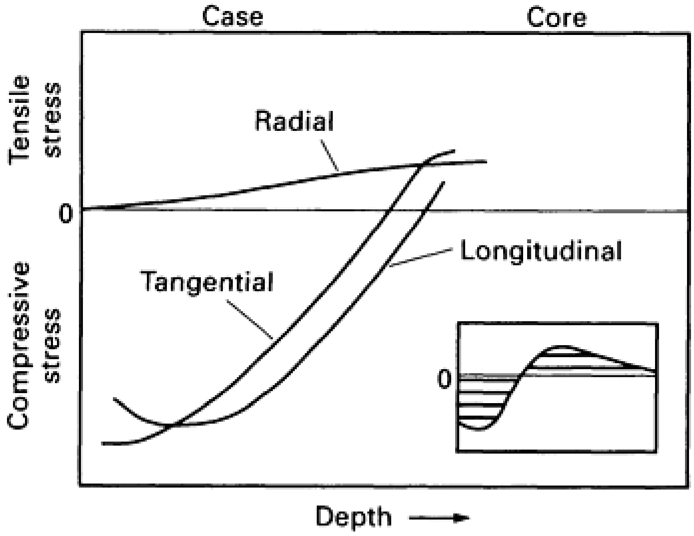

Fig. 21 Schematic diagram of residual stresses in carburized steels. Insert shows that surface compressive residual stresses are balanced by interior tensile stresses. Source: Ref 8

Surface compressive residual stresses in carburized steels arise from transformation and temperature gradients induced during cooling and the volume expansion that accompanies the transformation of austenite to martensite (Ref 55). The carbon profiles produced by carburizing introduce the M_s temperature and transformation gradients: the M_s temperature is lowest at the surface, where carbon content is the highest, and increases with increasing distance from the surface as carbon content approaches that of the core. Temperature gradients are due to heat flow and thermal-conductivity factors; at any given time during quenching, the surface temperature is lower than temperatures in the part interior.

In the early stages of cooling, martensite first forms at some distance from the surface, where the part temperature has fallen below the higher, interior M_s temperatures. The volume changes at this stage are readily accommodated by the surrounding austenite because of its low flow stresses and the high temperatures. The surface austenite does not transform because of its low M_s. The temperature continues to fall and eventually drops below the M_s in the surface regions. The expansion at this point is constrained by the interior martensite that has formed earlier, and as a result the surface microstructure is placed in compression. Many factors affect this process, including alloy and carbon levels, which set hardenability and M_s temperatures; case depths; temperature at the start of quenching; quenchant temperature; and the temperature-dependent plastic flow behavior of martensite and austenite. Despite the complexity of the interactions that affect the formation of residual stresses, hardened carburized parts with the martensite-austenite microstructures described earlier generally develop favorable compressive stresses.

Surface compressive residual stresses can be increased by shot peeping. Figure 22 shows the dramatic effect of shot peening at different velocities on the compressive residual stresses of carburized steel. These improvements in stresses translate into improved bending fatigue performance.

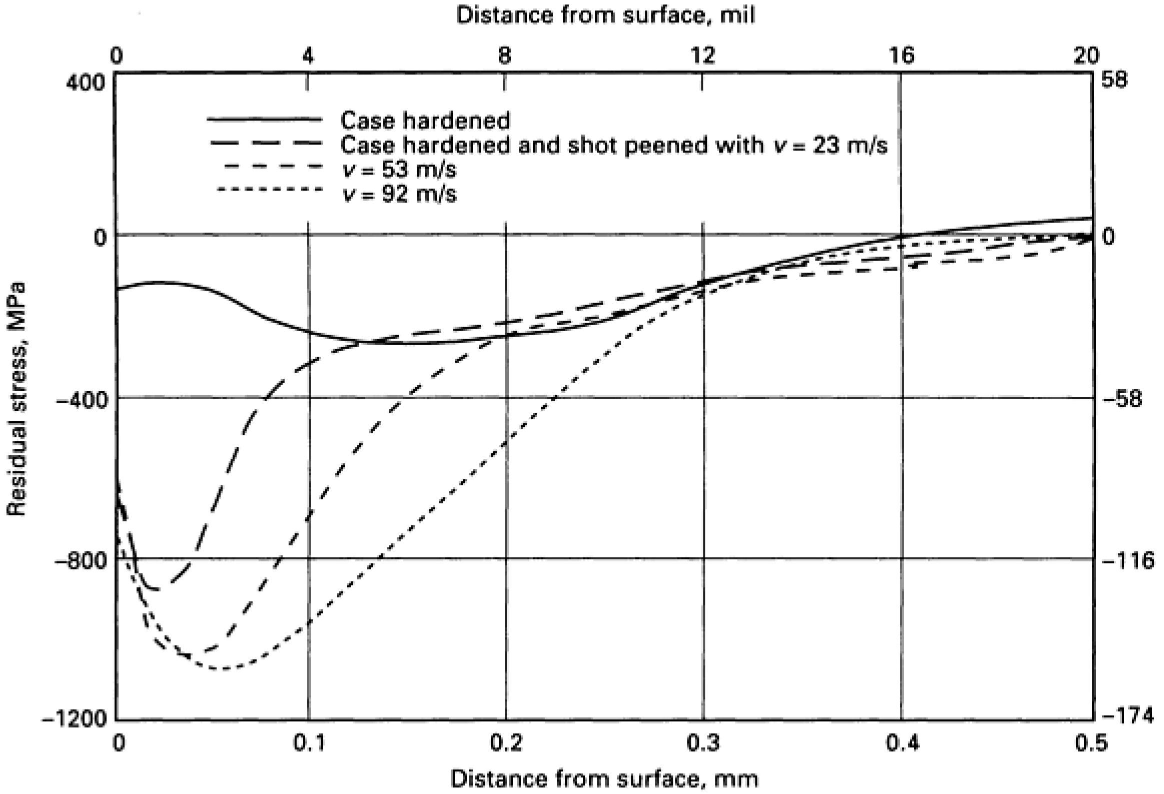

Fig. 22 Effect of shot peening at different velocities on compressive residual stresses in carburized 16MnCr5 steel (1.23% Mn, 1.08% Cr). Source: Ref 52

Residual stresses can be adversely affected by surface oxidation during gas carburizing. As discussed in the next section, certain alloying elements are preferentially oxidized and removed from solid solution in the austenite. As a result, hardenability decreases, and, in severe cases, pearlite instead of martensite forms at the surface (Ref 56). Thus the surface transformation occurs at high temperatures, and the beneficial effect of austenite-to-martensite transformation late in the quenching process is lost. Even if the oxidation is not severe enough to cause pearlite formation, surface M_s temperatures may be raised by the removal of some of the alloying element, resulting in a thin surface zone with lower compressive stresses.

Subzero, or cryogenic refrigeration is sometimes used to lower retained austenite contents (Ref 7). As a result, surface hardness increases. Also, dimensional stability in service is increased because there is less austenite available to transform to martensite by stress- or strain-controlled mechanisms. However, a number of investigations have shown that the refrigeration treatment of carburized parts lowers fatigue performance (Ref 48, 57, 58). The transformation of additional surface retained austenite would be expected to continue the process established during quenching to room temperature; that is, the volume expansion associated with the formation of new martensite would be constrained, and compressive stresses would be increased. Increased compressive stresses are in fact measured in the martensite of refrigerated specimens (Ref 7, 57, 58). However, Kim *et al.* (Ref 57) have shown that the stresses in the remaining retained austenite are tensile. Such localized tensile stresses would lower the applied stresses required to initiate and propagate fatigue cracks.

Surface and Internal Oxidation

The H_2O/H_2 and CO_2/CO equilibria in gas carburizing atmospheres cause the internal oxidation of certain alloying elements in carburizing steels (Ref 7, 59). Figure 23 shows the oxidizing potentials for various elements in endothermic gas at 930 °C (1700 °F). Chromium, silicon, and manganese, all commonly found in carburizing steels, oxidize readily, while molybdenum, nickel, and iron are not oxidized. The oxidation is diffusion dependent, and therefore the depth and extent of oxide formation is a function of carburizing time and temperature. The oxides may form on austenite grain boundaries or within austenite grains.

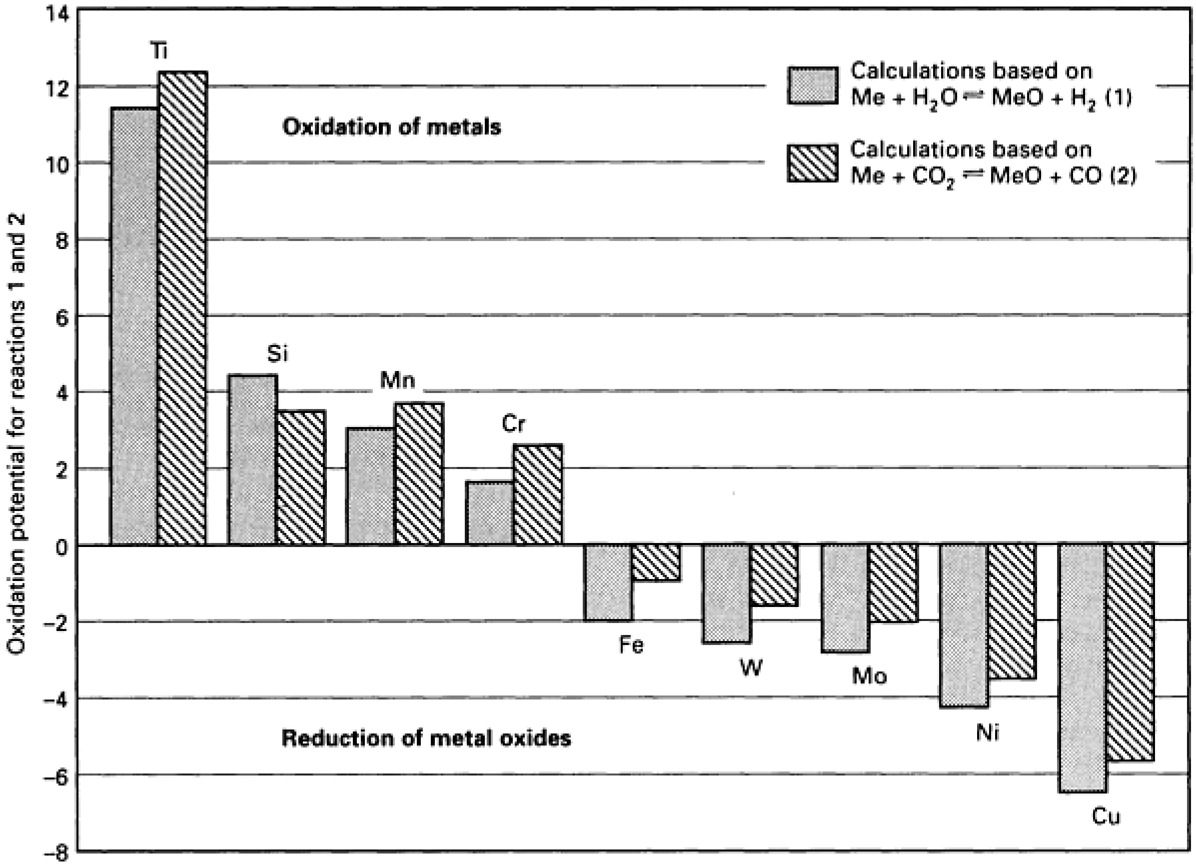

Fig. 23 Oxidation potentials of various alloying elements and iron in an endothermic gas atmosphere at 930 °C (1700 °F). Source: Ref 60

Figure 24 shows internal oxidation at the surface of a carburized specimen of a steel containing 1.06% Mn, 0.21% Si, 0.52% Cr, 0.50% Ni, and 0.17% Mo. The oxidation has followed the austenite grain boundaries to a depth on the order of

an austenite grain diameter, about 10 μm (0.4 mil). This depth of penetration is typical for steels carburized to a case depth of about 1 mm (40 mil).

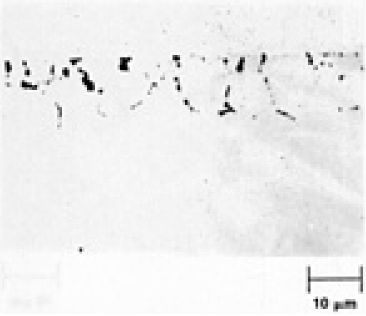

Fig. 24 Internal oxidation (dark features) at surface of gas-carburized steel containing 1.06% Mn, 0.21% Si, 0.52% Cr, 0.50% Ni, and 0.17% Mo. Light micrograph. Source: Ref 20

Figure 25 shows the surface oxidation of a carburized 20MnCr5 steel containing 1.29% Mn, 0.44% Si, 1.25% Cr, 0.25% Ni, and 0.0015% B. There are two zones of oxidation. The outer zone, about 5 μm (0.2 mil) deep, consists of chromium-rich oxides penetrating into the austenite grains. The other zone, about 30 μm (1.2 mils) deep, consists of manganese-rich and silicon-rich oxides along austenite grain boundaries. These oxide chemistries and morphologies agree with those presented by Chatterjee-Fischer (Ref 59). In addition, silicon appears to form intergranular dispersed oxide particles.

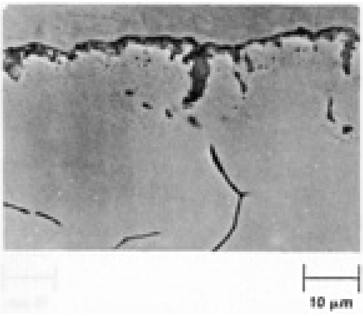

Fig. 25 Internal oxidation of gas-carburized 20MnCr5 steel containing 1.29% Mn, 0.44% Si, 1.25% Cr, 0.25% Ni, and 0.0015% B. SEM micrograph. Source: Ref 61

The grain-boundary oxides shown in Fig. 25 appear to be discontinuous. Examination of fractured specimens of the same carburized steel shown in Fig. 25 showed that the intergranular oxides grew as lamellae (Fig. 26). Thus the oxide structure appears to develop by a discontinuous or cellular transformation in which grain-boundary austenite initially containing nominal amounts of silicon and manganese decomposes to alloy oxides and austenite depleted in silicon and manganese. The discontinuous appearance of the oxides in Fig. 25 is therefore due to a sectioning effect through the oxide and austenite lamellae.

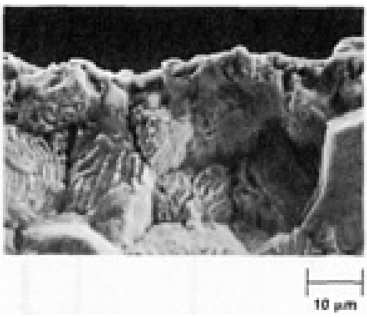

Fig. 26 Lamellar internal grain-boundary oxides on fracture surface of carburized 20MnCr5 steel containing boron. SEM micrograph. Source: Ref 61

The effect of internal oxidation on fatigue performance depends on the degree of oxidation. As noted in the section on residual stresses, if sufficient depletion of the alloying elements occurs, hardenability may decrease to the point at which pearlite and other nonmartensitic transformation products form. The latter surfaces have low hardness, tensile residual surface stresses, and reduced fatigue performance (Ref 56, 62, 63). The reduced surface hardness of some oxidized carburized steels has also been attributed to the decarburization that accompanies internal oxidation (Ref 64).

If the depth and degree of internal oxidation is limited, and if the surface structure of a carburized steel consists of martensite-austenite mixtures with surface residual compressive stresses, then there is little or no effect of intergranular oxidation on fatigue performance. Parrish (Ref 7) discussed evidence showing that oxidation less than 13 μm (0.5 mil) deep has little effect on fatigue. Pacheco and Krauss (Ref 20) showed that very good fatigue resistance could be attained in carburized specimens with the internal oxidation shown in Fig. 24, provided that the surface martensite-austenite microstructure formed in fine-grained austenite.

Fatigue Mechanisms

Identification of the best compositions and best microstructures for the production of carburized steels with high fatigue resistance has been difficult. All of the microstructural features described in the preceding sections influence fatigue performance. Many of the earlier studies that ranked various alloy steels reported relatively modest bending fatigue strengths, between 700 and 1000 MPa (100 and 145 ksi) (Ref 65, 66). Claims for the benefits of various alloying elements have been made, but little detailed microstructural and fractographic analysis has been performed to correlate mechanisms with benefits of alloying. Nevertheless, the results of studies that show low-to-moderate fatigue strengths probably reflect the properties of commercial carburized parts that are overwhelmingly successful in service because of conservative mechanical design. However, failures do occur (Ref 13, 67), and the causes, sometimes obvious, sometimes subtle, must be identified in order to improve consistently the future performance of carburized parts.

A few studies have shown that very high bending fatigue limits (≥ 1400 MPa, or 200 ksi) can be achieved in carburized steels under conditions of tension-tension cyclic (R = 0.1) loading (Ref 18, 20, 68, 69). Moreover these studies are beginning to identify microstructures associated with various ranges of fatigue performance. Polished surfaces to eliminate machining marks and other surface flaws, as well as rounded specimen corners or specimen designs that minimize edge effects, are necessary to eliminate fatigue initiation sites which obscure the effects of microstructure.

From the standpoint of microstructures, based on experimental fatigue studies (R = 0.1), there appear to be two major mechanisms of bending fatigue crack initiation. For conciseness, these two mechanisms are defined and referred to as type 1 and type 2 in the following discussion. Type 1 is associated with intergranular fatigue initiation at austenite grain boundaries with phosphorus-carbide structures. This mechanism is typically observed in direct-quenched carburized specimens and is associated with endurance limits up to 1260 MPa (183 ksi) (Ref 12). Thus quite reasonable levels of fatigue performance can be attained in carburized steels with a sensitivity to grain-boundary fracture. The other mechanism, type 2, is associated with transgranular fatigue crack initiation and correlates with bending fatigue endurance

limits greater than 1400 MPa (200 ksi). Figure 27 shows an example of type 1 initiation, and Fig. 28 shows an example of type 2 initiation.

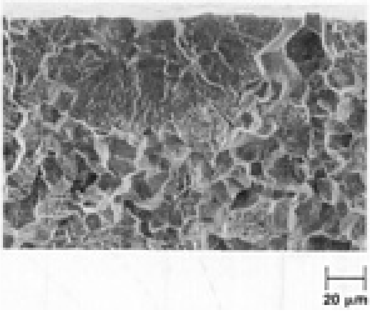

Fig. 27 Example of type 1 bending fatigue fracture initiation consisting of short intergranular crack initiation site, a region of transgranular crack propagation, and overload intergranular fracture through case. Fig. 28 Example of type 2 bending fatigue fracture initiation consisting of transgranular initiation and propagation, with gas-carburized 8719 steel. SEM micrograph. Source: Ref 20

Zaccone *et al.* (Ref 70, 71), working with simulated case microstructures, have shown that in type 1 initiation, small grain-boundary cracks form very early in the fatigue cycle, perhaps in the first cycle if the applied stresses are high enough to reach the threshold of grain-boundary cracking. This crack is arrested after traveling the length of only a few grains. The strain-induced transformation of retained austenite to martensite at the crack tip occurs and apparently creates compressive residual stresses that halt the crack (Ref 70, 71, 72). For this reason, retained austenite is beneficial for prolonging fatigue life under conditions of low-cycle, high strain fatigue. Although fatigue crack propagation rates are slowed by high retained austenite contents, fracture eventually occurs when a sufficient number of accumulated cycles cause the crack to reach the critical size for unstable overload fracture. Once the intergranular crack is arrested, propagation proceeds by transgranular cracking (Fig. 27). Overload fracture of specimens sensitive to type 1 initiation also tends to be largely intergranular until lower-carbon martensite is encountered.

Type 2, transgranular fatigue crack initiation, is dependent on slip mechanisms of crack formation during cyclic loading (Ref 73). Thus, a key feature of this mechanism, in contrast to type 1 initiation, is that a crack is not immediately generated during the first loading cycles. Cycle-dependent transgranular crack initiation develops in fine-grained case microstructures where conditions for intergranular cracking are mitigated. Low amounts of retained austenite or finely distributed retained austenite also favor type 2 initiation and therefore contribute to high performance under conditions of high-cycle fatigue because slip is more difficult in fine, largely martensitic microstructures (Ref 20, 70, 71).

Contact Fatigue Resistance of Gears and Bearings. Carburized steels in applications such as bearings and gears must also be resistant to rolling-contact fatigue (Ref 8, 13, 19, 67). The stresses that initiate failure under contact conditions are shear stresses that peak at some distance below the surface. Therefore cracks that lead to spalling develop at subsurface microstructural discontinuities such as oxide inclusion particles. Extreme cases of spalling are associated with case crushing or cracking initiated at the case-core interface. Figure 29 shows an example of a spall on a carburized SAE 4118 interface. If sliding is coupled with contact loading, surface pits develop. Very high contact loads cause microstructural changes within high-carbon martensite that are revealed by various types of etching (Ref 74, 75, 76). Generally retained austenite is regarded as a microstructural constituent that is beneficial for rolling-contact fatigue resistance (Ref 77, 78).

Carbonitriding of Steels

Revised by Jon Dossett, Midland Metal Treating, Inc.

Introduction

CARBONITRIDING is a modified form of gas carburizing, rather than a form of nitriding. The modification consists of introducing ammonia into the gas carburizing atmosphere to add nitrogen to the carburized case as it is being produced. Nascent nitrogen forms at the work surface by the dissociation of ammonia in the furnace atmosphere; the nitrogen diffuses into the steel simultaneously with carbon. Typically, carbonitriding is carried out at a lower temperature and for a shorter time than is gas carburizing, producing a shallower case than is usual in production carburizing.

In its effects on steel, carbonitriding is similar to liquid cyaniding. Because of problems in disposing of cyanide-bearing wastes, carbonitriding is often preferred over liquid cyaniding. In terms of case characteristics, carbonitriding differs from carburizing and nitriding in that carburized cases normally do not contain nitrogen, and nitrided cases contain nitrogen primarily, whereas carbonitrided cases contain both.

Carbonitriding is used primarily to impart a hard, wear-resistant case, generally from 0.075 to 0.75 mm (0.003 to 0.030 in.) deep. A carbonitrided case has better hardenability than a carburized case (nitrogen increases the hardenability of steel; it is also an austenite stabilizer, and high nitrogen levels can result in retained austenite, particularly in alloy steels). Consequently, by carbonitriding and quenching, a hardened case can be produced at less expense within the case-depth range indicated, using either carbon or low-alloy steel. Full hardness with less distortion can be achieved with oil quenching, or, in some instances, even gas quenching, employing a protective atmosphere as the quenching medium.

Steels commonly carbonitrided include those in the 1000, 1100, 1200, 1300, 1500, 4000, 4100, 4600, 5100, 6100, 8600, and 8700 series, with carbon contents up to about 0.25%. Also, many steels in these same series with a carbon range of 0.30 to 0.50% are carbonitrided to case depths up to about 0.3 mm (0.01 in.) when a combination of a reasonably tough, through-hardened core and a hard, long-wearing surface is required (shafts and transmission gears are typical examples). Steels such as 4140, 5130, 5140, 8640, and 4340 for applications like heavy-duty gearing are treated by this method at 845 °C (1550 °F).

Often, carburizing and carbonitriding are used together to achieve much deeper case depths and better engineering performance for parts than could be obtained using only the carbonitriding process. This process is applicable particularly with steels with low case hardenability, that is, the 1000, 1100, and 1200 series steels. The process generally consists of carburizing at 900 to 955 °C (1650 to 1750 °F) to give the desired total case depth (up to 2.5 mm, or 0.100 in.), followed by carbonitriding for 2 to 6 h in the temperature range of 815 to 900 °C (1500 to 1650 °F) to add the desired carbonitrided case depth. The subject parts can then be oil quenched to obtain a deeper effective and thus harder case than would have resulted from the carburizing process alone. The addition of the carbonitrided surface increases the case residual compressive stress level and thus improves contact fatigue resistance as well as increasing the case strength gradient.

When the carburizing/carbonitriding processes are used together, the effective case depth (50 HRC) to total case depth ratio may vary from about 0.35 to 0.75 depending on the case hardenability, core hardenability, section size, and quenchant used. A more shallow effective or total case depth can be achieved with a given carbonitriding process by using fine grain steels containing higher amounts of aluminum (Ref 1) or titanium. The nitrogen from the process forms nitrides with the aluminum or titanium. The combined nitrogen does not improve case hardenability.

The fundamental problem in controlling carbonitriding processes is that the rate of nitrogen pick-up depends on the free ammonia content of the furnace atmosphere and not the percentage of ammonia in the inlet gas. Unfortunately, no state-of-the-art sensor for monitoring the free ammonia content of the furnace atmosphere has yet been developed.

Case Composition

The composition of a carbonitrided case depends on the type of steel and on the process variables of temperature, time, and atmosphere composition. In terms of steel type, the case depth achieved during a given carbonitriding process will be lower in steels containing higher amounts of strong nitride formers such as aluminum or titanium.

The ammonia system required for carbonitriding often consists of a number of cylinders of liquid ammonia that are connected to a common manifold. In general, ammonia from only a part of the supply is employed; the remainder is held in reserve. The flow from each cylinder should be sufficiently low to prevent freezing of the valves. Only stainless steel valves and schedule 80 or stainless steel piping are recommended.

Outside bulk storage and vaporizing systems are much preferred to cylinder banks, considering the advantage of a constant, uninterrupted source on the uniformity of work quality. In general, when bulk storage is used, two-stage pressure regulation is used to ensure a constant and uniform ammonia flow. The first stage regulates the pressure for delivery to the furnace, whereas the final pressure regulation, at the furnace, controls the pressure to the process.

In terms of process variables, the higher the carbonitriding temperature, the less effective is the ammonia addition to the atmosphere as a nitrogen source, because the rate of spontaneous decomposition of ammonia to molecular nitrogen and hydrogen increases as the temperature is raised. At a given temperature, the fraction of the ammonia addition that spontaneously decomposes is dependent on the residence time of the atmosphere in the furnace: the higher the total flow of atmosphere gases, the lower the fraction of the ammonia addition that decomposes to nitrogen and hydrogen. Figure 1 shows that lower temperatures favor increased surface nitrogen concentrations. The addition of ammonia to a carburizing atmosphere has the effect of dilution by the following reaction:

$$2\ NH_3 \rightarrow N_2 + 3\ H_2$$

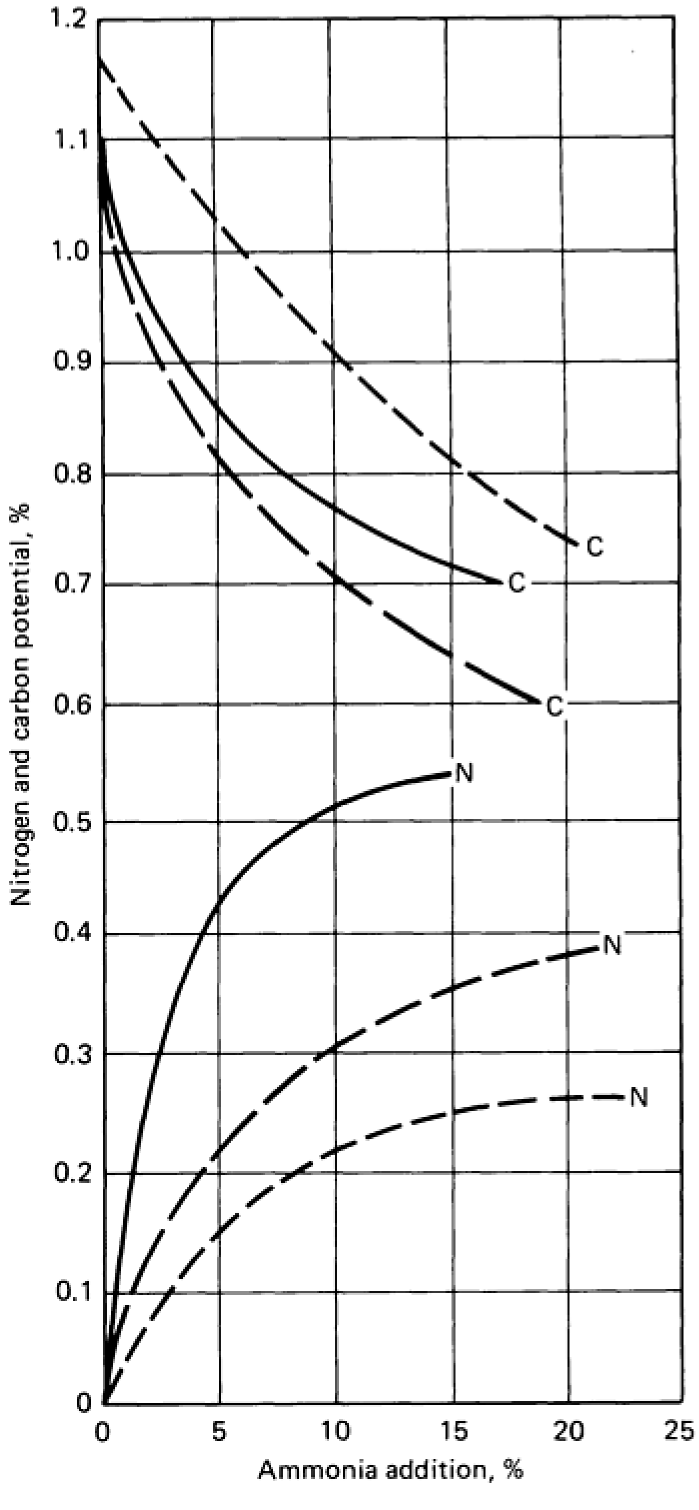

Fig. 1 Effect of ammonia additions on nitrogen and carbon potentials determined using low-carbon steel foil. For three sets of conditions: solid lines, 3 h at 850 °C (1560 °F) and 0.29% CO_2; broken lines, 1 h at 925 °C (1695 °F) and 0.13% CO_2; dashed lines, 1 h at 950 °C (1740 °F) and 0.10% CO_2. Source: Ref 2

Thus, as shown in Fig. 1, the carbon potential possible with a given carbon dioxide level is higher in a carburizing atmosphere than in a carbonitriding atmosphere. Dilution with nitrogen and hydrogen affects measurements of oxygen potential in a similar manner; the carbon potential possible with a given oxygen potential is higher in a carburizing atmosphere than in a carbonitriding atmosphere. Water vapor content, however, is much less affected by this dilution. Thus, the amount of dilution and its resulting effect on the atmosphere composition depends on the processing temperature, the amount of ammonia introduced, and the ratio of the total atmosphere gas flow rate to the volume of the furnace.

Carbonitriding can be carried out at such low temperatures as to produce a compound layer, so called because iron-carbon-nitrogen compounds are formed at the surface. In certain wear applications, this type of case structure is suitable.

To produce this layer of compound, large percentages of ammonia are required. It is usually unnecessary to liquid quench parts carbonitrided in this manner. However, because the diffusion rate of nitrogen and the rate of formation of the compound are so slow at temperatures below 705 °C (1300 °F), such practice is economically applicable only to shallow cases in applications in which dimensional tolerances would be difficult to maintain if the parts were treated at higher temperatures. When temperatures fall below the austenitic level, this process is called ferritic nitrocarburizing (Ref 3, 4).

Example 1: Effect of Atmosphere Dew Point on Case Composition from Carbonitriding.

Figure 2 shows carbon and nitrogen gradients and case hardness data for 1018 carbon steel and 8620 low-alloy steel that were carbonitrided for 4 h at 845 °C (1550 °F) in a batch-type radiant-tube furnace. These test data were obtained in a manufacturing plant under normal production conditions, employing a standard carbonitriding cycle. All test specimens were carbonitrided along with production loads of 23 kg (50 lb) of gears and shafts.

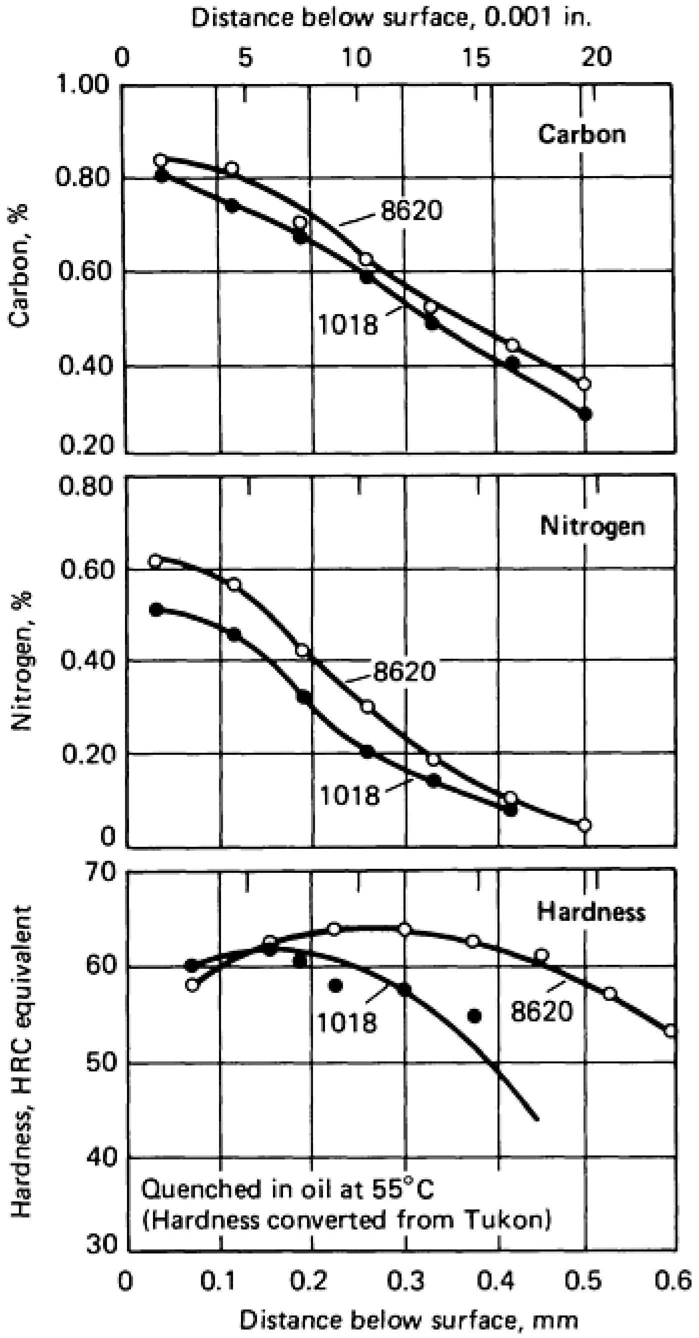

Fig. 2 Carbon, nitrogen, and hardness gradients for carburized 1018 and 8620 steels. For processing details, see text.

The carbonitriding atmosphere was controlled by an infrared control unit and consisted of an endothermic gas at 14.2 m^3/h (500 ft^3/h), ammonia at 0.7 m^3/h (24 ft^3/h), propane at 0.007 to 0.021 m^3/h (0.25 to 0.75 ft^3/h), and 0.32 to 0.34% carbon dioxide. The dew point of the atmosphere was maintained at -7 to -6 °C (19 to 21 °F) throughout the carbonitriding cycle. All specimens were quenched from the carbonitriding temperature (845 °C, or 1550 °F) into warm oil at 55 °C (130 °F); they were neither tempered nor subjected to subzero treatment.

As the dew point of a carbonitriding atmosphere is increased, carbon concentration decreases and nitrogen concentration remains fairly constant. This characteristic response is demonstrated by the data in Fig. 3 for a 1020 steel carbonitrided at 845 °C (1550 °F) for 4 h, which show that, with the ammonia content of the carbonitriding atmosphere set at high (5%) and low (1%) levels, an increase in the concentration of water vapor (decrease in atmosphere carbon potential) in the inlet gas lowered the profiles of carbon concentration but did not appreciably affect nitrogen concentrations. (Although the dew point of the atmosphere in the carbonitriding furnace, rather than the dew point of the inlet gas, is the controlling factor, data based on the inlet-gas dew point demonstrate the general effects of raising and lowering dew point on case composition.)

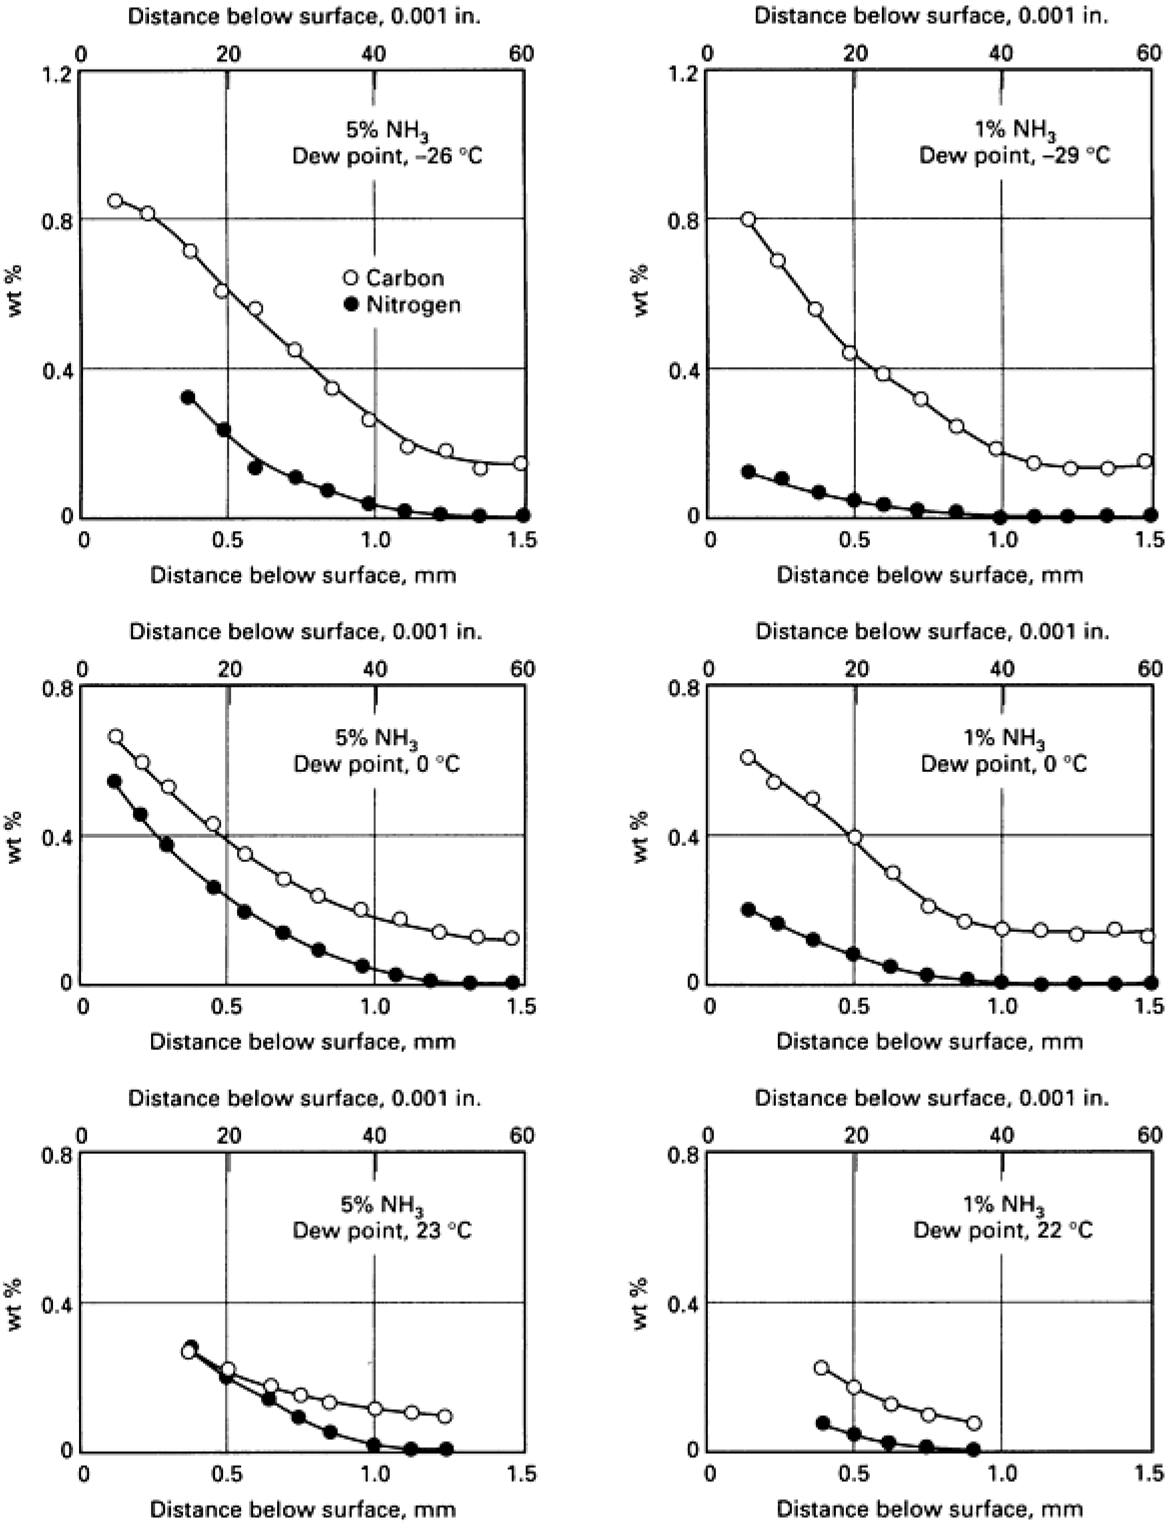

Fig. 3 Effects of ammonia concentration and inlet gas dew point on carbon and nitrogen gradients in a 1020 steel carbonitrided at 845 °C (1550 °F) for 4 h and air cooled. Inlet gas also contained 5% methane; balance, carrier gas. Source: Ref 2

Depth of Case

Preferred case depth is governed by service application and by core hardness. Case depths of 0.025 to 0.075 mm (0.001 to 0.003 in.) are commonly applied to thin parts that require wear resistance under light loads. Case depths up to 0.75 mm (0.030 in.) may be applied to parts (such as cams) for resisting high compressive loads. Case depths of 0.63 to 0.75 mm (0.025 to 0.030 in.) may be applied to shafts and gears that are subjected to high tensile or compressive stresses caused by torsional, bending, or contact loads.

Medium-carbon steels with core hardnesses of 40 to 45 HRC normally require less case depth than steels with core hardnesses of 20 HRC or below. Low-alloy steels with medium-carbon content, such as those used in automotive transmission gears, are often assigned minimum case depths of 0.2 mm (0.008 in.).
